In other patients it is sometimes practical to inform them, particularly if they already more than suspect it, that they have a progressive ailment. They may be assured that everything will be done to reduce pain and suffering and to keep up their good health as much as possible. Persuasive suggestions to face the remaining months with calmness and courage may be very reassuring. The patient may be told that while one's life span is limited, one may extend and enjoy it by the proper mental attitude. A guidance approach helps reduce the disturbing effect of environmental factors and permits the patient to divert interests toward outlets of a distracting nature. Where the patient is so disposed, he or she may be encouraged to cultivate religious interests in which one may find much solace.

The patient's time may be so arranged so as not to sit in utter desolation waiting for death. One may also be taught the technique of self-hypnosis to induce relaxation, diminish tension, reduce pain, and promote a better mental outlook. Mendell (1965) states that patients respond to his statement: "You are not alone. The struggle is not over. You don't have to worry that what can be done is not being done. 1 am with you and aware of what you are undergoing. I am with the forces that are to help you, and if anything develops, I will bring it to you immediately." An attitude should be inculcated in the patient that one has fulfilled one's task well and that it is now time to let oneself relax.

Such an attitude may permit of the peaceful, even happy, acceptance of the end of life. Actually, few dying patients do not appreciate the imminence of death, even though their psychological defenses tend to deny it. The therapist may keep emphasizing that the patient, through courage, is doing much for his or her family. What the patient needs is someone to understand and to help mobilize existing resources, to listen closely with respect and not pity, to display a compassionate matter-of-factness, and above all to help him overcome the fear of isolation. The greatest problem in working with the dying patient is the therapist's own feeling of helplessness, guilt, and fear of death.

The work of Cicely Saunders, Director of St. Christopher's Hospice (Liegner, 1975) is evidence that for dying patients a great deal can be done toward making their last days comfortable, painless, and free from anxiety. Administration of medications ("polypharmacy") to render the patient symptom-free has been routine at St. Christopher's. Diamorphine (heroin) every 4 hours orally, Thorazine and its derivatives, and other medications that are indicated for special conditions, such as dexamethasone for brain metastases and increased intracranial pressure, may be given during the day and night. The physical atmosphere should be clean, cheerful, and comfortable. The members of the staff must be supportive and participate in working through the stress of separation anxiety. Discussion about incurability and dying are not avoided, and the fact is accented "that death is a continuum of life and is not to be feared." Under these conditions the patients may respond to the passing of another patient with little dread or fear.

If the patient who knows that he or she is dying can be shown that the acceptance of death is a positive achievement rather than resignation to nothingness, much will have been accomplished in making the remaining days more tolerable. Understanding the patient's anxiety, guilt feelings, and depression through empathic listening may be extremely reassuring. Helping members of the patient's family to deal with their hostility and despair may also be an essential part of the therapist's task. Cautioning them on the futile search for expensive and nonexistent cures may, incidentally, be in order. At all times the focus is on relieving the patient's physical pain and distress, on making one comfortable in one's home, and on assuaging mental turmoil. If this is done, peace will

usually follow. A good relationship with the patient's family during the last days will help them to an acceptance of the reality of death and lessen the pain of bereavement.

Where death has occurred, the therapist may be called on to render help to the bereaved. Different members of the family will respond with their distinctive reactions to the incident. The detached and presumably adjusted member may actually need more support than the one who is ostensibly upset and manifestly grief stricken. Since members are bound to respond to the emotional tone of those around them, the manner and mode of communication of the therapist will influence the healing process. Cooperativeness, understanding, sympathetic listening, and an expressed desire to help can inspire friendship and trust in the therapist. As Beachy (1967) has pointed out, it is unwise to whitewash the facts of suffering and death or to try to evade the evolving emotional reactions, however unreasonable they may seem. A completely open, factual manner that is not falsely oversolicitous is best, and where needed, the continued care and attention of a clergyman or other supportive person may be advisable. The value of therapy with groups of terminally ill patients makes this modality one that should be considered in selected cases (Yalom & Greaves, 1977).

Readings on this subject may be found in Aldrich (1963), Cassem (1974), Christ (1961), G.W. Davidson (1975), Eissler (1955), Feifel (1959), J. Fletcher (1972), GAP Symposium (1965), Gerson & Bassuk (1980), Kennedy (1960), Krupp & Kligfeld (1961), Kubler-Ross (1969), Langer (1957), Makadon et al. (1984), Morgenthau (1961), Pack (1961), Reeves (1973), P.S. Rhoads (1965), Rund & Hutzler (1983), Saul (1959), A. Schwartz (1961), Standard & Nathan (J955), Tagge et al. (1974), Wahl (1960), A.F.C. Wallace (1956), Weisman (1985), Worcester (1935), Worden (1982), and Zilboorg (1943).

A common denominator in all mental illness is stress, which is a trigger that can set off many deleterious physical and psychological reactions. It is a potent precipitant of emotional disorders and therefore of vital concern to the psychotherapist.

In the course of daily living a certain amount of stress is unavoidable. To an extent this is constructive since it "oils up" the physiological mechanisms essential to adaptation, much as a machine requires periodic use to prevent the constituent parts from drying up and rusting. People often seek ways of stressing themselves temporarily with some pleasurable excitement like competitive sports and games, or exposing themselves to mildly frightening experiences like horror movies or murder mysteries. This not only helps keep the various body organs and systems in tune, but also enables the fight-or-flight mechanisms of the organism to hold themselves in preparation for some more-than-normal stressful emergency.

What we are concerned with in mental health practice are not these adaptive responses to everyday stress, but the effects on the individual of stressful events to which a proper adaptation cannot be made. Specifically we want to know what to do for the patient who is being victimized by abnormal and incapacitating stress reactions, and more importantly, how to modulate or remove the stressful stimuli that are causing the problems.

PHYSIOLOGICAL CONSEQUENCES OF STRESS

It is estimated that stress reactions are a major factor in the etiology of physical illness like heart disease, stomach ulcers, and even cancer to name a few. Knowledge of the involved physiology may be helpful in understanding how this comes about. Simply put, what stress does, as Selye (1956) has shown, is to activate a massive conditioned non-

specific reaction to prepare for appropriate coping with an actual or anticipated threat. The psychological component of this response is part of our animal heritage having evolved over millions of years as a survival mechanism in the face of danger. Once a situation is *perceived* and *evaluated by* the brain as dangerous, several subcortical centers come into play. Two systems are primarily involved that ordinary operate to regulate the normal functions of the body. Both depend on complex chemical compounds (hormones) in the hypothalamus. One of these hormones, cortisol, is so essential to life that its concentration in the blood must be steadily maintained within narrow limits. Cortisol is vital in preparing the body physically to overcome a threatening stress stimulus. What cortisol does is break down aminoacids from muscle and connective tissue into glucose to supply the body with energy. In addition, it regulates cell metabolism, stabilizes plasma membranes, elevates the mood, and has an antiinflamatory effect. This over a short-term period is helpful in dealing with stress. But if excessive cortisol manufacture continues over an extensive period, which is the case in prolonged and continued stress or chronic intermittent stress, cortisol starts doing damage. It breaks down too much muscle tissue, produces clotting failure, weakens bone structure encouraging fractures, depresses the body's immune reactions causing susceptibility to infection, and sometimes produces bizarre behavior. In recent years it has been discovered that another brain hormone liberated by the same adrenal steroid feedback mechanism responsible for cortisol is beta-endorphin, which has a pain-killing morphine-like action, but that in too great concentration, that is when stress is prolonged, may also have an unwholesome effect.

Additionally important to body function is the second system, the sympathetic nervous system and the catecholamine hormones epinephrine and norepinephrine released by the adrenal medulla. In short-term stress this system is activated to increase cardiac output, help respiration by dilating the bronchioles, distribute blood from the inside of the body to muscles and the heart, lessen fatigue, increase alertness and facilitate energy supplies by liberating glucose from muscles and liver and releasing fatty acids from fat deposits. This is all to the good in dealing with temporary stress, but if this action goes on over an extended period, physiological damage can occur in the form of hypertension, gastric ulcers, cardiac arrhythmia, and other organ malfunctions. Increased

plasma cholesterol and elevated low density lipoprotein may predispose to atherosclerosis and coronary insufficiency.

SOURCES OF STRESS

Sources of stress are legion and it would be an insuperable task to list all of them since they vary with each individual. On an environmental level we need merely to catalogue the kinds of problems social agencies deal with to realize that endless troubles stressfully plague human beings apart from cataclysms of climate, war, accidents, and catastrophic physical illness, which after all are not too common in the lives of most people. Noteworthy for the majority are tensions caused by difficult interpersonal relationships with families, spouses, authorities and peers, bereavements, material or fancied threats to the safety, security, and life of the individual such as violent assaults, rape, serious accidents and illnesses, blows to self-esteem, undermining of autonomy and identity, anger that is blocked in expression, and the inability to fulfill important personality needs which may in susceptible persons become stress sources. The origins of many of these difficulties are rooted in past conditionings. Incomplete separation-individuation, devaluated self-esteem, accumulating hostilities, guilt feelings, and personality drives that interfere with harmonious interactions are a few of the surviving anachronisms and traits that generate troubles.

Belief systems sometimes contribute anomalous sources of stress even though the individual recognizes their irrational source. Authentic cases of death may follow the breaking of a taboo or the spells cast on a victim by shaman, voodooist witch doctor or medicine man. Among civilized people, a deep conviction of hopelessness, with expectation of death may bring on irrecoverable illness with loss of appetite and a wasting away, with a calm acceptance of one's inevitable doom. Years ago Walter Cannon wrote about how supernatural fear can bring about a fatal outcome, and he pointed out the fact that some surgeons refused to do a major operation on a patient who was terrorized by the conviction that he or she would not survive.

There are additionally a plethora of aversive events and factors in daily life that can

have a cumulative stressful effect. The individual may to some extent be aware of the damage these mischief-mongers cause and may force himself or herself to tolerate them, either on the basis that the problems are insoluble and there is no escape, or because one feels destined to endure them. More often there is no awareness of the damage they cause and years may go by before the victim realizes that something is wrong and can no longer go on physically or emotionally.

A good deal of literature has been published on selective areas of stress a most interesting contribution having been made by Holmes and Rahe (1967) who developed a Social Rehabilitation Rating Scale designating areas of stressful changes in one's life situation in hierarchical order, assigning to them "life change units" from 100 to 11. At the top of the list, the first three items are the death of a spouse, divorce, and marital separation. These are followed by a large number of other damaging incidents, with somewhat lesser scores. The authors found that a total of 200 or more life change units in a year was matched by an increased incidence of myocardial disease, infections, peptic ulcer, and assorted psychiatric disorders.

Bereavement as a stress source commonly occurs with the death or permanent departure of a person with whom there has been a close relationship (parent, spouse, child, lover). It may develop with removal from one's home, neighborhood, or work situation as in relocation and retirement. The reaction of grief may appear immediately after the critical separation incident, or manifest itself following weeks or months. The classic investigation of Erich Lindemann (1944) revealed five main reactions: (1) somatic symptoms (physical distress, shortness of breath, muscular weakness, tension, subjective discomfort); (2) preoccupation with the image of the lost object; (3) guilt (self-accusations for the situation); (4) hostile reactions (anger at being abandoned; irritability at people in general); (5) behavioral alterations (restlessness, forcing oneself feverishly into activities; enhancement of dependency, feelings of unreality, imitation of attitudes and behavior of a deceased through identification). Reaction formations such as forced cheerfulness or stoicism may mask some of these symptoms.

Grief that follows a lost home precipitates similar reactions to those resulting from the death or permanent departure of a valued person (Fried, 1963). Clearance of urban slum areas, the devastation caused by tornadoes and floods, invasion, and the massive destruction of war has resulted in forced relocation and massive bereavement and personal suffering. The sense of loss of intimacy with one's surroundings, disruption of customary social networks, absence of familiar groups of people, results in a sense of disorientation, the fragmentation of identity, and a grieving for the lost familiar neighborhood.

Retirement, without adequate preparation or training for post-retirement activities and hobbies can impose stressful burdens on a person whose sense of importance, worth, and self-esteem has been contingent on gainful employment. Lacking methods of restoring feelings of being needed the individual may respond with despair, depression, and a longing for return to the previous status. The sense of grief and bereavement parallel those that follow the loss of an important love object.

Why bereavement and separation have such intense effects on people has engaged the attention of many observers. It is the belief of some that these are tangentially related to the fear of death that exists on some level in all people. No satisfactory formula has ever been evolved to neutralize this death fear in spite of such expediencies as belief in immortality, reincarnation, soul survival, and the like. There are those who contend that fear of dying cannot be avoided since it is a biological and evolutionary phenomenon residing within the structure of man. There are others who believe that such fear is not biological, but rather bound to the peculiarities of human development. At its core is the infant's primitive reaction to object loss precipitated by separation from the mother. No matter how secure the individual may seem, the terror of abandonment-separation-death slumbers ominously in the unconscious and symbolically fastens itself to later separation experiences and to any bereavement contingency that threatens personal physical and emotional security. Obviously the more wholesome the rearing of the child, and the more stable the personality structure, the better the coping tactics in dealing with separation. But even in well adjusted individuals the repressed death obsession may awaken with

severe deprivations and life-threatening crises. In unstable persons, fears of annihilation can appear explosively with minor separations and insignificant losses which are interpreted as threats to one's integrity.

Terminal cancer patients and those experiencing severe myocardial disease may be realistically confronted with the imminence of death; such patients often barricade themselves from the terror of dying by denial mechanisms, a conspiracy entered into by visiting persons who, dealing with their own anxieties of mortality, try to flourish a false facade of hope. Slips of speech and disturbing dreams only too pointedly indicate the patient's distrust of such denial maneuvers.

We cannot dismiss the fact that constitutional factors sometimes enter into the generation of stress through hypersensitive biochemical and neurophysiological systems that fire off excessively with even minor stimuli. Nor can we neglect cultural elements that endow certain events with a portentous meaning. *The meaning the individual imparts to any stimulus, external or internal, will determine its stressful potential.* The most insidious sources of stress issue from unconscious conflicts, the individual attempting to rationalize inner turmoil by attributing it to outside sources. Indeed, disturbing stressful situations may deliberately be created to provide objectivity for one's inner feelings.

REACTIONS TO STRESS

Research on stress has shown, sometimes to the exasperation of the experimentor, that the severity of the stresses bear little relationship to the intensity of the resultant physiological and behavioral disruption, even in the same experimental subject at different times. A number of intervening variables appear to be operative, some of which are confoundingly elusive. What is of primary importance is the cognitive set that imparts special meaning to the stressor. The reaction of any individual to stress is regulated by the sense of one's own vulnerability and the perception of one's capacity to cope with, adjust to, or overcome the source of trouble. Mastery of a stress situation in the past akin to the present one, is a positive factor, while failure is a negative element in determining stress tolerance. Most individuals will react to a life-endangering situation with fear or panic. But

a suicidally inclined soul, intent on self-destruction, or a religious martyr, who expects rewards in heaven, may actually promote a life-terminating event. Highly motivated, well doctrined soldiers exposed to skilled prebattle morale building will enter stressful combat with fierce enthusiasm. Soldiers who do not know what they are fighting for are deplorably handicapped during combat.

Are there any personality measures that can tell us how an individual will react to stress? Coping adequacy is related to flexibility of defenses, one predictive measure being the stability of the individual in the face of previous life crises. Andreasen et al. (1972) studied hospitalized burn patients, and found that patients with adjustment difficulties prior to the burn and those with premorbid psychopathology coped poorly with their injury. In an interesting piece of research on physiological and psychological responses to stress, Katz et al. (1970) have shown that "the ego's defenses are obviously able to buffer the individual from threat with great efficiency" and, even to block expected biochemical reactions. So far no reliable test has been found that can measure defenses and that can predict what an individual will do under certain stressful circumstances. Responses are highly specific. In this author's practice, both amateur and seasoned actors on screen, stage, and TV have been seen whose stage fright prior to the opening night performance approached shock reactions, yet with the arrival of doomsday, before a live audience, performed brilliantly with scarcely a whisper of anxiety. On the other hand, the author has seen composed, self-confident individuals including some veterans, decorated for bravery in battle, fall apart when asked unpreparedly to make a speech before a group. No prior psychological test could have predicted these transformations.

Cultural attitudes often determine reaction patterns. For instance, tolerance of pain and the ability to disregard it stoically may be considered virtuous in some societies, contrasting with the complaining, demanding, groaning, angry responses found in other cultural groups. As Zborowski (1977) has stated, stress in part is "a cultural experience in perception as well as in interpretation, and as such is responded to by behavior and attitudes learned within the culture in which the individual is brought up." Such philosophical defenses as a penchant to accept adversity as inevitable, the endorsing of a

fatalistic attitude that man is destined to suffer pain and discomfort, and confidence in faith and prayer as ultimate means of gaining protection through the divine order can greatly subdue reactions to stressful stimuli. Accordingly, stress is subject to the psychological embellishments of the responder who draws on inherent physiological and psychological sensitivities. In individuals with a tendency to depression, stress often functions as an important precipitant. Controlled studies have shown that stressful life events precede the outbreak of major depressions in predisposed individuals. Other syndromes than depression may be precipitated by stress, and it is a challenging hypothesis that predispositions to a specific response may exist in such persons. Brown and Birley (1968) found that 60 percent of patients suffering from a schizophrenic episode had experienced strong stressful situations some weeks prior to the onset of the illness. Only 19 percent of the control group were similarly affected. Past conditionings also provide a fertile paradigm for behavioral patterns. Thus an individual victimized as a child by the abandonment or death of a parent may respond to mild separations in adult life intensely, even catastrophically.

Where physiological responses to stress continue over a period of time, we may expect complications of physical illness and organ damage (Rahe & Arthur, 1977). What inspires the choice of organ afflicted is still hard to say. On the surface we would assume that the weakest link in the physiological chain would break down under the stressful pounding. This then would be a matter of hereditary weakness of an organ system, or previous damage to the organ wrought by a past illness or pathological assault. Because chronic stress affects immunological reactivity and predisposes to autoimmune reactions, some authorities believe that nonspecific damage can occur, postulating as one example rheumatoid arthritis. However, here too a genetic predisposition cannot be ruled out.

Many authorities believe that variant personality typologies generate different degrees of stress and show different modes of coping with adversity. While most authorities downplay the thesis of Alexander (1950) that the organ disrupted by stress is determined by the basic character structure, there may be some tendency in certain dependent, "orally" disposed individuals whose dependent need is frustrated, to

oversecrete digestive juices as if they seek to incorporate food, which from infantile associations is equated with love. Continued gastric hyperacidity may thus result in peptic ulcer. Special personality constellations are believed to activate selected organ systems. A hard driven, time-hungry, competitive, restless personality, type A personality described by Friedman and Rosenman (1959, 1974), is said to be predisposed to coronary disease. There seems to be some experimental evidence for this. Van Egeren and his coworkers (1983) found that social stresses, like competitive rivalry and goal frustration affected the ventricular myocardium differently in type A than the less driven, calmer type B persons. Computer analysis of the electrocardiograms revealed in type A persons a statistically significant depression of the ST segment and a reduction of T wave and R wave amplitude. There are additional studies that show that type A individuals in comparison with type B individuals have more frequent arrhythmias, and increased sympathetic adrenergic responses (rises in blood pressure, accelerated heart rate, and mobilization of epinephrine and norepinephrine) to stress which provide added evidence for greater liability to cardiac illness in type A individuals.

Attempts have been made to correlate other personality typologies with diabetes, ulcerative colitis, cancer, asthma, migraine, and arthritis. One example is the study of a large group of patients with chronic insomnia in different parts of the country (Kales et al, 1983). A consistent pattern was the handling of stress and conflicts, especially about aggression, by internalizing rather than expressing emotions, which apparently promoted physiological disturbances during sleep.

Important to differentiate in evaluating this complex data are physical manifestations of conversion reactions that fulfill defensive psychological needs and are products of the voluntary sensorimotor system. Here the physical symptom (e.g., paralysis, anesthesia, etc.) constitutes a symbolic communication coached in body language. We are inevitably led to the conclusions that organ choice is multifactorial and must be individually evaluated.

Physiological reactions to stress that result in organ damage are obviously inimical

to adequate coping. Psychological defenses similarly may be maladaptive. The adequacy of the coping method depends on a number of factors, principally whether the defense employed succeeds in halting the deleterious effect of the stress response on the physiological level, and whether, on a psychological level, it compromises the present or future adjustment of the individual. A stressed executive earning a large salary and enjoying tenure in an organization can achieve temporary peace of mind by resigning his or her position, but in the long run may be cutting one's own throat and become even more severely stressed while waiting for the meager unemployment check in line with other job hopefuls. Studies indicate that adequate methods of coping include humor, anticipation, rationalization, and philosophizing (Ford 1975; Vaillant, 1971).

MANAGEMENT OF STRESS

There is enough research evidence[8] to make plausible the following facts about stress: (1) the impact of a stressful event, physical or social-psychological is modulated by the expectations, perception, and the unique meaning given the stressor by the subject; (2) the reaction of any individual to stress is regulated by a sense of one's own vulnerability, and the perception of the capacity to cope with, adjust to, or overcome the source of the trouble. (3) Mastery in the past of a stress situation akin to the present one, is a positive, failure a negative factor in determining stress tolerance; (4) graded exposure to a stressful situation, with mastery of some aspects, tend to desensitize the subject to the effects of the stressor; (5) stressful reactions following failure to cope with a threat, or missing the mark on an assigned task, encourage deterioration of responses at later trials; (6) verbalization about one's feelings, and the presence of people who the individual trusts, increases tolerance of stress, reducing psychological and psychosomatic symptomatology. These research findings, paralleling what common sense would tell us, form the basis around which the management of stress can be organized.

The first step in management is to identify the operative stressors. If they are purely environmental, a counseling approach may do more good than depth-oriented psychotherapy. In most cases, however, it is rare that external stressors are not reinforced

by the motivational connivance of the patient who may even have initiated the troubles and then subversively sustains them. Here attempts to deal with the stressors by counseling and millieu therapy will be blocked by the emotional needs of the patient. Should this happen, the therapist will have to institute an approach focused on rectifying the personality operations of the patient.

Initiation of an effective treatment program will depend on the condition of the patient when first seen. A four-part "stress response syndrome" (Horowitz, 1976) is commonly experienced by persons exposed to an acute traumatic event such as bereavement, surgery, a serious accident, a catastrophic blow to security or self-es-teem, or anything that is interpreted as an irretrievable loss. The first phase is characterized by an initial shock reaction with a dulling of perception and feelings of unreality. Second, there is an attempt at denial in order to push out painful emotions related to the incident. The person may act and talk as if nothing has happened, or there may be a minimization of the incident. Following this, a third phase occurs with gradual intrusive feeding into consciousness of the true significance of the event and an experiencing of previously blocked emotions like pain and deprivation. This may alternate with bouts of emotional withdrawal when anxiety is too strong. Fourth, the change in life status that the traumatic event makes inevitable is accepted. This working-through cognitive processing phase may go on for years. It may never be completed being interrupted by images and phantasies of the lost object or previous stabilizing life situation. Patients react uniquely to each phase in accordance with their personality needs and neurotic defenses.

During the first phase of the reaction, therapy is best focussed on terminating, if possible, any identifiable stressful stimuli. This may necessitate removing the patient physically from the stress source provided such rescue will not complicate matters. Where it is essential to live with and adapt to a stressful environment, the person will need to desensitize to its effects and develop ways of modifying or eliminating its most hurtful elements. A relationship with an empathic, knowledgeable person here is most important and the degree of directiveness, support and empathic reassurance must be titrated against the existing confusion, helplessness, and disorganization. In severe reactions,

psychotherapy may be necessary. Hypnosis and the *temporary* administration of an anxiolytic medication may be helpful. The objective is to bring the patient back to a realistic appraisal of the situation. If possible, one should avoid anxiolytics especially in addictive personalities. Should they have to be prescribed, their use must be terminated as rapidly as possible so that the patient does not become dependent on them.

By the time the patient presents for help to a psychotherapist he or she will undoubtedly have made some attempts at self-regulation and environmental manipulation through control, attack, or escape measures. These will show up in manifestations of denial, detachment, displacement, projection, and rationalization. Such defenses are implemented with the aim of dealing with, neutralizing or removing the perceived threat. An insidious escape measure is the use of mind-altering drugs (sedatives, tranquilizers, alcohol, marijuana, cocaine), which will complicate therapy. As soon as some stabilization occurs and the relationship with the therapist is sufficiently firm, resort to substance use or abuse will need to be terminated and this may require aggressive handling. Other untoward defenses are acting out manifestations, outbursts of anger and violence, masochistic activities, unusual sexual practices, withdrawal, and restless agitation. Complications may have ensued as a result of these responses, which, though disturbing and requiring handling, should not sidetrack the therapist's pursuit of mediating the initiating stress.

If the patient is in the denial phase of the stress reaction, during which an attempt is being made by the patient to blot out the presence of the threat by acting as if it did not exist or by minimizing it as through humor or joking, the therapist will have to alter the approach. Without withholding support and reassurance, denial is countered by continued careful confrontations interpreting the purpose behind the patient's disputative maneuvers. In acute stress reactions denial may be so severe as to practically paralyze the person. Phobias and conversion symptoms may be pressed into service to avoid reminders of the stressful situation. Amnesia, fugue states, delirious attacks, tremors, paralysis, sensory disturbances and paralyzing phobias may develop and constitute the immediate reason why the patient comes to treatment. Repression is never complete and

periodically the repressed stressful experience or conflict will feed back into consciousness stimulating bouts of anxiety. So long as denial exists, this back and forth movement will continue. It is essential here to dose the patient with increments of the disavowed or repressed material through confrontation and interpretation of existing fantasies, dreams, and behavioral distortions. Where denial is extreme, hypnosis and narcosynthesis may be of some help in breaking through the resistance, but will require administration by a professional skilled in their use.

The next phase of therapy may well be the most difficult one since it requires a working through of the insights gained in treatment and putting these into corrective practice. During this phase there will be periods of anxiety and depression as the patient reexperiences the trauma, as well as repressive renunciatory interludes.

Therapy is usually performed under a handicap because of continued stubborn distrust of one's environment and of authority in general. This promotes detachment, easily aroused anger, and reluctance to engage in psychiatric or psychological treatment. Where therapy is attempted, the transference may become so ambivalent as to interfere with treatment.

Enjoining the patient to verbalize feelings, the temporary use of medication, and perhaps exposure to hypnosis may open the way to establishing a relationship with the therapist who is then in a better position to institute counseling, cognitive therapy, or dynamically oriented psychotherapy. Should transference still interfere with treatment, group therapy may be tried which, because transference is split and more diffused, may be better tolerated than individual treatment in these highly stressed individuals.

While less dramatic than acute gross stress reactions, but no less devastating in their effects are *chronic stresses of an intermittent nature.* Stress here is due either to an environment from which the individual cannot or will not escape and to which one responds adversely, or to disturbed relationships with significant others like parents, siblings, spouse, children, employer, etc. Usually personality problems are basic and are subsidized by intrapsychic conflicts which sponsor such defenses as projection, fantasy,

dissociation and obsessive rumination that interfere with adequate coping.

A prime goal in dealing with chronic intermittent stress is evolving defenses aimed at a more constructive adaptation and, if possible, the elimination of the sources of tension. Of vital importance is the shoring up of morale, which has usually become vitiated because of the long period of suffering. Regular relaxing exercises, meditation, or self-hypnosis can help a person avoid resorting to tranquilizers, hypnotics, alcohol and smoking.

Attitudes can influence one's physiological and psychological responses. For example, in physical illness an optimistic outlook, the will to live, faith in one's physician, commitment to achievement and conviction of recovery help stimulate the immunological system, speed healing in surgery, shorten physical illness, and, according to some recent research, even inhibit the growth of cancer cells. On the other hand, abandoning hope, giving up one's claim on life, a belief that one is doomed, apathy, and the unwillingness to fight puts a damper on recovery, heightens tension, and hastens death. Norman Cousins (1976) has written an excellent article on the value of a positive outlook. In all cases of stress some form of cognitive therapy is usually called for, which adds an important dimension to the other interventions being employed. In working with such terminal ailments as AIDS this boosting of morale is especially important.

Attitude change through cognitive therapy may also be helpful in prolonged and obdurate *bereavement reactions* aiding in the resolution of grief. The grief work seems to be essential in liberating the individual from the bondage of the cherished object, preparing for a different outlook, and the development of new relationships. What interferes most with a working through of the separation crisis is denial of one's true feelings in the attempt to insulate oneself from painful stress. It may require a good deal of effort on the part of any helping person to gain the individual's confidence, counter the hostility, and break through the wall of detachment that prevents the victim from enduring the pain essential in coming to grips with the loss.

The development of a relationship with some trusted person or counselor is almost

mandatory to help the individual acknowledge and accept feelings and to begin to move toward other relationships. Discussions of misgivings, guilt feelings, idealizations, and memories encourage emotional catharsis. In most cases improvement will come about within a period of about 6 weeks. Where there is denial of one's feelings of guilt and pain, the somatic symptoms, restlessness, insomnia, and nightmares may go on for a prolonged period. A kind of paranoidal distrust often prevents the individual from getting close to people and it will require a good deal of tactful persuasion to promote resumption of close social contacts. The most extreme reaction to bereavement is precipitation of a deep depression with suicidal ideas or actual attempts to kill oneself. One usually encounters a history of previous depressive incidents in such extreme reactions. Antidepressive medications and, where suicide is a possibility, ECT may be required.

A question often asked is how much social support should be rendered in dealing with the effects of stress? In most cases where the stressful situation overwhelms the coping capacities of the victim, social support bolsters up the reserve of the individual. However, it should be withdrawn as soon as possible lest it reinforce helplessness and dependency. In chronic stress especially one should avoid operating as a good genie taking over responsibilities that should be handled by the patient. Indeed there is evidence, as shown by work with cancer patients that supportive activities for patients not undergoing chemotherapy or radiation treatments may "increase negative mood and decrease self-perceptions of worth, mastery, acceptance of the patient role, and acceptance of death." (Revenson et al, 1983). The very rendering of social supports in some persons acts as a stress source (Dunkel-Schetter & Wortman, 1982; Brickman et al, 1982).

Another question relates to the value of prevention. There is a good deal of evidence that anticipating impending stress may be helpful in dealing with it when it comes. For instance according to a study at the Harvard Medical School retirement is a risk factor in coronary heart disease (Gonzales, 1980). Job-related dissatisfactions are also a risk factor that may lead to a decision to leave one's work as the lesser of two evils. Cultivating proper attitudes toward retirement may prove to be a saving grace. A conception of

retirement as a worthy reward for years of dedicated work helps overcome the stressful conviction that it is a punishment for growing old. Where the individual faces an inevitable loss, behavioral practice sessions with role playing and encouraging the person to verbalize feelings may serve a valuable purpose. On the basis of the theory that people can adapt to any stress if they acquire adequate coping facilities, training in stress management may be a priority item in those in high-risk situations (Meichenbaum et al, 1975; Ford, 1975; Vaillant, 1971). Despite unsubstantiated claims of psychological cures rendered by exercises like running and calisthenics, there is evidence that regular exercise and other measures to improve physical fitness help individuals cope better with a high proportion of life changes like divorce, death of a loved one, and switching jobs (Science News, Vol. 130, August 2, 1986).

If an impending stressful event is anticipated such as subjection to major surgery, the expected death of a spouse or family member suffering from an incurable illness, fearful reactions to forced retirement, etc., there is no substitute for counseling sessions with a respected person who is able to supply realistic information in advance and reassuringly to handle the individual's anxieties and concerns. High morale is an important factor in stress coping, and it is best obtained by proper prior preparation or realistic indoctrination. Excessive fears or denial of concern are both conducive to poor coping. Studies show that "A moderate amount of anticipatory fear about realistic threats is necessary for the development of effective inner defenses for coping with subsequent danger and deprivation." (Janis, 1977). During counseling or psychotherapy, contingencies are assessed, resources and supports assayed, and appropriate options and adaptations reviewed.

60
Psychotherapy in Special Conditions

The principles of psychotherapy that have been outlined and the technical procedures that have been delineated apply to all emotional problems and conditions irrespective of clinical diagnosis. It may be possible, with the proper working relationship and the adroit use of appropriate techniques, to approach the goal of some personality reconstruction in any syndrome. Experience, however, has shown that certain conditions make extensive therapeutic objectives difficult to achieve. Experience also indicates that they seem to respond favorably to specific techniques or combinations of methods. In this chapter we shall consider the problems and technical modifications encountered in the treatment of neurotic, psychophysiological, personality, and psychotic disorders.

ANXIETY DISORDERS (ANXIETY NEUROSIS, PHOBIC NEUROSIS, ANXIETY STATES)

Some anxiety is a universal human experience considered by existentialists as basic to the nature of existence. It is common to all physical and emotional ailments in which the problems are conceived of as a threat. Anxiety usually generates a host of defenses marshalled to neutralize its effects. Some defenses, however, contribute to greater maladaptation than the anxiety experience itself, for example, recourse to avoidance behavior, inhibitions of function, or overindulgence in drugs and alcohol; When anxiety becomes excessive, it is regarded as a pathological syndrome to which several labels are applied, such as panic disorder, agoraphobia, generalized anxiety disorder, social phobia, simple phobia, obsessive-compulsive disorder, and posttraumatic stress disorder. Except for the anxiety, the specific features of these syndromes are fashioned by the unique personality and cognitive styles of the patient, by family dynamics, and by variable features in the environment. Although anxiety as a symptom is found in many disorders such as depression, schizophrenia, and organic brain disease, the panic, phobic, obsessive-compulsive, and generalized anxiety disorders constitute a distinctive and discrete assembly of entities (Lesser & Rubin, 1986) that are probably biologically based and affect

only approximately 8 percent of the population.

Panic Disorder Without Agoraphobia (DSM-III-R Code 300.01) Panic Disorder With Agoraphobia (DSM-III-R Code 300.21)

The identifying feature of this disorder is that intensive anxiety and catastrophic feelings of impending doom are apt to erupt unexpectedly or in relation to situations that realistically should not be threatening. Faintness, trembling, dizziness, heart palpitations, sweating, depersonalization, chest pain, and paresthesias overwhelm the individual and cause him or her to seek safety at home or in a doctor's office. If the condition repeats itself under the same conditions, phobic defenses may be organized, leading to anticipation of the attacks and further discomfort. The patient may resort to alcohol and barbiturates. Panic disorder must be differentiated from symptoms of certain physical conditions such as hypoglycemia, hyperthyroidism, and pheachromocytoma and from panicky attacks in patients with depression, schizophrenia, somatization disorder, and organic brain disorder. There is some evidence that early separation anxiety is a precursor to the condition and that a genetic predisposition may exist.

In treating the condition it should be kept in mind that appeals to reason have little effect and that insight will be deluged and rendered worthless by the flood of anxiety that overwhelms the individual. The best therapeutic focus is on the biochemical and conditioning links in the behavioral chain. When panic attacks have diminished or disappeared, cognitive therapy may be valuable, and if unconscious conflictual elements are suspected, psychoanalytically oriented psychotherapy may be attempted.

Drug therapy with antidepressants (see Table 56-1) gives us a choice of three classes of medication: tricyclics, MAO inhibitors, and a benzodiazepine antidepressant, alprazolam. Each has its advantages and disadvantages. Tricyclics, such as imipramine (Tofranil), are the most common medications used, but they may require as long as 8 weeks before a substantial response occurs. Moreover, anticholinergic side effects, such as dry mouth, blurred vision, and rapid heart beat, may upset some patients. Tofranil is started with 10 to 25 mg daily to reduce the patient's fear of side effects. Gradually, over a

2-to-4-week period, the dose is raised to 100 to 200 mg/day. If in 8 to 12 weeks the response is poor, the dose may be increased to 300 mg. Should tachycardia and heart palpitations frighten the patient, a beta blocker such as propranolol (Inderal) may be tried. A MAO inhibitor such as phenelzine (Nardil) requires restrictions of diet and avoidance of certain medicaments that some patients find inconvenient. The beginning dose is 15 mg/day, increased by 15 mg every 3 to 4 days until 60 mg are taken daily. The medication should be given in the morning and at noon to avoid possible insomnia. If after 8 to 12 weeks the effect is not impressive, the dose may be raised to 75 to 100 mg. If a side effect of muscle twitching occurs, 150 to 300 mg of vitamin B_6 should be given. One should never go from a regime of tricyclic therapy (which was not effective) to MAO inhibitors without stopping medication for 2 weeks. Alprazolam (Xanax) works within 1 to 2 weeks but may produce some drowsiness, and, taken over a long period, it can be addictive. It is started with 0.25 or 0.5 mg two or three times daily, increased every 3 days by one pill to 4 mg/day. A combination of Xanax 1-3 mg/day and propanolol (Inderal) 40-160 mg/day has resulted in an almost total relief of both panic attacks and anticipatory anxiety (Sheki & Patterson, 1984). Patients, especially those on tricyclics and MAO inhibitors, should be informed that medications require weeks to take effect. The results will depend on consistency in taking the medications.

Some patients absolutely refuse to take these medications. For these patients, relaxation therapy, systematic desensitization and then in vivo desensitization should be employed. In any case the latter therapies are almost indispensable even when drug therapy has controlled the panic. Moreover, if other links in the behavior chain are pathologically implicated, therapies bracketed to these links may productively be employed (see table 57-1). Thus group, couple, and family therapy are valuable if serious interpersonal problems exist; milieu therapy to resolve environmental difficulties; cognitive therapy for rectification of faulty attitudes, self-statements, and belief systems; and dynamically oriented, psychotherapy for personality difficulties of long standing that act as sources of continuing anxiety. In most cases psychotherapy will be needed, with a focus on interpersonal problems, such as marital conflict.

Generalized Anxiety Disorder (DSM-III-R Code 300.02)

Symptoms of a generalized anxiety reaction include restlessness, jitteriness, sighing, fidgetiness, sweating, heart pounding, sensations of tingling in the extremities, gastrointestinal symptoms, urinary frequency, a lump in the throat, flushing, great apprehensiveness, anticipation of catastrophes, fear of losing control, death fears, edginess, irritability, fatigue, and insomnia. The anticipatory expectations relate to unrealistic events or those in which possibilities are not sufficient to justify the patient's massive emotional response. In this way the anticipated happenings may be distinguished from a fear reaction that is stimulated by realistic threatening circumstances. Fears of death, disease, violence, sexual perversions, and so on are often at the basis of undifferentiated excessive anxiety, which may readily be activated by minimal unfortunate or threatening outside events, for instance, sickness in the family, the discovery on physical examination of a minor organic ailment, or an unfortunate environmental happening. The rapid heartbeat, rise in blood pressure, chest pains, and distress in breathing may convince the victim that he or she is suffering from cardiac illness, initiating persistent visits to practitioners and specialists who may diagnose the condition as "psychosomatic," the functional nature of which the patient usually fails to believe.

Most patients with generalized anxiety are so upset by their symptoms that relief from suffering constitutes their only motivation. Because they feel helpless and frightened, they are apt to demand an authoritative, directive relationship in which they are protected and through which they seek to obtain immediate symptomatic relief. To abide by these demands, the therapist may decide to employ emergency measures, which prove temporarily successful in abating anxiety. Some measures will help bring the individual to a point where the anxiety is reduced and spontaneous reparative forces come into play (see Supportive Therapy, Chapter 9). Such supportive treatment may be all that is needed to eliminate suffering, especially if the basic ego structure is reasonably sound and has broken down under the impact of severe external stress. Palliative measures may alleviate anxiety in these cases even if the problems are internally inspired. Should supportive

tactics prove to be successful, most patients will lose their incentive for further help and be content to function in their symptom-free state, even though it may be impermanent. If treatment is unsuccessful, they may lose confidence in the therapist and go elsewhere in search of relief.

It is important, therefore, to persuade the patient to accept more than supportive therapy. This may prove to be a greater task than the therapist has bargained for. Because repression is a chief defense against sources of anxiety, the patient may be unwilling to challenge habitual coping mechanisms, even though they are inadequate in dealing with the difficulty.

Treatment of pathological anxiety reactions must be adapted to their intensity, the needs and motivations of the patient, and the readiness to accept help. We now have a battery of medications that are successful in dealing with anxiety on a symptomatic level. It is always best to see if one can abate anxiety through psychosocial measures before resorting to medications, because, unless the sources of the anxiety are handled with the object of modifying or removing them, the patient will be tempted to use pills as a way of life. This is particularly important when employing the benzodiazepine drugs, which, though relatively safe and less addictive than barbiturates, are still subject to abuse. Alternatively, we may focus on vulnerable links in the behavioral chain (see Table 57-1) and use interventions that have proven helpful in dealing with these links. For example, we may in interviewing a woman with anxiety recognize that many of the patient's problems are organized around ambivalence toward a spouse. To subdue the patient with drugs, acting as if the marital situation can be bypassed, will not help the patient come to grips with the source of her trouble. Marital therapy would not preclude our dealing with any other pathogenic links in the behavior chain with suitable coordinate interventions. If she was so demoralized by anxiety that she could not use psychosocial treatments effectively, we could add anxiolytics to our therapeutic interventions.

Among the most suitable anxiolytics for achieving symptomatic stabilization in from 1 to 6 weeks are alprazolam (Xanax), 0.75 to 4.0 mg/day, diazepam (Valium), 4.0-40

mg/day, lorazepam (Ativan), 2-6 mg/day, oxazepam (Serax), 30-180 mg/day, and clorazepate (Tranxene), 15-60 mg/day. Elderly patients require a reduced dose. The actual dose is titrated to the patient's response, starting with the smallest dose and working up. We can expect some relief in from 1 to 2 weeks, with optimal effect after 6 weeks.

A new anxiolytic that undoubtedly will receive extensive testing is buspirone (BuSpar). This medication has been found to be as effective as the above drugs and to produce less drowsiness and sedation (Cohn & Wilcox, 1986).

Phobic Disorders (Phobic Neurosis, Anxiety Hysteria)

As a defense designed to control anxiety, the phobic reaction constitutes one of the most common syndromes that the psychotherapist must handle in everyday practice. When we consider the structure of a phobia, we must recognize that a maze of primary and auxiliary phenomena embrace this defense. First, the phobia, apart from the simple conditioned fear reaction, is generally a facade that conceals an underlying, earlier causative factor. Second, it is a manifestation that protects the individual from constant and intense anxiety. Third, a phobia gradually changes in its dimensions by generalizing to stimuli that are more and more remote from the initiating phobic excitant. Fourth, as the phobia spreads and circumscribes the individual's activities, the person feels increasingly undermined, self-confidence is progressively shattered, self-image is more and more devalued, and the individual may become depressed and even phobophobic. Loss of mastery revives regressive defenses and needs, including childish dependency promptings, which, if gratified, further contribute to feelings of helplessness.

Agoraphobia (DSM-III-R Code 300.22)

The most common and paralyzing phobia is agoraphobia, which usually manifests as a fear of being alone or of being adrift and helpless in public places such as shopping centers, transportation vehicles, tunnels, bridges, and elevators. In many cases the phobic reaction follows one or more experiences of severe panic while away from home. Safety is

sought within the confines of one's home, and the individual becomes housebound, venturing out only in the company of a spouse, parent, or other member of the family. There is both great dependency on and hostility toward the protective agent whose own neurotic needs to control may be gratified by the patient's helplessness. In this way a mutual neurosis is nurtured and kept alive amid hypocritical protests on both sides. Therapy for agoraphobia is directed principally at the panic against which the agoraphobia is the defense. In vivo desensitization and other adjuncts, such as the antidepressants described above for panic disorders, are also indicated. If the marital or family relationship is symbiotic, marital and family therapy are indispensable. Experience teaches that unless the family member most intimately involved with the patient is also in therapy, he or she will experience disrupted homeostasis and try to undermine the patient's treatment.

Social Phobia (DSM-III Code 300.23)

Here the individual is fearful of exposing himself or herself to the scrutiny, judgment, and possible condemnation of others. Such people justify avoiding situations where their "nervousness," shyness, weakness, inferiority, or ineptitude will be detected. In the extreme form, patients apply judgmental criteria to themselves and develop a fear of manifesting any failings even when they are alone. A common fear of such individuals is of shaking, spilling food, belching, or showing other peculiarities in behavior while eating with one or more people. Stage fright is a frequent form of social phobia found in countless numbers of people, including experienced performers. Erythrophobia, or fear of blushing, and insistence that people can detect expressions on one's face that will be misinterpreted as a sign of "craziness," nymphomania, or homosexual interest are peculiarly resistant to reasoning even when colored movies display the patient in close-ups with normal facial expressions under varied circumstances. The patient may seem to be close to a paranoidal condition here but lack other symptoms that would justify this diagnosis. Secondary depression sometimes accompanies social phobia, stimulated by the patient's conviction of helplessness in being able to do anything about his or her reaction.

Therapy for social phobia is organized around behavior therapy, particularly desensitization, with repeated exposure to the phobic situation. Too early attempts at in vivo desensitization or flooding are not recommended since the patient may panic and thus reinforce the phobia. Assertiveness training, relaxation therapy, hypnosis, and systematic desensitization using imagery can prepare the individual for exposure to the phobic stimulus that he or she dreads. Cognitive therapy may help deal with attitudinal distortions. Group therapy and psychodrama can also be of great value in giving the individual opportunities for performance desensitization and reality testing. The benzodiazepines (e.g., Valium, Atavan) may sometimes be employed as a preliminary form of treatment. They subdue anxiety, but there is always the danger that they will become a primary shield and lead to habituation. Of value for stage fright is 40 mg of propranolol (Inderal) taken shortly before performance. It helps control the shaking, rapid heart beat, and palpitations but does not dull the mind or interfere with muscular coordination, frequent consequences of tranquilization with anxiolytics. Psychoanalytic therapy has not proven to be of much help in the usual run of social phobias, in part because most patients with social phobias are not motivated to receive such intensive help and are unable to tolerate the anxiety inherent in altering ego-syntonic personality distortions. Analysis of pre-Oedipal stresses, in a more supportive object-relations format, is sometimes successful with motivated patients who have not responded to other therapies.

Simple Phobias (DSM-III-R Code 30029)

Phobias of insects, dogs, mice, bats, snakes, lightning, heights, swimming, closed spaces, air travel, and the like may be conditioned-avoidance responses that are patterned after parental phobias or that followed upon anxiety-provoking experiences with the objects or situations in question (near drowning, air crash, etc.). They may yield to behavior therapy with imagery, desensitization, relaxation exercises, and gradual exposure, first to pictures of the phobic objects and situations, then to imitation objects (toys, insects, mice, etc.), and finally to in vivo desensitation and implosive therapy, perhaps at first in the presence of the therapist. A claustrophobic patient, for example, may lock oneself in a closet in the therapist's office for gradually increasing periods. Group

behavior therapy with participants suffering from the same or similar phobias can accelerate treatment, especially during the phase of in vivo desensitization.

Sometimes, however, simple phobias turn out to be not so simple. In such cases anxiety over one's unconscious dangerous drives have been displaced onto external objects and situations that have become disguised symbols of the repudiated inner drives (Oedipal strivings, perverse sexual cravings, hostility, etc.). For example, a person may avoid knives and other potentially lethal objects as a defense against repressed anger. Because of its apparent protective quality, the phobia may become fixed, the patient manifesting the greatest obstinacy in facing it. The treatment of choice is dynamic psychotherapy, which in the most stubborn cases will necessitate setting up and resolving a transference neurosis using the technique of classical analysis. In some cases hypnoanalysis may expedite therapy, but this requires a subject capable of entering a somnambulistic trance (Wolberg, 1964a).

Obsessive-Compulsive Disorder (DSM-III-R Code 300.30)

In obsessive-compulsive disorders ideas, usually with obscene, violent, necrophobic, or thanatophobic content, flood the mind and liberate aversive feelings of guilt, shame, and anxiety. The phenomenon sometimes takes the form of an inner voice that commands the person to do antisocial acts. Attempts to neutralize these ego-alien thoughts may in some cases provoke certain compulsive movements or rituals, which, seemingly absurd to an observer and even to the patients themselves, temporarily relieve the painful feelings. Attempts to control or resist obsessive ideas and the compulsions they inspire generally are in vain and may even activate the obsessions. Compulsive acts that oppose rational conduct may be executed in secret. Obsessives usually chastise themselves for their weakness and betrayal of common sense. Fears of losing control, of becoming psychotic, and figuratively or literally of being possessed by demons complicate the picture and add to the victim's misery (Nemiah, 1985).

The etiology of the disorder is still obscure. There are indications that a biochemical factor of some kind exists in this illness perhaps related to serotonin imbalances.

Hypothesized also is an affiliation with depression, since many patients exhibit biological markers of an affective disorder. Some authorities postulate that there are anatomical abnormalities in the cingulate gyrus and hippocampus. Though psychological mechanisms in obsessive-compulsive disorders offer themselves luxuriously to psychoanalytic inquiry, psychoanalysis and psychoanalytic therapy have failed to bring about hoped-for results in alleviating obsessive and compulsive symptoms.

Clinically, several types of obsessive patients are commonly seen (Insel, 1983). The largest number are those who fear contamination and who then indulge in washing or scrubbing rituals. Such "washers" may, to their dismay, spend a good deal of their time in the bathroom. A second large group are the "checkers," who have to check repeatedly that they have completed an act because they fear that dereliction may bring harm to themselves or others. A third group are the "stallers," who may take forever to execute a simple task; for example, the completion of normal activities such as dressing or eating may take hours. A fourth group are the "worriers," who are preoccupied with Cassandra-like fears of evil acts and catastrophes that are about to happen; usually patients do not perform rituals to neutralize them. Although each patient exhibits the unique traits of his or her personality structure, obsessive persons demonstrate remarkably similar behaviors in every country the world over.

Many therapies have been unsuccessfully employed to bring relief to these suffering and handicapped individuals. Of all treatments, behavior therapy has scored the greatest successes in controlling obsessive and compulsive symptoms (Rachman et al, 1973; Rachman, 1976; Wilson TG, 1976; Marks et al, 1975; Marks, 1981; Foa et al, 1985). The most effective method (scoring up to 80 percent benefit) is in vivo desensitization with practice sessions of (1) deliberate prolonged exposure (45 minutes to 2 hours) to thoughts, fantasies, and situations that inspire disturbing symptoms; and (2) coordinate blocking of compulsive responses (hand washing, checking, ritualistic behavior) that have temporarily served to neutralize anxiety in the past. In implementing this approach, which consists of 10 to 20 sessions, graded exposure to increasingly intense stimuli from 45 minutes to 2 hours and the absolute blocking of responses for long periods (sometimes for

days) requires a motivated patient willing to endure the anxiety and suffering that such restrictions entail.

Obviously the patient will protest vociferously and express dread of being exposed to dangers. It will require tact, understanding, and great persuasion, utilizing the working relationship skillfully, to convince a patient to try this intervention.

The treatment protocol evolved by Stekete and Foa (1985) for exposure and response prevention details the sequence of treatment and contains useful appendices and a case study that illustrates the application of specific procedures. Approximately 3 to 6 hours are spent in gathering information and in treatment planning. The patient is then given a full explanation as to what to expect. The scenes to be used in imagery (flooding), the situations to be met in in vivo desensitization, and the responses and rituals to be prevented are delineated. A decision is made as to whether the patient's home or a hospital is to be used, and the aides (family members, friends, nurses) to assist the patient in the assignments are chosen. Since massed sessions produce better results, a minimum of 3 sessions weekly are given. The total number of sessions are between 15 and 20. At each session the first few minutes are spent in discussing what has happened since the last visit. Next, the patient is exposed to the target thoughts and fantasies and is enjoined to try to fantasize that he or she is actually in the imagined situation. Every 10 minutes, levels of anxiety are monitored. This exercise, which lasts from 1 to 2 hours, is at first highly anxiety provoking, but eventually the anxiety lessens. In advance of the sessions, a series of five graded upsetting scenes are prepared to be presented in low to high order, and each is used until the anxiety diminishes greatly or is gone. After this exposure, the patient is confronted by the therapist with the situations he or she fears most (touching dirt, being prevented from checking a gas stove, etc.) and the therapist models normal behavior (e.g., touching dirt and refraining from washing). Projected slides, pictures, movies, or video recordings may be used to convey the feared situations (funerals, homosexuality, etc.) if the actual situation cannot be confronted. In the case of "washers," no washing of hands is allowed (sometimes for as long as several days), and only a brief shower is permitted every fifth day. In the last few sessions, the patient is instructed as to

normal modes of behavior. Thus "washers" are enjoined to wash their hands only before meals, after bathroom use, and after handling especially dirty objects. Following the intense treatment period, a self-exposure maintenance program (practiced at least weekly) is prescribed as a preventive measure. When necessary, interpersonal skills training, assertiveness training, marital therapy, and family therapy may be prescribed. A follow-up self-help group may be valuable. Only when absolutely essential should hospitalization be prescribed since many provocative situations are likely to be absent in a hospital setting.

As accessory therapy, relaxation exercises may periodically be employed for tension relief (Jacobson, 1974; Benson, 1974). Another technique that some patients find useful is "thought stoppage" (Wolpe, 1958). Here thoughts to be controlled are identified and deliberately practiced at the same time as one shouts "Stop" and perhaps coordinately bangs one's hand against one's thigh. Or one may wear a rubber band around the wrist and flick it to deliver a painful stimulus. Attention should then be diverted elsewhere. Systematic desensitization (Wolpe, 1958) may also occasionally be effective if tension is high. The patient may be enjoined to engage in regular practice sessions of fantasies, such as being exposed to extremes (often to a most ridiculous degree) of his or her symptoms and perhaps their consequences. The logotherapeutic technique of paradoxical intension *(q.v.)* is a form of this type of therapy. At home the patient may be requested to engage in such varied tension-relieving exercises as keeping a diary record of accomplishments (such as response resistance or blockage) and his or her reactions.

Because depression has been so frequently observed in obsessive patients, a variety of drugs have been tried, including clonidine, loxapine, and the tricyclic antidepressants. The latter class of drugs has proven especially beneficial both for their antidepressant and antiobsessional effects (Mavissakalian et al, 1985). Clomipramine (Anafranil) in particular has proven to be valuable and in many cases has enabled an intractable patient to become cooperative. This medication appears to have a specific antiobsessional effect that is distinct from its antidepressive property (Singh & Sexena, 1977). I have found clomipramine almost indispensable in working with some obsessive-compulsive patients

since by muting symptoms motivation is greatly improved. The initial dose of clomipramine (which is available in Canada, Mexico, and Europe and may soon be released in the United States) is 25 mg three times daily, increased to 150 mg/day as required (maximum dose 200 mg and 300 mg for hospitalized patients). Adolescent and elderly patients should be given 20-30 mg daily, increased by 10 mg daily, if necessary, depending on response and tolerance. A history of glaucoma, liver damage, or blood dyscrasias or pregnancy contraindicates treatment. Use of a MAO inhibitor drug following the use of clomipramine necessitates a delay of 14 days, the same as for any other antidepressant drug. Anticholinergic effects as with other antidepressants, are to be expected. In some cases a combination of clomipramine and clonopin reinforces the beneficial effect. Physical examinations and blood tests should be done periodically. The combination of clomipramine and in vivo desensitization is at this date the best treatment for the symptomatic relief of obsessive-compulsive illness.

Any therapist who believes that the relief of obsessions and compulsions in the obsessive patient is all that is necessary is, however, in for an unpleasant surprise. Although dealing with the biological and conditioning links in the behavioral chain is important, this will not resolve all the problems encountered by the patient any more than relieving painful and distracting hemorrhoids will cure a coordinate sinus condition. Additional implicated links in the behavioral chain (see Table 57-1) require attention since the troubles they cause will sometimes cry out for help. In certain patients, symptom alleviation enhances the chances for a reasonable adjustment, including the usual evasions and compromises essential in our society. Other patients may find their liberated energies merely intensify their interpersonal, environmental, and intrapsychic problems. Here interventions related to these areas of trouble are indicated. Counseling, interpersonal therapy, group therapy, marital therapy, family therapy, and milieu therapy are indicated for dealing with difficulties in special areas. Cognitive and dynamic approaches enable the individual to give a more authentic meaning to his or her symptoms than the misinterpretations usually assigned to them (such as that he or she is destined to psychosis, sexual perversion, cancer, murderous acting-out, etc.). Recognition that fantasies and impulses are manifestations that possess a symbolic significance and that

they do not have to be taken literally can be reassuring to many patients, even if it is not completely curative.

The great problem is not only how to deal with the unexpected outbursts of nascent anxiety, which become particularly pronounced when obsessional ideas periodically break loose, but, more significant, how to manage the hostile, disturbing character structure that is a component of the disorder in many patients.

Obsessive-compulsive neurosis does not respond to insight therapy as well as do other neurotic syndromes. It can be done, of course, but the therapist must be extremely skilled in handling the transference and must have much fortitude to tolerate the vicissitudes that will come up in the course of treatment. Years of futile probing into the unconscious and careful unravelment of the sources and meanings of rituals may accomplish little. The obsessional personality is an expert in "one-upmanship." He or she engages in a verbal tug-of-war, must get in the last word, undermines psychotherapy as a process, and derogates the ability of the therapist to provide help. Yet obsessional patients bitterly complain that they are not being helped. What is important in therapy is to deal with the immediate transactions between therapist and patient and to prevent the patient from entering into gambits through which he or she can conspire to wrest control from the therapist. The therapy for compulsive-obsessive personality disorders must, therefore, take into account the patient's dependence, profoundly hostile impulses toward people, need for detachment, tendency to "isolate" intellect from feeling, and the magical frame of reference in which the patient's ideas operate. Salzman (1966) points out that the obsessive-compulsive defense of persistent doubting, negativism, unwillingness to commit oneself, and striving for perfection, omnipotence, and omniscience are attempts to control the universe and to guarantee one's safety, security, and survival. This defense acts as a block to constructive learning. Free association and concern with past memories are used as a screen behind which the obsessional person conceals his or her coping maneuvers. According to Salzman (1983), what is essential in working with obsessional patients is to be continually aware of their obstructive personality characteristics; their defensiveness, which causes them to reject the therapist's observations; their need for

control; their striving for perfection; and their doubt, ambivalence, and tendency to obfuscate issues. This calls for great activity on the part of the therapist, a focus on the present, a need to deal with the patient's grandiosity, continual reexamination of issues so as to facilitate working-through, and "risk-taking" by the therapist.

Most therapists find working with the patient on an analytic level a most difficult and frustrating experience. Classical analysis is usually ineffective and therapy can become interminable as the patient and therapist become locked into a sadomasochistic relationship, very much like a bad marriage, that can go on for years. This does not mean that one has to cast a dynamic approach to the winds. I have found it helpful with many obsessive cases to work dynamically with derivative rather than nuclear conflicts, showing the patients, how the characterological distortions of dependency, hostility, low feelings of independence, devalued self-esteem, and tendencies toward detachment operate in producing disruptions in their relationships with people and their attitudes toward themselves. Patients must be shown how their personality characteristics inevitably create the stress and generate the anxiety that initiate many of their disruptive defenses. Although a patient may seemingly accept such explanations and interpretations, they will at first have little effect on his or her behavior. The therapist will have to demonstrate the workings of the patient's dynamics in his or her everyday life over and over again until a tiny chink occurs in the patient's defensive armor. Most penetrating will be the elucidation of how the patient's personality problems display themselves in the transference with the therapist. A tremendous amount of dogged perseverance will be necessary which can tax the tolerance of the most empathic therapist. Countertransference must be watched assiduously and used as constructively as the therapist can manage given the undisciplined, resistive, and helter-skelter behavior of the patient. Therapists who have the stamina and forbearance to work with their patients beyond the profits of symptom relief toward alteration of the character structure will have to resign themselves to the battle conditions of tempestuous long-term therapy, which, while unnerving in the beginning, may very well prove worthwhile in the end. Some helpful leads may be found in the section in this chapter on the therapy of personality disorders. The articles by Barnett (1972), E. K. Schwartz (1972), Salzman (1966, 1983),

and Suess (1972) contain interesting pointers.

The prognosis for obsessive-compulsive neuroses will depend upon the severity of the condition and the residual ego strength. It will also depend upon the length of time the patient has been ill. In some cases obsessive-compulsive patterns appear to be of relatively recent duration, the compulsive difficulty having developed as a result of external pressures and problems to which the patient could not adjust. The prognosis for these patients is much more favorable than it is for patients who have been ill since puberty. Some psychiatrists recommend that patients who do not respond to medications, behavior therapy, and psychotherapy and whose anxiety and suffering become unendurable ultimately submit to leucotomy, which, in some cases, will control symptoms when everything else fails. Tippin and Haun (1982) report that more than 69 of 110 obsessive patients who had modified leucotomy operations were symptom-free or improved and needed no further treatment. Understandably, this radical form of therapy will be resisted and should not be used except under extraordinary circumstances.

Posttraumatic Stress Disorder (DSM-III-R Code 309.89)

Under unusually harsh and catastrophic conditions of stress, therapists may confront reactions of great physiological and cognitive severity, beyond what we encounter in the face of such adversities as bereavement, marital conflict, chronic illness, and other calamities (see Chapter 59). These conditions include such natural disasters as earthquakes, floods, hurricanes, famine, transportation and industrial accidents, rape, assault, torture, and bombings. For the most part, posttraumatic stress disorders are mainly consequent to the disasters of war. Especially prominent is combat fatigue among soldiers of the participating armies. The most common reaction is an anxiety state characterized by tension, emotional instability, somatic symptoms, insomnia, and nightmarish battle dreams. Less common are conversion, depressive, and psychophysiological reactions. Acute temporary psychotic-like episodes may also occur.

Knowledge of the dynamics of war neurosis made certain preventive measures possible in World War II. Soldiers who had had training that had made them feel they

could defend themselves under all circumstances, who had been shown that they had adequate weapons of attack, who had confidence in their leaders, and who had obtained sufficient indoctrination and morale building were best prepared to resist a breakdown. An important element in prevention was group identification. Cooperation with others was essential, and the individual had to be made to feel that he was part of a team and that he had enough of an idea of the battle situation and the planned strategy so that he would not be caught by surprise.

The incidence of war neuroses is proportionate to shattered morale and to feelings of isolation from fellow soldiers. An organized body of men fighting for a cause that they consider just can best overcome war stress and hardship.

Adequate information regarding the significance of the conflict, assignment to units with congenial companions, fair discipline, commanding officers who merit respect, periodic relief from duty in the combat zone, and confidence in the assigned weapons all contribute to better morale and greater stress tolerance. Teaching soldiers that fear is normal and that one can function with it may be reassuring. A history of previous emotional disorders, an unstable family situation, and poor socioeconomic conditions in civilian life are usually though not always bad prognostic signs. Some solders maladjusted in civilian life relish the conditions and even dangers of army life. Upon termination of army service, having adjusted adequately up to this time, a certain number of such individuals are unable to adjust to civilian life. A phenomenon that was noted among officers and enlisted personnel in Korea and Vietnam was separation anxiety, which developed when the end of their service was near and the solder had to leave his companions. This occurred even among soldiers in combat units. The group identification which held the individuals together was reluctantly given up.

In spite of preventive attempts, stress reactions of varying degrees of intensity may occur, particularly in response to precarious conditions of combat. A more vulnerable soldier may manifest panicky reactions during which thinking gets disorganized, nonproductive somatic symptoms become pronounced, and behavior tends to become

maladaptive, exposing the individual to even more danger. In combat situations during fierce shelling, for example, the soldier may flee safety areas and run wildly away, exposing himself to shrapnel and gunfire. Overwhelming stress may produce a temporary shock-like reaction followed by what seems to be recovery.

Even the most stable combatants are apt to exhibit a good deal of muscle tension, faintness, giddiness, tachycardia, palpitations, shaking, and tremors during an engagement. The bravest soldier will experience fear, which prevents him from throwing caution to the winds. In many cases gross stress reactions are brought on by killings, fatigue, loss of sleep, hunger, and cold over a prolonged period. Homesickness, uncertainty about the future, physical discomfort, and sexual deprivation may be as traumatic as actual engagement in combat. Reactions will usually follow responses to past situations of acute stress. One of the most important factors in subduing these reactions is good leadership, including thoughtful directing of activities toward maintaining morale.

Experience in treating gross stress reactions in the last war indicated that removing soldiers from forward areas to hospitals in the rear tended to aggravate the difficulty. Good results were obtained when treatment was organized around the expectation of returning to duty. It has been observed that an aversive attitude toward "nervousness" and "weakness" by frontline troops acts as a deterrent to neurotic combat reactions. Expectations that a soldier who "breaks down" will be moved away from the battle zone, released from the army, and perhaps compensated for his disability encourage neurotic symptoms. Group identification tends to reassure the individual and bolster morale. The need to be accepted by the group is one of the most important safeguards against "breaking down." A soldier removed from his unit and sent to a hospital is a candidate for psychological disability, which will stir up guilt feelings and devalued self-esteem. The security of the hospital setting paradoxically prevents him from making a rapid recovery. During the last war, rest outside of a hospital, good food, and the opportunity to verbalize fears and other feelings to a reassuring person proved most successful. Tranquilization, narcosyntheses, and hypnosis in serious cases were employed with rapid success in susceptible subjects. Combat exhaustion, if treated early, did not necessarily result in

neurosis. A moderate anxiety state cleared up in 24 hours with rest, reassurance, and some tranquilization if needed. It was assumed that the soldier would go back to the front. Where there was reluctance to return to battle duty, appeals to patriotism, courage, and "not letting one's buddies down" often built up the person's courage and determination. Encouragement to verbalize fear and disgust was vital, since the soldier in this way released tension and discovered that others shared his anxieties.

The value of respecting the soldier's "gripes" in building morale has long been recognized. The role of the leader is important, too, and an intrepid commanding officer has always been of great service. It is amazing how often a change in attitude in a soldier can prevent neurotic collapse. Under constructive leadership, a soldier has the best chance of pulling himself together and of dealing with his need to protect himself from danger while discharging his duties honorably to preserve acceptance from his peers.

In many cases an incubation period ensues during which what Kolb (1982) has termed "secondary reflective cognitive consequences of the catastrophic experiences" surface in the form of survival guilt, shame, and heightened sensitivity to stimuli directly or remotely resembling the initial stressful assault. Mardi Horowitz (1976), in pointing out this reaction, has emphasized the importance of existential threat as a basic cognitive factor in posttraumatic states.

The posttraumatic reaction may occur within 6 months of the trauma (the acute subtype) or after 6 months and even after several years (the chronic or delayed sub-type). Often it develops after the individual has become stabilized and has resumed habitual functioning. Reactions here draw upon latent personality strengths and on the degree of repression that has sealed off appropriate emotional reactions to the offensive stressor. After the individual has apparently digested the implications of what has happened, he may respond with depression, bouts of anxiety, restlessness, aggression, guilt feelings, obsessions, insomnia, nightmares, fugue states, and amnesia, which may continue indefinitely. In the majority of cases, however, an adaptation is made, even though certain symptoms continue, and, after a period of adjustment, these symptoms may become fixed.

In some instances detachment, aggression, startle reactions to noise, muscle tension, tremors, depression, insomnia, battle nightmares, psychosomatic complaints, and bouts of anxiety may be very difficult to handle. In serious cases, outbursts of violence, detachment, and paranoia may interfere with a constructive social adjustment. Guilt feelings about one's behavior in the army, particularly related to the killings and personal feelings of cowardice, may sponsor a good deal of recrimination and self-punishment.

Therapy for posttraumatic stress disorders may require some time, especially if alcohol or drugs have been employed to quiet the symptoms. Even when these are brought under control, a good deal of working-through of the guilt feelings may be required. Hendon et al. (1983) have evolved a useful questionnaire as a first step, along with an excellent outline for a five-session evaluation of the problem. Most important, a provision should be made for continuing therapy after the initial sessions have opened the door to suppressed feelings. Working through such feelings is important. Otherwise the patient will be left in a more vlunerable state than before. Once a treatment is started, exploration of the meaning of the combat experiences and the devices the veteran uses in covering up his guilt and pain are in order.

Treatment of stress reactions in civilian life (hurricanes, floods, explosions, mass bombings, etc.) should be started as soon as possible, since delay permits the neurosis to become more highly organized and allows the secondary gain element to take hold. First aid helps victims of disasters to return to proper functioning in a short time. Preventive measures are of incalculable value if a disaster is anticipated and potential victims are apprised of dangers as well as suitable protective and ameliorative actions that may be taken. Practice drills under simulated disaster conditions, faithfully repeated, help to establish appropriate patterns if and when emergencies occur.

Responses of people to both unexpected and expected dangers will vary depending on the specific meaning of the danger situation to them and their residual stabilities and habitual coping mechanisms in the face of stress. They will also respond uniquely to any warning signals. Among the gravest dangers to the group are the wildly uncontrolled

panic reactions of a few unstable individuals, which can have a contagious influence on the rest of the group. If the leader knows in advance which members are apt to manifest unrestrained fear, he or she may select them in advance and assign them definite tasks so as to divert their energies.

Even with drills, exercises, and warning signals, the impact of a disaster is bound to provoke immediate reactions of anxiety and confusion. These, however, should soon be replaced by adaptive responses encouraged during the practice sessions. As soon as the violent impact of the disaster has subsided, organized activities will take place. Working together and helping the more physically and emotionally disabled has a profoundly reassuring effect. People who are unable to compose themselves may need special treatment. For example, a person who shows blind panic will require firm restraining by two or three people to avoid spreading panic throughout the group. Drug therapy may be necessary as described in the section on dealing with panic reactions in emergencies (see Chapter 58).

In treating disaster victims whose neurotic or psychotic responses do not subside with the termination of the emergency, the first principle is to permit them to verbalize feelings; the second, to accept their reactions, no matter how unreasonable they may seem. Supportive therapy coupled with sedation or tranquilization will usually suffice to restore the person to his or her previous state. Imagery plays an important part in working through these disorders (Horowitz MJ, 1970, 1976; Brett 1985) and may serve as a productive therapeutic vehicle, especially in hypnosis.

If a patient has a continuing stress reaction that threatens to become chronic, narcotherapy *(q.v.)* and hypnotherapy *(q.v.)* are often effective for purposes of symptom removal. In instances where anxiety is extreme, one may utilize an "uncovering" type of technique. Here hypnosis and narcotherapy are also of help. The recovery of amnesias, and the reliving of the traumatic scene in action or verbalization, may have an ameliorative or curative effect.

While hypnotherapy and narcotherapy accomplish approximately the same results,

the emotions accompanying hypnotherapy are often much more vivid, and the cathartic effect consequently greater, than with narcotherapy. There are other advantages to hypnosis. The induction is usually brought about easily without the complication of injections and without posttherapeutic somnolence. Additionally, hypnotic suggestions are capable of demonstrating to the patient more readily his or her ability to gain mastery of functions. On the other hand, narcotherapy is easier to employ and does not call for any special skills.

If it is essential to remove an amnesia, the patient is encouraged under hypnosis or narcosis to talk about the events immediately preceding the traumatic episode and to lead into the episode slowly, reliving the scene as if it were happening again. Frequently the patient will approach the scene and then block, or he or she may actually awaken. Repeated trance inductions often break through this resistance. Also, it will be noted that the abreactive effect will increase as the patient describes the episode repeatedly. Apparently the powerful emotions that are bound down are subject to greater repression than the actual memories of the event.

Hadfield's (1920) original technique is still useful. The patient is hypnotized and instructed that when the therapist's fingers are placed on the patient's forehead, the patient will picture the experiences that caused the present breakdown. This usually produces a vivid recollection of the traumatic event with emotions of fear, rage, despair, and helplessness. The patient often spontaneously relives the traumatic scene with a tremendous cathartic effect. If the patient hesitates, the therapist must encourage a detailed description of the scenes dominating the patient's mind. This is the first step in therapy and must be repeated for a number of sessions until the restored memory is complete. The second step is the utilization of hypnosis to readjust the patient to the traumatic experience. The experience must be worked through, over and over again, until the patient accepts it during hypnosis and remembers it upon awakening. Persuasive suggestions are also given, directed at increasing assurance and self-confidence. After this the emotional relationship to the therapist is analyzed at a conscious level to prevent continuance of the dependency tie.

Horsley (1943) has mentioned that when the ordinary injunctions to recall a traumatic scene fail, several reinforcing methods can be tried. The first has to do with commanding the patient to remember, insisting that he or she will not leave the room until memory is completely restored for the traumatic events. The second method is that of soothing, coaxing, and encouraging a total recall ("You are about to remember the troubled scenes that will remind you of your experiences.") If this is unsuccessful, the patient is told that although the memory has not yet come through, it will upon awakening reveal itself in any way the patient sees fit. Instruction to recall more details in a dream the same or the next night is given.

Various hypnoanalytic procedures, such as dramatization, regression and revivification, play therapy, automatic writing, and mirror gazing, may be utilized to recover an obstinate amnesia (Wolberg, 1964a). The reaction of patients to the recall of repressed experiences varies. Some patients act out the traumatic scene, getting out of bed, charging about the room, ducking to avoid the attacking objects and people. Other patients live through the traumatic episode without getting out of bed. Some individuals collapse with anxiety; they should be reassured and encouraged to go on. If the patient voices hostility, he or she should be given an opportunity to express grievances and dislikes. Clarification of feelings of injustice may afford considerable relief.

It must be remembered that the object in therapy is to dissipate feelings of helplessness and of being menaced by a world that the patient no longer trusts. The sense of mastery and the ability to readjust oneself to life must be restored. The best reactions to hypnosis are obtained when it is executed as close in time to the trauma as possible. This may prevent organization of the condition into a chronic psychoneurosis. Follow-up therapy is essential, with integration on a waking level of the material brought up during the trance. If the anxieties relating to the disaster have precipitated hysterical, phobic, compulsive, and other reactions characteristic of the ways that the patient has dealt with anxiety in everyday life, long-term insight therapy will usually be required.

In chronic stress reactions, treatment is difficult because of the high degree of

organization that has taken place and because of the strong secondary gain element involving monetary compensation and dependency. The recovery of amnesias should always be attempted, but even where successful, this may not at all influence the outcome. An incentive must be created in the patient to function free of symptoms, even at the expense of forfeiting disability compensations, which in comparison to emotional health may be shown to be diminutive indeed. (See also Chapter 59; Crisis Intervention, Chapter 57; and pertinent parts of Chapter 58 on emergencies.)

DISSOCIATIVE DISORDER (HYSTERICAL NEUROSIS, DISSOCIATIVE TYPE)

Dissociative disorders manifest themselves in disturbances of consciousness, memory, and identity. In *multiple personality disorder (DSM-III-R Code 300.14)* a dramatic interruption of the habitual personality is periodically produced by the intrusion of a seemingly foreign personality or personalities that inspire variant behaviors often at odds with the usual patterns of the individual. In *psychogenic fugue (DSM-III Code 300.13)* the person wanders off away from home with the assumption of a new identity and amnesia for the previous identity. In *psychogenic amnesia (DSM-III Code 300.12)* disturbances in recall are characteristic. These blank spots may occur without identifiable cause or may follow an accident or catastrophic incident. In *depersonalization disorder (or depersonalization neurosis) DSM-III-Code 300.60)* the reality sense is impaired with feelings of detachment from oneself.

The basic defense employed in dissociation reactions is repression. Therapeutic techniques are best organized to resolve the repression and deal with inner conflicts. Transference analysis, especially the working through of a transference neurosis, is ideally suited to therapy of this disorder, but may not be possible for practical reasons and because of patient resistance. When transference analysis cannot be used, a less intensive psychoanalytically oriented psychotherapy may be employed. From the viewpoint of mere handling and removal of symptoms, hypnosis is classically of value. Although hysterical symptoms can often be eliminated in relatively few hypnotic sessions, the dramatic, infantile, and self-dramatizing personality constellation associated with this reaction will

require prolonged psychotherapy, preferably along reconstructive lines. Unfortunately, even though insight therapy is accepted by the patient, a great many impediments will become manifest during the course of treatment in the form of intellectual inhibitions and other devices to reinforce repression.

Whereas insight therapy is the best treatment for this condition, circumstances of obstinate resistance, faulty motivation, and profound secondary gain may prevent any other than a supportive approach.

Symptom removal by authoritative suggestion, with or without hypnosis, is occasionally indicated, particularly where the symptom produces great personal discomfort and interferes with the individual's social and economic adjustment. Some symptoms serve a minimal defensive purpose in binding anxiety. The inconvenience to the patient of such symptoms is an important incentive toward their abandonment. If the symptom constitutes a plea for help, love, and reassurance on the basis of helplessness, the therapist, by ordering cessation of symptoms, virtually assures the patient of support and love without the need to utilize symptoms for this purpose. Should the patient sense that his or her demands are not being fulfilled, a return of symptoms or histrionic acting out may be expected.

Although some symptoms vanish with a strong authoritarian suggestive approach, one must not overestimate the permanency of the apparent cure since the original motivations that sponsored the symptom are not altered in the least and a relapse is always possible. Consequently, whenever the therapist can do so, the patient should be prepared for future therapy by explaining the purposeful nature of the symptom and its source in unconscious conflict.

Since hysteria often represents a reaction to unpleasant circumstances that stimulate inner conflicts, a guidance approach is sometimes utilized in appropriate cases to adjust the patient to environmental demands from which he or she cannot escape and to help the patient modify existing remediable situational difficulties. It may be possible to get a hysterical individual to make compromises with the environment so that he or she

will not be inclined to overreact to current stresses. Here, too, an attempt must be made to acquaint the person with the fact that the symptoms, though inspired by external difficulties, are actually internally sponsored. Once the patient accepts this fact, therapy along insight lines may be possible.

The treatment of hysteria through hypnotic symptom removal and by guidance therapy are least successful if the symptom serves the purpose of providing intense substitutive gratification for sexual and hostile impulses.

Difficulty will also be encountered if the symptom tends to reinforce the repression of a traumatic memory or conflict, as in amnesia. The extent of amnesia varies. It may involve a single painful experience in the past, or it may include a fairly wide segment of life. It may actually spread to a point where the person loses his or her identity and forgets the past completely. Amnesia serves the defensive purpose of shielding the individual from anxiety. The intractability of an amnesia, consequently, is related to the amount of anxiety bound down and to the ego resources that are available for coping with the liberated anxiety. The fear of being overcome by anxiety may be so great that an impenetrable block to recall will exist despite all efforts to reintegrate the person to past memories. Indeed, the fear of uncovering a memory may be so strong that the person will resist trance induction.

When resistance to hypnosis is encountered, a light barbiturate narcosis, either oral or intravenous (see the section on Narcotherapy), may remove the block. A trance, once induced, is deepened, and a posthypnotic suggestion is given the patient that he or she will henceforth be responsive to hypnosis without narcosis.

It must again be emphasized that, although certain hysterical symptoms may be treated rapidly through short-term supportive treatment, the basic personality problems associated with the hysterical disorder require a considerable period of reconstructive therapy.

SOMATOFORM DISORDERS

A number of psychophysiological autonomic and visceral disorders are included in this category, namely, somatization disorder, somatoform pain disorder, hypochondriasis (or hypochondriacal neurosis), body dysmorphic disorder, and conversion disorder (hysterical neurosis, conversion type). In *somatization disorder (DSM-III-R Code 300.81),* the patient presents a variety of somatic complaints resulting in frequent consultations with physicians. Despite batteries of negative tests, and medical reassurance that no organic basis exists for the symptoms, the patient is never fully convinced that this is so. Such "psychosomatic" or "psychophysiological" manifestations are complicated by a depressive and anxiety overlay, which adds to the suffering of the individual. An exaggerated form of this symptomatology is found in *hypochondriasis (or hypochondriacal neurosis) DSM-III-R Code 300.70.* Here the symptoms, though intense, are still not of a delusional nature, and some appeal to reason is possible. A special condition in this category is preoccupation with presumed defects in the appearance of one's face and body in the absence of any real anomaly *(body dysmorphic disorder [dysmorphobia])* that may drive the victim to a succession of plastic surgeons for correction that never comes about. Where pain for over six months constitutes the complaint factor and persists in the absence of organic pathology, we may be dealing with a *somatoform pain disorder (DSM-III-R Code 307.80).* This must be differentiated from a *conversion disorder (or hysterical neurosis, conversion type (DSM-III-R Code 300.11),* which usually takes the form of a neurologic disease (paralysis, aphonia, visual disorder, anesthesia, astasia-abasia, and hysterical contractions) or of such morbidities as persistent vomiting, false pregnancy (pseudocyesis) and other peculiar symptoms that are basically symbolic manifestations of inner conflict. In many conversion syndromes a casual attitude (la belle indifference) accompanies the outwardly alarming symptoms. Somatoform disorders are often rooted in disturbances in the personality organization; some are engendered by defects in the earliest contacts of the infant with the mother. The personality structure of the patient, consequently, contains dependent, hostile, and masochistic elements that tend to obstruct a good working relationship. Because the ego is more or less fragile, anxiety, mobilized by the transference and by interpretation, may be intolerable. Insight therapy may, therefore, have to be delayed in favor of discreet supportive techniques during which the patient is

permitted to relate dependently to the therapist.

The negative elements of the relationship with the therapist must constantly be resolved, and the therapist must be alert to hostile manifestations, which the patient will perhaps try to conceal. Once a good working relationship is established, exploration of inner strivings, needs, and conflicts with cautious interpretations may be attempted. Most patients with somatoform disorders find it difficult or impossible to think abstractly, however, and revelations of conflict seem to do little good. They cannot seem to describe their affects and to relate their fantasies, and they fail to respond to free association and interpretation (Nemiah, 1971). Exaggeration of the patient's physical symptoms is a common sign of resistance. When symptoms increase in intensity, the patient may be tempted to leave therapy. Treatment is generally a long-term proposition, since the deep personality problem associated with the symptoms resolves itself slowly. Essentially, therapy may follow the design for the management of personality disorders (q.v.).

A constant danger during insight therapy is the unleashing of excessive quantities of anxiety, usually the result of too speedy symptom removal or too rapid dissipation of defenses. Often the somatic disturbance represents the most acceptable avenue available to the patient for the discharge of anxiety and hostility. Because the ego has been unable to handle these emotions on a conscious level, the mechanism of repression is invoked. When coping devices are threatened without a coordinate strengthening of the ego and the person becomes prematurely aware of unacceptable conflicts and strivings, there is definite danger of precipitating a crisis. The patient may release such intense anxiety that he or she will employ symptomatic contingencies to bind this emotion. The patient may, for instance, develop depressive or compulsive symptoms or display detachment and other characterological defenses. Anxiety may, nevertheless, get out of hand and shatter the ego in fragile personalities even to the point of precipitating a psychosis. In hysterical conversion disorders symptoms may astonishingly be temporarily dissipated by strong authoritative commands as during hypnosis. Little impact is registered on the underlying personality distortions.

It may be impossible to do more for the patient than to give supportive therapy. For instance, persuasion and guidance may enable the patient to organize his or her life around the defects and liabilities, to avoid situations that arouse conflict and hostility, and to attain, at least in part, a sublimation of basic needs. The object here is to bolster the ego to a point where it can handle damaging emotions more rationally as well as to improve interpersonal relationships so that hostility and other disturbing emotions are not constantly being generated. In some instances such therapies help to liberate the individual from the vicious cycle of neurosis, facilitating externalization of interests, increasing self-confidence, and indicating ways of discharging emotions. Minor tranquilizers, such as Librium and Valium, may be administered periodically if symptoms are especially harsh. Considerable relief from symptoms may be obtained through relaxation exercises, meditation, hypnosis, and biofeedback (see Chapter 56). Behavior therapy works better than dynamic psychotherapy.

The therapeutic relationship is kept at as positive a level as possible, an attempt being made to show the patient that the symptoms are not fortuitous, but that a causal relation exists between symptoms and difficulties in dealing with life. The circumstances under which symptoms become exaggerated are investigated with the objective of determining areas of failure in interpersonal functioning. Once a pattern is discerned, its significance and origin are explored. Finally, the patient is encouraged to put into action the retrained attitudes toward life and people. In some cases sufficient ego strength may be developed to make psychoanalytically oriented psychotherapy possible.

Where the patient is coordinately under the care of an internist, cooperation between the therapist and internist will improve the results.

PERSONALITY DISORDERS

Personality problems plague every human being. They are an inevitable consequence of cultural and family aberrations that cannot help but influence child-rearing practices. The great majority of people manage to live with and around disturbing personality problems and to make a reasonable adjustment to everyday pressures and

responsibilities. When problems become intolerably distressful, however, maladjustment may ensue.

Personality disorders encompass a heterogeneous group of traits, tendencies, and patterns of behavior that impair social and occupational functioning. Some of these disorders have a long history dating back to childhood. In the DSM-IIIR classification a number of syndromes fit this description: (1) Disruptive Behavior Disorders (conduct disorder, attention-deficit hyperactivity, oppositional-defiant disorder), (2) Anxiety Disorders of Childhood (separation anxiety disorders, avoidant disorders of childhood or adolescence, overanxious disorder), (3) Eating Disorders (Anorexia nervosa, bulimia nervosa, pica, rumination disorder of infancy), (4) Gender Identity Disorders (gender identity disorder of childhood, transsexualism, (5) Tic Disorders, (6) Disorders of Elimination, (7) Other Speech Disorders, (8) Other Disorders (reactive attachment disorder, stereotyping/habit disorder, elective mutism, identity disorder). Some of these disorders may in history-taking be identified as early manifestations of the pathology for which the patient now seeks help. In many, perhaps most cases, we have problems in tracing the histories of personality disorders because the individual usually forgets, conceals, distorts, or rationalizes early difficulties.

Urgent, inflexible, "ego-syntonic," and resistive to change, personality disorders interfere drastically with adjustment. There may be some awareness of the nature of the problem but it cannot seem to be controlled.

When a patient presents for therapy, the complaint is generally a disturbing symptom or a stressful event that has upset the habitual equilibrium. Most patients do not see the connection between their personality operations and their symptoms at the beginning of therapy. A too early emphasis on such a connection will tend to be confusing. It is important to consider that personality is the machinery through which the individual regulates his or her relationships with life and people. Individuals regard their traits as integral a part of themselves as their skin, and a premature effort to peel away traits that are disruptive will be staunchly resisted. Why this is so is not difficult to understand.

During development, the individual evolves defenses to cope with stresses brought about by hurtful or depriving circumstances. Such defenses endure as a way of life far beyond their period of usefulness. They become welded into the intrapsychic structure, and the original events that initiated them are repressed and more or less relegated to unconscious oblivion. In adult life, they nevertheless continue to operate insidiously, independent of reality. Individuals may even attempt to create conditions that will justify their reactions, as if they seek to master a challenge and to complete the unfinished business of their past.

Treatment with the goal of some reconstructive change is a long-term proposition. It cannot be completed in 6 or 20 or even 40 sessions. It requires detailed work during which the patient is brought to an awareness of the nature of his or her problem and its investment in past history. Once some insight is achieved, the working-through process slowly takes place, aided by homework away from the therapist's office in the crucible of life experience itself. Permanent change may require several years of dedicated treatment. A sequence of operations usually takes place: (1) the disorder is clearly identified; (2) the consequences of the patient's behavior are delineated; (3) motivation to alter offensive patterns are developed; (4) exploration of the origins and purpose of the disorder may be required; (5) modes of rectification of attitudes and a reconditioning of behavior are designed; and (6) termination of treatment is carefully structured.

In the treatment of a personality disorder, we may accordingly execute the following *baseline interventions:*

1. *The patient is brought to an awareness of the traits he or she pursues that create problems.* Detection of these traits will not be difficult from the case history as revealed by the patient, from reports of informants if these are available, and particularly from the patient's attitudes and behavior toward therapy and the therapist. Some patients are at least partially aware of their maladaptive patterns; some appear to be oblivious to their nature and the effect on themselves and others. One cannot jump in immediately and vigorously confront the patient with his or her self-defeating attitudes and corrosive conduct unless a good working relationship has been established. The patient will either not listen or

will assume he or she is being unfairly attacked and misunderstood. But as soon as the therapist feels that a reasonably sound therapeutic relationship exists, confrontation blended with empathic understanding may be necessary and invaluable. If repression acts like an interfering block of concrete, analysis of dreams, transference, and acting-out may be helpful in expediting awareness. Interpretations must be carefully titrated to the patient's ego strength and level of anxiety.

Interpreting character drives in a way that will be therapeutic is an art because reactions to interpretations of anger, offensiveness, denial, disbelief, or detachment can have a negative effect on the therapeutic alliance.

One way of softening the negative impact of interpretations is to couch them in universal terms. In this way, one hopes to avoid a disintegration of the therapeutic relationship. For example, the following statements were offered patients:

> (Strong dependency traits in a man) "Many people come through a difficult childhood with scars that burden them. Because of an unfulfilled early life, they try to make up for satisfactions they failed to get by looking for and getting dependent on a better, more idealized parent figure. Could it be that you are reaching for a more fulfilling relationship, which you believe your wife is not supplying?"

> (Masochistic tendency) "There is really nothing so unusual in the way you are reacting. People who are angry at what has happened to them often are very guilty and may seek to punish themselves for even feeling angry." (Detachment) "It is only natural that when a person feels hurt there is a need to escape from one's feelings. Sometimes not feeling emotions or physically getting away from people is an effective defensive maneuver. But there are penalties one pays for detachment."

> (Perfectionism) "Doing things perfectionistically is one way people have of protecting themselves. The only trouble is that nobody can ever be perfect, and if perfection is a goal one always has to suffer."

By avoiding confronting the patient directly with a character defect, one may obliquely be able to penetrate defenses. Once the patient acknowledges a problem openly, confrontation can then be more direct and personal. The therapist should watch the patient's reactions to interpretations to see whether the patient is strong enough to tolerate and make use of them. Initial reactions should not be taken at face value. As long as there is evidence that confirm the assumptions of the therapist, interpretations should carefully be woven into questions, continuously presenting these to the patient in the

hope that the patient will eventually make the proper connections.

In the case of a man with untoward aggression, his acting-out patterns were vivid enough so that it required little from me to get him to realize that his behavior was problematic, although he attempted to justify and rationalize it. Interpretations fell on deaf ears, even though explanations were deliberately modulated. It was obvious that he defended against using them in the early phases of treatment.

2. *The aversive consequences of the patient's patterns are reviewed in detail.* These are abundant and usually well-known to the patient, although he or she will ascribe them to being misunderstood or discriminated against. A wealth of excuses, resentments, and recriminations will drown the patient's judgment. The therapist will soon realize that no matter how severe the punishment is that follows untoward behavior, the patient is completely unable to control it. Indeed it may become evident, as happened in my patient, that he or she masochistically seems to welcome punishment.

3. *Detailed determination of the function of the disturbed patterns must be elaborated.* Here dynamic thinking is indispensable since the purpose behind the manifest symptomatology is often not explicable in terms of everyday logic. In our patient under discussion it became apparent through exploration of his dreams, associations, and behavior toward me that he was trying to mask underlying passivity, low feelings of independence, and a nonmasculine image he believed he was displaying to the world. Blustering verbal attacks and an appearance of belligerence served the purpose of presenting a macho front. He had guilt feelings about homosexual fantasies but apparently never acted them out. Interest in women was high, and he enjoyed heterosexuality. He was, however, unable to establish an enduring relationship with any one woman. Discussions about his irrational fantasies created motivation to inquire further into their nature.

4. *In some cases it is important to explore the origins of the personality disorder in past formative relationships.* Memories of early determining experiences are usually blurred and their connection with present-day behavior obscure. As therapy proceeds, some memories and connections become clearer. The transference may reveal significant feelings toward early care-taking agencies that are being projected toward present-day

authorities. The most dramatic revelations will occur when an actual transference neurosis precipitates. A few motivated patients may be susceptible to the classical analytic technique, which will most reliably produce a transference neurosis. Countertransference, if studied assiduously, may also yield data about some of the patient's projected unconscious processes. One occasionally finds that the patient's behavior is molded by identification with a parental figure and that the patient is acting-out the hidden designs of these figures with the therapist, or outside persons (projective identification). In many cases a modified analytic approach, dealing with derivatives of nuclear conflicts, is all that is possible. Presentation of a schema such as outlined in Chapter 44 may enable the patient to reconstruct past experiences and to assign to his or her personality patterns a more significant meaning. This will help establish better controls.

Our patient became aware of his continuing dependency, his futile search for an idealized maternal figure, his delayed separation-individuation, his resentment of women as symbols of the controlling and castrating mother, his feelings of low independence and masculinity, and his compensatory strivings for more effective affirmation of his masculinity through power drives, aggression, and fantasies of penis acquisition via homosexual fantasies. These insights fascinated him but still were not sufficient to cure his personality disorder. It did provide him with motivation to want to halt some expressions of self-defeating aggression.

5. *The acquisition of more constructive modes of reacting to provocative stimuli may be expedited through the employment of cognitive and behavioral techniques.* Here the patient may keep a diary of successes and failures in controlling his or her symptoms under various circumstances. Cognitive therapy helps rectify faulty self statements. Assertiveness training, group therapy, and psychodramatic role playing may aid in the reconditioning process if the patient is unable to achieve greater control through simple homework practice. These adjunctive measures were all employed with our patient because of his continuing resistance. Many patients will not need all of these measures.

6. *As soon as the patient manifests some control over his or her patterns and substitutes more productive behavioral alternatives, termination of therapy is in order, with injunctions given to continue homework practice.* A 5-year follow-up of our patient revealed continuing assertiveness without need for aggression, as well as gratifying signs of personality

maturity.

7. *Severe chronic personality disorders do not lend themselves to a "quick fix."* Reinforcements in the environment keep their patterns alive, and resistances to change interfere with progress. Some cases of personality disorders, antisocial personality disorder, and very severe borderline personality disorder, for example, may require treatment in an institution staffed by personnel sufficiently well trained to deal with encrusted characterological patterns that will not yield to anything other than reconditioning in a therapeutic milieu.

The above outline of therapy for personality disorder is a barren description of treatment that of necessity extends over a long period and that requires innovative management. While treatment focuses ideally on intrapsychic and interpersonal links in the behavioral chain, difficulties related to other links may claim priority and need to be treated with special techniques, as well as the baseline interventions described above (see Table 57-1). Diagnosis of personality disorder is usually made on the basis of the most obnoxious or maladaptive traits that are being exhibited. Blatant and unpalatable, these may mask other less disagreeable but equally important personality distortions. Not uncommonly, two or more diagnostically distinct personality disorders may appear in the same person. The classification of character types into diagnostic entities is convenient but faulty to the extent that traits shift and vary with prevailing needs and existing stresses imposed on the individual. Accordingly, at irregular times, different impulses and demands may appear that will inspire a complex array of defenses and reaction formations and suggest many different classifications. Nevertheless, distinctive diagnostic categories are listed in the DSM classification system.

Paranoid Personality Disorder (DSM-III-R Code 301.00)

Individuals with this disorder, which rarely produces sufficient discomfort to bring an individual to therapy for the personality problem alone, exhibit an unwarranted sensitivity to actions in the environment that they believe are designed to annoy, humiliate, or take advantage of them. Such suspicions are impervious to reason. Most persons with this disorder come to treatment for symptoms such as depression, anxiety,

phobias, and other manifest disturbances. Only when the therapist gains their confidence will they reveal some of their peculiar ideas. When attempts are made to bring logic into the picture to prove the ideas incredulous, the relationship may begin to disintegrate. Indeed, these patients may consider the therapist allied to their enemies. It is difficult to convince them that they are trying to preserve themselves by building an impenetrable wall between themselves and others and that secrecy, guardedness, jealously, lack of humor, and involvement with fantasies of being humiliated and downgraded are symptoms of a disorder.

The best way to manage therapy with the paranoidal individual is to listen respectfully to his or her qualms and not argue about them. When the patient expresses concern about being threatened and humiliated by others, the therapist might say: "Anyone who is going through what you are is bound to be upset." One deals with the patient's emotional turmoil and does not try to ridicule or belittle his or her twisted cognitions.

Because of the vulnerability of the relationship with the therapist, the patient is apt to regard criticism as a blow to his or her self-esteem, initiating depression, rage, or anxiety. Criticism is interpreted as evidence that the therapist does not approve of him or her. The patient is apt to intellectualize the entire therapeutic process, using knowledge either as resistance or as a means of fortifying against change. Despite all logic, the patient strives to wedge therapy into the framework of his or her distorted attitudes toward life. Feelings of rejection and distrust are exhibited, and at the slightest challenge from the therapist, defenses crumble, leaving the patient in a state of anger and despair. The patient may then show a psychic rigidity that refuses to yield to reason or entreaty.

Some therapists attempt to gain the goodwill of paranoidal patients through a form of strategic therapy in which they act as if the patient's ideas are factual and even become a partner in the patient's bizarre schemes. This may work at first to solidify the relationship since the patient may accept the therapist as an exceptional friend who does not ridicule his or her ideas and judgments. Unless the therapist is an excellent actor, the

acutely sensitive patient will detect a fraudulent note in the play-acting maneuvers.

Some patients achieve relief from severe symptoms such as depression with antidepressants, and eventually are able to accept the therapist as a sincere friend who wants to help rather than harm. They may then begin to express some doubts about their suspicions. At this point, one may institute cognitive therapy carefully designed so as not to convey the impression that the patient is peculiar or psychotic.

Dependent Personality Disorder (DSM-III Code 301.60)

The character trait of extreme dependency sponsors relegation of responsibilities to other persons and avoidance of decision making. The individual allows a spouse or parent to arrange the most simple matters and has little incentive to promote action on his or her own. The dependence is actually one manifestation of a widespread deficit in separation-individuation, the product of faulty early development. Inability to transcend the dependency stage of development results in severe damage to the self system, including evolvement of compensations and reaction formations such as those described in Chapter 44. An inability to manage the ordinary stresses of life may result in adaptive breakdowns, with ensuing anxiety, depression, phobias, and other neurotic difficulties.

Treatment poses special problems. Dependent persons often show up for treatment not because they feel a need for change but rather because parents, marital partners, or friends insist that something be done for them. Visits to the therapist in such cases are a mere formality. Such patients expect that no change will occur and will be resistant to any effort to get them to participate in the treatment process. The limit of their cooperativeness is to expose themselves to the therapist during the allotted hour.

Dependent patients seek to establish themselves with the therapist in ways that resemble the infant's imposition on the parents. They do not seem to be interested in developing resources within themselves. Rather, they desire to maneuver the therapist into a position where constant favors will be forthcoming. They will abide by any rules of therapy in order to obtain this objective, even to the apparent absorption of insight. It is

most disconcerting, therefore, to learn that assimilated insights are extremely superficial and that the patients are less interested in knowing what is wrong than in perpetuating the child-parent relationship. They actually seem incapable of reasoning logically, and there is an almost psychotic quality to the persistence of their demands for support and direction. Sometimes the residual hostility is expressed in aggressiveness, which is usually masked by passive maneuvers such as procrastination, obstinacy, recalcitrance, and stubbornness, hence the term "passive-aggressive character disorder."

Interpretations of the patient's dependency are usually regarded as chastisement. He or she will assume that any attempt to put responsibility on his or her shoulders is a form of ill will expressed by the therapist. The patient will demonstrate reactions of disappointment, rage, anxiety, and depression and will repeat these reactions in spite of lip service to the effect that he or she wants to get well.

In treating a dependency reaction, it is essential to recognize that hostility is inevitable in the course of therapy. The demands of dependent people are so insatiable that it is impossible to live up to their expectations. Only when such people begin to experience themselves as people with constructive assertiveness and independence are they able to function with any degree of well-being. This goal, unfortunately, may in some instances never be achieved.

Supportive therapy that propitiates the patient's dependency needs is of extremely temporary effect. It is advisable, where possible, to promote a therapeutic approach in which the individual learns to accept responsibility for his or her own development in the hope that the patient will utilize this opportunity to grow.

There are some individuals, however, whose self-structure has been so crushed that they will resist any attempt to make the therapeutic situation a participating one. Here the treatment program may have to be directed at a limited therapeutic goal. The therapist will then have to become resigned to educating the patient to function with his or her dependency strivings with as little detriment as possible.

Behavior therapy is sometimes very helpful. Conditionings are organized so that the patient is rewarded for making his or her own decisions. It is to be expected that the patient will resent this vigorously, accusing the therapist of refusing to accept responsibility. The therapist may then explain that pandering to the patient's demands for support and making decisions for him or her only tends to infantilize the patient. It would make the patient more dependent and more unable to develop to a point where he or she could fulfill himself or herself productively and creatively. The therapist does not wish to shirk responsibility but withholds directiveness out of respect for the patient's right to develop. Although patients may still resent the therapist's intent, they may finally understand that unless they begin to make their own decisions, they will never get to a point where they are strong within themselves. Behavioral assertive training may prove helpful.

Some patients who seemingly are fixated on a dependent level may, with repeated reinforcements and assertiveness training, finally begin to accept themselves as having the right to make their own choices and to develop their own values. Unflagging persistence, however, is the keynote. In therapy the patient will exploit every opportunity to force the therapist to assume a directive role. Nevertheless, when the patient sees that the therapist has his or her welfare at heart, he or she may be able to develop more independence and assertiveness. The shift in therapy from a directive to a nondirective role calls for considerable skill, and it must be tempered to the patient's incentives and ego strength. Unless such a shift is made at some time, psychotherapy will probably be interminable, and the patient will continue on a dependent level requiring the ever presence of the therapist or some other giving person as a condition to security.

Should it become apparent that one cannot work along participating lines and that the patient's only objective is to become dependent on the therapist, visits may be cut down to 15- to 20-minute sessions once weekly or bimonthly, and/or the patient may be referred to a supportive social or reeducative group with periodic fulltime sessions when required.

Obsessive-Compulsive Personality Disorder (Compulsive Personality) DSM-III-R Code 301.40

Compulsive personalities are obsessed with orderliness, preoccupied with trivia, irritatingly perfectionistic, immovably obstinate, overconscientious, and addicted to work and what they consider demanding daily responsibilities. They have little time for leisure and enjoyment, and their relationships with people are often organized around manipulations for their own ends. Lack of confidence in themselves forces many of these individuals to engage "experts," whose advice they rarely follow, to instruct them in "what to do." Maintenance of control becomes a preoccupation, and every thought and action is measured carefully so they will not be caught off guard. Occasionally, particularly in emergencies and under the impact of great stress, controls may shatter and behavior becomes impulsive and disorganized. It becomes apparent then that forced control at all times is a means of preventing the possibility of being destroyed by unpredictable disasters. Because of the fears of making mistakes, some compulsives ruminate about alternative solutions and find it difficult to arrive at decisions. They then ask for advice, which they question and doubt, and make a nuisance of themselves pillorying people with questions. Feelings of warmth and tenderness are subordinated to cold intellectualizations and formal stiffness in manners. The more adjusted compulsive persons are cautious, conscientious, conservative, and conforming solid citizens, and for this reason are often put in positions where punctilious work is demanded. Too frequently, the joy of living is sacrificed to a sense of responsibility. Certain cultures encourage and reward some compulsive traits that are considered desirable, not abnormal.

Though obsessive compulsive personality disorder seems related to obsessive-compulsive disorder, relatively few persons with compulsive personalities succumb to an actual neurosis. They come to therapy because their controlling defenses have failed to function, resulting in underlying fears of shattering. Symptoms of anxiety and depression constitute the complaint factor. Environmental stresses such as severe financial problems, physical illness, forced retirement, and marital difficulties may have taxed coping capacities.

If the individual has adequately adapted to the compulsive personality most of his or her life and if it has not been responsible for a serious physical ailment (such as cardiac disease in the compulsive Type A personality), the objective in treatment is restitution of the old personality controls. Resolution of identifiable environmental stress (via counseling, environmental manipulation, etc.) and medicinal management of symptoms related to the implicated biological links (anxiolytics, antidepressants, etc.) are instituted when indicated. Relaxation therapy is often of great value, and many of these patients are good subjects for hypnosis and biofeedback. Marital therapy may be employed. Cognitive therapy to change attitudes, as toward forced retirement, may be tried, but the patient's stubborn clinging to established belief systems may be difficult to overcome.

Because many of these patients are intellectually keen, some alteration of stubborn personality traits may be possible through persistent application of the "baseline interventions" described at the beginning of this chapter. Supplying the patient with a chart delineating how personality drives operate may prove helpful since this permits the patient to put his or her patterns into an ordered arrangement that can be studied as assigned homework.

Passive-Aggressive Personality Disorder (DSM-III-R Code 301.84)

Persons who display extraordinary resistance to demands being made on them in their education, work, and social relationships may be suffering from a passive-aggressive personality disorder. This diagnosis is, along with "atypical, mixed, or other personality disorder," a kind of wastebasket into which varied reaction patterns are dumped. One often gets the impression that many passive-aggressive individuals utilize their resistance as a form of aggression. They refuse to allow themselves to be "pushed around." In their way, their "forgetting," inefficiency, procrastination, and oppositional tendencies serve the purpose of supporting a spurious independence.

At the core of these traits is a severe developmental disturbance characterized by incomplete separation-individuation. The high level of dependence may be concealed or masked by projecting it onto a religious deity who is worshipped for hoped-for rewards in

the present (e.g., winning at Lotto) or in the future (e.g., reserving an established seat in heaven). Where it is expressed toward a human target (i.e., parent, spouse, lover, authority, etc.), the individual will usually downgrade the strength, wisdom, and designs of his or her chosen host as failing to achieve the virtues of an idealized parental figure. Patients will project toward this person great though controlled hostility for failing them in their need and additionally will blame them for taking away their independence. Hostility may assume the form of aggression, scapegoating, or sadism toward others; or it may be fed back internally with self-punitive and other masochistic maneuvers. Low independence may produce self-criticism and a devaluated self-image, which may sponsor fantasies of being inferior, physically damaged, or sexually inadequate. Compensations take the form of perfectionism, overambitiousness, grandiosity, and compulsive drives to prove one's strength and power. Resorting to alcohol and drugs to overcome anxiety and depression may complicate the picture.

Therapy of patients with a passive-aggressive personality disorder is difficult because of the strong ego-syntonic nature of the associated traits and the ambivalent transference that is bound to emerge. One may deal with such symptoms as anxiety and depression on a short-term basis, but the basic personality structure will continue to stir up problems for the person. Implementation of the "baseline interventions" (page 1167) is desirable, recognizing that a dynamic long-term approach is essential to make any impression on the individual.

During the course of treatment the patient will seemingly modify attitudes toward the therapist, but in this alteration the therapist must search for areas of resistance. For instance, a submissive, ingratiating attitude, which is often a cover for a fear of abandonment, may, upon interpretation, be replaced by an apparently sincere attempt to search for and to analyze inner problems. The therapist may, if the patient is observed closely, detect in this new attitude a fraudulent attempt to gain security by complying with what the patient feels is expected of him or her. While the patient appears to be analyzing his or her problem, the real motive is to gain security by adjusting to what he or she considers are the demands of the therapist. In this way the process of therapy itself

becomes a means of indulging the neurosis.

In analyzing resistances, their sources in infantile attitudes and conditionings usually become apparent. Eventually it is essential to bring the patient to a realization of how the machinery with which he or she reacts to the world now is rooted in early conceptions and misconceptions about life. The interpretation of passive-aggressive character strivings does not suffice to change their nature, for they are the only way the patient knows of adjusting.

A breakdown of character strivings often brings out in sharp focus the repressed needs and impulses from which the strivings issue. When the patient becomes cognizant of what produces insatiable destructive interpersonal attitudes, he or she has the best chance of taking active steps toward their modification.

In certain cases, particularly if there are time limitations, the only thing that can be accomplished is to compromise with the existing disorder in as painless a manner as possible. Environmental manipulation may be necessary to take pressures off the patient. The patient may be shown how to adjust to the reality situation. For instance, if a woman has a strong striving for perfectionism that drives her incessantly into positions that she cannot handle with her intellectual and physical equipment, she may be shown how she can confine herself to a project that she can master proficiently. Whereas the scope of her operations may be limited, she can indulge her perfectionistic strivings in a circumscribed way, gaining some measure of gratification in this. If she is inordinately dependent on strong people, it may be pointed out that she can maintain a certain freedom of action in spite of the fact that she has to lean on authority. If she has an insatiable need to dominate, avenues for its toned-down exercise may be suggested. This approach, of course, merely panders to the patient's neurosis, but it may be the only practical approach for the time being; in many cases it will make the patient's life immeasurably more tolerable.

Whenever possible, patients should be brought to an awareness of the nature, genesis, and dynamic significance of their passive-aggressive character trends. They should be encouraged to observe how mercilessly they operate in everyday life and to

scrutinize why they cannot change their attitudes toward people. Desirable as this may be, a shift in therapeutic orientation toward insight may stir up a hornet's nest in the relationship with the therapist.

Though character trends in the passive-aggressive person are constantly shifting, they are usually interrelated and the fusion makes for a picture that is unique for each individual. Behavior is not the static product of a group of isolated trends; rather, it is a complex integrate of a number of drives. The product of this intermingling differs from any of the component strivings. That is, if the person is compulsively modest, is fired by perfectionism, is quiet at some times and arrogant and aggressive at others, some of these traits will tend to neutralize and some to reinforce each other. Nevertheless, for treatment purposes, we should consider them part of a conglomerate and not deal with them as isolated and distinctive entities.

Power Patterns

While not listed as a separate personality disorder in DSM-III-R, compensatory power impulses predominate in some individuals. Here all that seems to matter in life is forcefulness and strength. The feelings and rights of other people are disregarded. There is a blind admiration for everything invincible. The person is contemptuous of softness and tenderness, and self-esteem is seemingly dependent on the ability to be dominant. As in dependency, the dynamic force behind the power impulse is a profound sense of helplessness and an inability to cope with life with the available resources. A motive behind the power drive is to coerce people to yield to one's will, which provides bounties of various sorts.

The treatment of power drives is oriented toward building up frustration tolerance and increasing the capacity to withstand tension without resorting to aggression. A reeducative or behavioral approach may be effective in helping these patients develop inner restraints capable of controlling their impulses. It is essential to be firmer in working with this type of pattern than with either dependency or detached reactions. These patients must be constantly reminded that there are limits beyond which they

cannot go and that they must face responsibility for their actions. The dynamic significance of their power drive must be constantly pointed out, particularly its use as a means of shoring up the patient's devalued self-image. Patients should be encouraged to make efforts toward the expansion of their personal resources so as to minimize the need for power ploys.

A man may display unprovoked aggression whenever he tries to assert himself or when he feels deprived. Figuratively, he uses an elephant gun to kill a sparrow. He rationalizes his behavior to the effect that people pay no attention unless one forces them to do so. Behind this attitude is a feeling of helplessness and a fear of being rejected or attacked when one expresses one's rights. Consolidated is the conviction that one must display an image of strength and invulnerability to prevent exploitation. When people back away from his violence, this proves to the patient that they are unwilling to pay attention to his reasonable demands. He then becomes all the more angry, demanding, and forceful. The end result of his obnoxious conduct is that he is rejected and cannot hold a job even though he is intelligent and highly qualified. Depression forces him to seek psychiatric help. In therapy we can deal rapidly with the complaint factor of depression by prescribing an antidepressant medication, which in a few weeks may dissolve his malaise. If this is all he wants from therapy, the patient will then terminate treatment secure in the belief that he is cured and that he can now set off to find a new job. Undoubtedly the pattern will repeat itself because his illness has not been dented, let alone resolved. To go beyond mere symptom relief to correction of personality deficits will entail an extensive carefully planned stretch of psychotherapy.

If dependency and power drives are fused, the individual may be shown how he functions in a dual manner, seeking security from stronger people by shows of helplessness or wresting security from them by force and aggression. The chief resistance the therapist will encounter is transference, which may not be resolvable until the patient connects his reactions to historical developmental data.

Schizoid Personality Disorder (DSM-III-R 301.20)

The schizoid personality disorder is organized around the defense of detachment. The individual is often referred to as a "loner" or "isolate" with whom it is difficult to establish a relationship. There is a consuming flatness of mood with an inability to resonate through the spectrum of normal feelings from happiness to sorrow to anger. People who seek to establish contacts with schizoid personalities complain that they are withdrawn, isolated, and "standoffish" ("I'd like to shake him into reacting and feeling"). Daydreaming and living in fantasy are common. The schizoid personality disorder must be differentiated from the schizotypal personality disorder, which is closer to schizophrenia and in which there are distortions in thinking (ideas of reference and influence, depersonalization, peculiar fantasies, and paranoidal notions), odd manner of speaking, and episodes of eccentric behavior.

Such isolated and detached individuals, who shy away from establishing close interpersonal relationships and yet maintain a good hold on reality, rarely come to therapy for the disorder itself. If, however, the need for a relationship of some kind becomes pressing or, more likely, the individual is caught in a relationship from which there is no escape, anxiety may occur and motivate the victim to seek professional help. The disorder, with its features of coldness, aloofness, and absence of concern with and indifference to the feelings of others, is a protective screen and consequently resists therapeutic alteration.

Detachment may be the means elaborated by the individual to protect himself or herself from intense dependency strivings. A close relationship poses dangers of being overwhelmed, for in it the patient may envisage a complete giving up of his or her independence. Detachment may also be a technique of avoiding injury or destruction that the patient believes will occur when he or she comes close to a person. Finally, it may be a method by which the patient protects himself or herself from fears of attacking and destroying others.

In treating a detached patient, one must anticipate that there will be difficulty for a long time in establishing a close relationship, since this tends to mobilize fears of injury

and inspires the building of a protective wall. Much active work will be required in detecting and dissolving resistances to change. The detached patient often has a tendency to intellectualize the entire therapeutic process. The patient will particularly shy away from expressing feelings because he or she will conceive of them as dangerous.

Great hostility is bound to arise, which may be disconcerting principally because it is usually unexpressed or liberated in explosive outbursts. The therapist must realize that hostility is a defense against interpersonal closeness. It is extremely important that the therapist be as tolerant toward the patient's provocations as possible. The patient will probably attempt to goad the therapist into expressions of counteraggression to justify attitudes toward people as untrustworthy and withdrawal from the world because it is potentially menacing.

Sometimes the patient may be encouraged to participate in social activities, competitive games, and sports. Commanding, restrictive directions should, however, be avoided. With encouragement, detached people may begin to relate to others. In groups they drift cautiously from the periphery to the center as they realize that they will not be injured in a close interpersonal relationship. Group therapy may sometimes be most rewarding in certain detached, schizoid individuals, as long as no pressure is put on them to participate. Social groups with a wide range of activities may be prescribed.

A common reaction in the therapy of schizoid personalities is anxiety, which is manifested by disturbing nightmarish dreams or by actual anxiety attacks. The reaction will usually be found when the patient experiences for the first time real closeness or love toward the therapist. The emotions terrorize the patient and cause him or her to fear injury of an indefinable nature. It is essential to deal with this reaction when it occurs by giving the patient as much reassurance and interpretation as is necessary. Detached patients whose defenses have crumbled may go into a clinging dependent attitude when they realize the full weight of their helplessness. Supportive therapy may have to be given here, in an effort to provide the patient with an experience in which he or she receives help without being domineered or smothered with cloying affection. Should anxiety

become too disturbing, anxiolytic medications may temporarily be prescribed.

Schizotypal Personality Disorder (DSM-III-R Code 301.22)

The schizotypal personality disorder is closer to schizophrenia than the schizoid personality disorder. Emotional instability, peculiarities of ideation, involvement with superstition and magical thinking, and perhaps bizarre preoccupations as with clairvoyance and "out-of-body" experiences convey a feeling of strangeness and a psychotic-like tinge, although a definite psychosis is not present. Ideas of reference, fragmentary illusions, and odd mannerisms may be present. The patient often seeks therapy because of depression, anxiety, and depersonalization that have come on spontaneously or as a result of a stressful experience. Insight into cognitive dysfunctions is lacking, and motivation is confined to achieving freedom from disturbing symptoms. It is futile to reason with or to argue these patients out of their peculiarities of thinking and oddities of behavior. Therapy should be confined to dealing supportively with symptoms while establishing a friendly helping relationship. Anxiolytic, antidepressant, and carefully administered neuroleptic treatment in small doses may be indicated.

Narcissistic Personality Disorder (DSM-III-R Code 301.81)

In recent years an interest in the dynamics and therapy of narcissistic subjects has been revived. Scrutiny of the earliest phases of ego development have led to a number of hypotheses on how the disorder evolves and its influence on treatment (Kohut, 1971). Attempts have been made, with variable results, to differentiate narcissistic reactions from borderline cases and schizophrenia, which are distinctive ailments even though a strong bond exists among these entities. Problems in all three have occurred in the primary stages of separation and individuation. Object relationships, as a result, become distorted and shallow and are oriented around how they can enhance the individual's status and interests. Fusion and dependency are basic themes; love objects are imbued with both terrifying and grandiose qualities. In therapy the transference reaction, which is essentially narcissistic, encourages regressive episodes with fear of the loss of the love object, paranoidal symptoms, and a fear of mutilation. The regression is never as deep in

narcissistic personalities as in borderline or schizophrenic patients.

Therapists experience much difficulty in treating the character disorder of excessive narcissism. Persons with this problem seem to have such a need for personal admiration that they conceive of therapy as a means of making themselves more worthy of praise.

Unlike the mature person who gains security from cooperative endeavors in attitudes of altruism and sympathy, narcissistic individuals concentrate most of their interest on themselves. Self-love may actually become structured into grandiose strivings, omnipotent impulses, and megalomania. Although the image of the individual appears to be bloated, analysis readily reveals how helpless and impoverished he or she actually feels. There is danger here of precipitating depression or excitement by presenting insights prematurely. The shock-absorbing capacity of the ego must always be weighed, and interpretations must be given in proportion to the available ego strength. In markedly immature individuals little development may be expected other than a somewhat better environmental adaptation through guidance techniques.

Many of these patients often band together in Bohemian groups, posturing and posing, displaying a haughty defiance of convention, garbing themselves in outlandish dress, arranging their hair out of keeping with the accepted style as a way of expressing their exaggerated exhibitionistic, omnipotent, sadistic, and masochistic impulses. Language for them serves to release tension and not as a genuine means of communication. As long as they impulsively discharge their tension and anxiety in acting-out, they will not be too uncomfortable. "They are hunting eternally for satisfactory and secure models through which they may save themselves by a narcissistic identification. On the surface it appears later as a scattered, superficial pseudo competitiveness" (Greenacre, 1952). There is little motivation for therapy, which is usually sought not by the person but by a concerned parent or friend who is shocked or frightened by the patient's behavior. Under these circumstances psychotherapy proceeds under a great handicap, the patient generally breaking appointments or manifesting such resistance that the therapist's tolerance is put under the severest test. The only incentive that the patient has for

treatment is to please the parent or referral agency, usually to avoid the catastrophe of having his or her allowance cut off. If the person is unable to release tension because of the absence of or removal from environmental resources, anxiety may then come to the surface. Symptomatic discomfort will then act as a motive for help.

Classical psychoanalysis is disappointing in its results with narcissistic patients, but if a semblance of a relationship can be maintained, a modified analytic approach, perhaps drawing inspiration from object relations theory or self-psychology (see Chapter 11) may be useful. Some guidelines for therapy are found in the section on borderline personality disorder that follows.

Borderline Personality Disorder (DSM-III-R Code 301.83)

From the numbers of papers and books published and the frequency of seminars given, borderline patients have replaced white rats as the prime research subjects in the psychological field. Research has yielded some interesting hypotheses about the origins and the dynamics of borderline personality disorder, but it has not definitively established reliable ways of managing the difficult and fragile groups of patients embraced by this diagnostic category. Characteristic is a fluctuating assembly of symptoms that markedly cause subjective distress and impair social and occupational functioning. These include lack of impulse control leading to patterns of unstable and impulsive behavior that seemingly make no sense and involve the patient in difficulties with authority and peers. There are shifts in mood ranging from feelings of emptiness and boredom to temper outbursts and violent bouts of anger that are inappropriate and occasionally lead to quarreling, fighting, suicidal attempts, and other destructive activities. There may be confusion about one's identity in relation to self-image and gender. Fluid, unexpected changes in attitudes, moral precepts, values, and belief make it difficult to reason with and securely adapt to the person. Sometimes, especially when under great stress, transient, quickly recoverable, psychotic episodes occur. Characterologically, the individual manifests dependency, immaturity, detachment, and a wide variety of shifting traits.

Unlike the mature personality whose coping mechanisms are reality-oriented, the

borderline patient retains and employs the archaic defenses that were evolved during infancy and childhood in relationship to parental agencies. Prominent among these are projection, displacement, withdrawal, autism, dissociative processes (splitting of the ego), denial, and hysterical and obsessive-compulsive maneuvers. These combine with a fragmentary delusional system that is repressed but used as a coping device whenever the patient is under extraordinary stress. The existence of this system may be exposed during narcosynthesis or with the administration of small quantities of the psychotomimetic drugs.

Borderline patients are sometimes falsely classified as schizophrenics. Gunderson et al. (1975) have shown that there is little justification for this, since borderline patients do not exhibit distinguishing schizophrenic symptoms and differ in the quality of the thought disorder. Kernberg (1974) has described the personality organization of the borderline as one in which there is ego weakness with primitive mechanisms of defense, such as splitting, denial, omnipotence, devaluation, and early projective tendencies; a shift toward primary process thinking that may come through only in projective testing; and pathological internalized object relations. Kohut (1971) has expounded on the early traumatic disturbances in the relationship with the archaic idealized self-object and the damage to the maturing personality that continues because of this trauma. Fixation to aspects of archaic objects fashions the regression that occurs during analytic therapy.

The psychotherapy of borderline personality disorder is a long and difficult procedure, largely because of the fragile character of the patient-therapist relationship (Eisenstein VW, 1951; Bychowski, 1950). Borderline patients often seek help on an emergency basis when a crisis occurs or when symptoms such as anxiety and depression become intolerable. Some recognize that their interaction with people is disturbed and that they are unable to make a satisfactory social and occupational adjustment. At the start of therapy the therapist may be regarded as a curative deity who will rapidly dissolve the patient's troubles. This idea rapidly vanishes when immediate cure is not forthcoming. Disturbing transference reactions then interfere with the patient's ability to cooperate with treatment routines. There seems to be a deficit in the quality of the "observing ego,"

that part of the self that can judge one's pathological maneuvers. This interferes with establishing a trustful and realistic therapeutic alliance and encourages disturbing transference. How to deal with these reactions is a matter of controversy. Therapists such as Kernberg (1975) believe that the best method is to attempt reconstructive personality change by encouraging regression, by allowing the transference to build up, and then to interpret it. Others like Zetzel (1971) and H. Friedman (1975) have a dimmer view about the possibilities of reconstructive change in borderline patients and are firm in their belief that all that can be done is to keep transference under control and improve adaptation. Still others try pragmatically to move from one to the other paradigm as required. There are advocates and dissenters who support or ridicule each of these three viewpoints.

Disagreements about the most suitable approach probably occur because borderline disorders are constituted by a wide variety of patients who genetically, constitutionally, developmentally, and experientially are different. Moreover, patients are exposed to therapists whose training, skills, philosophies, and personalities may or may not provide a good match. No hard and fast rules about preferential treatment choice can therefore be made for all cases, but a flexible approach may be rewarding (Katz S, 1982).

Most therapists are dubious about curing patients with borderline pathology. They therefore adopt the course of supporting the defensive structure by avoiding unconscious conflict, minimizing concentration on the past, and providing symptom relief in the medium of a benevolent relationship with as much setting of limits as situations warrant. They will then adopt interventions that deal expediently with remediable pathology related to pathological links in the behavioral chain, for example, psychopharmacology for severe anxiety and depression, relaxation exercises for tension, desensitization techniques for phobias, behavioral therapy for impulsivity and self-destructiveness, environmental manipulation for situational disturbances, and cognitive therapy for distortions in thinking. They will veer from counseling, reassurance, confrontation, education, and concern with dynamics within the limits of their training and as required by the immediate needs of their patients. Therapy is usually conducted on a once- or twice-a-week basis. Modifications in method include the following:

1. Establishing a warm supportive relationship is of paramount importance.

2. Time restrictions in the session must be elastic.

3. A long testing period is to be expected. It may often be very difficult for the patient to make a relationship with the therapist.

4. Environmental manipulation may be inescapable.

5. Working with the patient's family to reduce pressure on the patient is frequently indicated.

6. The interview focus is on reality, the patient's relapse into daydreaming or delusion being interpreted as a reaction to fear or guilt.

7. Avoiding the probing of psychotic-like material is advisable.

8. Active reassurance and advice giving may be necessary.

9. Directive encouragement is given to the patient to participate in occupational therapy, hobbies, and recreations.

10. Neurotic defenses are supported and strengthened.

11. Challenging or disagreeing with the patient's distorted ideas is delayed until a good relationship exists.

12. The patient may at the start of therapy be told what to expect during therapy, especially that at times he or she may be upset with the therapist for not doing more for him or her. The patient may want to quit therapy. If the patient does quit, he or she is welcome to return (Katz, 1982).

13. Therapy may last a long time, perhaps the rest of the patient's life.

The importance of keeping the relationship with the therapist as non-distorted and productive as possible with a minimum of acting-out is paramount. When necessary, there is a search for maladaptive defenses and, when there is evidence of interference with transference, (1) elaboration of how they influence the patient's relations with others, (2) confrontation and interpretation of defenses that sponsor a negative transference, (3) the setting of limits in the therapeutic situation, and (4) the employment of modalities such as

hospitals, and foster homes when needed. Combined individual and group psychotherapy for the borderline patient has special advantages and a specific function. It is at present used widely for borderlines in private offices, clinics, and institutions where insight into the necessity for treatment and an ability to relate to a therapeutic situation remain at least partially intact.

While the one-to-one relationship of individual therapy satisfies dependency needs, the borderline patient also feels threatened by it. Many of these patients profit in a group therapeutic setting where they feel less dependent and the therapist appears less powerful. In the security of the group the members relate to each other and to the "democratic" authority figure of the therapist with more freedom and less anxiety than in any other situation. The group atmosphere facilitates expression of one's feelings. It makes interaction and with it socialization desirable and rewarding. The all-or-none conflict that leads to emotional inhibition and withdrawal out of fear of one's own destructive impulses is worked through under the protective leadership of the therapist and by testing the reality of anticipated dire consequences following expression of one's emotions. In the social situation of the therapy group, with its graded anxiety-releasing potential and the opportunity for reality testing, the borderline patient may find his or her first constructive experience in human relationships and may grasp a glimpse of understanding into the positive sides of socialization.

In working with dynamic vectors, care must be taken to prevent the patient's anxiety from getting too extreme. It is better to deal with the secondary elaborations of nuclear conflicts (derivative conflicts) as reflected in personality interactions (see Chapter 44) than with the nuclear conflicts directly. This may be especially useful if the patient displays evidence of obstructive transference and resistance and has enough of an "observing ego" to handle interpretations. Some of the techniques of A. Wolberg described later in this section may be helpful here. Management of counter-transference is a most vital part of therapy because in trying to understand one's untoward feelings and reactions the therapist can obtain important clues regarding basic conflicts that are being extruded through projective identification.

The prescription of psychotropic drugs may be indicated if the patient urgently requires calming or depression is bogging him or her down. Here one must recognize that the reports by patients of benefit may not coordinate with that of outside observers. Drugs may be poorly tolerated in borderlines, and even minor side effects may tempt the patient to discontinue medications. Haldol (Soloff et al, 1986) and Navane (Serban & Siegal, 1984) in moderate doses may be useful for anxiety and emotional instability as well as for psychotic-like symptoms. MAO inhibitors, such as Nardil, have been recommended for depressions associated with experiences of rejection (Klein DF, 1977). Benzodiazepines (Xanax, Valium, Ativan) may occasionally be useful for strong anxiety, recognizing the potential for abuse and that they may stimulate destructive actions. Tegretol in some cases has lowered tendencies toward impulsivity. Lithium has also been used when emotional instability was extreme (Rifkin et al, 1972).

Psychological testing for borderline patients has its advantages. Frieswyk (1982) believes that testing is especially valuable when manifestations of borderline pathology are subtle. We may detect "potential for acting-out, depressive mood swings, suicide, psychotic decompensation, as well as circumstances most likely to evoke untold reactions." We are helped to estimate the patient's capacities for a therapeutic alliance and "potential responses to different treatment modalities."

Short-term hospitalization may be required during critical phases of adjustment, particularly when the patient encounters rejection in a close relationship, is fired from a job, is involved in an accident, or during family crises. When serious regression has been stirred up by negative transference, an explosive reaction or suicidal gesture may require control in a protective setting. A halfway house sometimes is all that is required. The therapist must guard, however, against the patient's desire to use hospitalization as a repetitive escape device.

Reconstructive Psychotherapy

Borderline patients have traditionally been considered unsuitable candidates for psychoanalysis, but in recent years, inspired by the work of such analysts as Kernberg

(1975), Gunderson et al., (1975), Masterson (1976), Kohut (1971), Rinsley (1980), and others, and under the influence of object relations theory, certain modifications in psychoanalysis have been introduced geared toward the hitherto considered impossible goal of reconstructive change. Unfortunately, the writings of some of the innovators have been vertiginous and difficult to understand. Moreover, there are fundamental disagreements regarding the best way to implement psychoanalytic psychotherapy.

Although true classical psychoanalysis is generally contraindicated, some analysts agree with Kernberg that regression should be promoted in order to activate pathological object and self representations and their projection onto the analyst in the transference. Consequently, the therapist is enjoined to be technically neutral and non-interfering. Primitive transference, which rapidly precipitates, should immediately be interpreted in here-and-now terms. Suggestive and manipulative techniques are best avoided, but the patient's condition may necessitate some structuring of daily routines. The therapist is empathic but must be as non-interfering as possible, activities should be confined to clarification and interpretation and external arrangements left to others. Genetic reconstructions cannot be made early in treatment because self and object representations are too fuzzy and undifferentiated and projective identification and splitting are too imminent. Later in therapy when there is a better differentiation and part-object relations have given way to more mature (whole-object) relations, genetic reconstructions may be effective. This form of treatment is long-term, with session frequency no less than three times weekly. Because primitive transferences may activate psychotic processes, hospitalization may be necessary to protect the patient and others. If the patient's defenses are sufficiently strong to prevent acting-out, therapy may proceed outside of a hospital, perhaps with day-hospital arrangements, and if living with a disturbed family is intolerable, in a foster home. This modified analytic approach, known also as "expressive psychotherapy," may not be possible if the patient's secondary gains through exploitation of the illness are too powerful and milieu distortions are so strong as to necessitate constant environmental manipulation. Social isolation may also be too prominent, ego weakness too intense, and antisocial tendencies too dangerous. In addition, there may be too little motivation, too low economic wherewithal, too poor

psychological mindedness, and too limited capacity for introspection to recommend this kind of treatment. Finally, the therapist may have too little training and sophistication in the use of the requisite techniques and too little confidence in their effectiveness to give the method a fair trial.

A large group of analysts question the value of expressive psychotherapy with its promotion of regression as the principal technique and think that it may pose dangers for the patient. They believe that the therapist must be more active and maintain an openly empathic front and provide a reassuring "holding," limit-setting, structured environment irrespective of the intensity of disturbance of the patient. This group, following the leads of "self-psychology," has evolved an elaborate concept of the "self-object" and of personality development that encourages a conception of the borderline patient as less of a laboratory of pathological strivings that require activation and interpretation in an atmosphere of technical neutrality and more of a creation of faulty conditioning and inadequate development with deficits that must be repaired in a nurturant relationship. The patient is helped to tolerate his or her transference reactions and then to replace destructive and angry feelings that emerge in the transference. Only very much later is interpretation utilized.

A modified analytic approach that has proven effective with some borderline patients is illustrated by the work of Arlene Wolberg (1952, 1959, 1960). She recommends that reconstructive treatment must be slowly and carefully organized because of the ever-present projective frame of reference and the danger of throwing the patient into anxiety that will force the patient to use his or her delusional system as a defense, thus pushing the patient over the border into an active psychosis. Freud's account of his management of the patient described in his paper "An Infantile Neurosis" contains tactics that may be used with borderline patients: "The patient ... remained ... unassailably entrenched behind an attitude of obliging apathy. He listened, understood, and remained unapproachable. His shrinking from an independent existence was so great as to outweigh all the vexations of his illness. Only one way was to be found of overcoming it. I was obliged to wait until his attachment to myself had become strong enough to

counterbalance this shrinking, and then played off this one factor against the other" (*Collected Papers,* Vol. III, pp. 477-478). In view of the degree of sadomasochism in the borderline patient, the treatment process must take into account the severe anxiety to which such patients are constantly subjected, the peculiar composition of the ego, which tends to be organized around oppositional tendencies (sadism), stubborn negativism, the need of the patient to fail in certain situations, the passivity, the projective framework, the psychotic-like transference, and the characteristic failure of the various defensive structures. Special techniques are needed.

The first phase of treatment must involve what A. Wolberg (1960, 1973) has called "projective techniques." These are methods of coping with the sadomasochism of the patient, the acting-out tendencies, the denial and dissociative mechanisms, the autism (fantasy life), and the negativism so that the therapist does not become embroiled with the patient in a sadomasochistic relationship. Three projective techniques are recommended: (1) "the use of the other," (2) "attitude therapy," and (3) "ego construction," i.e., reinforcement of the patient's constructive ego trends.

In the "use of the other" the therapist takes advantage of the tendency of borderline patients to deny their own feelings and ideas and to project them onto others. When they speak of "others," therefore, they are actually talking about themselves in a masked way to avoid anxiety. Should the therapist do what is ordinarily done with neurotic patients, i.e., interpret the projection and confront the patient with the defense, borderline patients will be unable to organize themselves and to utilize the interpretation constructively. Instead they will become more resistive and deny the validity of the interpretation, incorporating the interpretation into their sadomasochistic operations by beating themselves with it and advancing it as another reason to hate themselves or, on the other hand, by becoming paranoid against the therapist and using the interpretations as a rationalization for the distrust. The relationship with the therapist is bound to disintegrate under these circumstances; a transference neurosis may precipitate out abruptly; psychotic manifestations may emerge. For these reasons the therapist must preserve the projective defenses of the patient and always (at least during the early stages of treatment) talk

about the motives and maneuvers of the "others," allowing the patient to make personal connections or to deny them as he or she wishes. Such a method will help cement a positive relationship with the patient. Dreams are handled in the same way, never pointing an accusing finger at the patient. Fantasies that have motivated the acting-out are analyzed in a manner similar to dreams: the therapist does not challenge or confront the patient. One merely explores. One does not justify or reassure the patient, even though one acts empathic.

The "others" in the interpersonal encounters are analyzed by conjecturing as to •why they feel and act as they do and what their motives could possibly be. The therapist does not charge the patient with the fact that he or she is like the "others." Eventually when the working relationship consolidates, the patient will acknowledge this. When the first statements are made by the patient that "this is like me," the therapist simply agrees and does not pursue it further. Each time that the patient says "this is like me," the therapist agrees that is *might* be true. Should the patient repeatedly bring up the consociation, the therapist may suggest that this is a pattern worth exploring. The therapist may query, "How does the pattern operate? It is not too obvious in the sessions. This could be worth exploring."

"Attitude therapy" is a projective device used to point up the patient's patterns of operation within any given interpersonal relationship. Inevitably he or she will bring up details of a personal encounter that are highly prejudiced and contain a paranoidal flavor. Accurate accounts will be resisted since this will reveal the patient's acting-out proclivities that mobilize his or her guilt. The therapist must not be put off by the patient's maneuvers; the therapist keeps asking for details, but not to the point where the patient becomes overly defensive. In such a case the therapist discontinues questioning, indicating that it is causing too much anxiety in the patient. When other incidents are reported, however, questioning is begun again.

Eventually the patient's true attitudes and feelings, which contain fragments of the fantasies motivating the acting-out, will be revealed. The therapist may then say,

"Incidents like this can be very upsetting." As the patient brings up accounts of further encounters, definite patterns will emerge. Eventually the therapist will be able to help the patient consolidate his or her thoughts, attitudes, feelings, and behavior in these situations. The interpretations are in the form of broad statements that in a roundabout way, through focusing, indicate a connection between thoughts, feelings, fantasies, anxieties, and patterns of acting-out behavior. Questions are posed in such a manner that the patient makes the associations. If the therapist offers the patient an interpretation before he or she is ready for it, i.e., before the patient has mentioned the possibility several times, then the therapist may become involved in the patient's obsessive mechanisms. The patient will weave the therapist into the warp and woof of his or her fantasy life and chew on the information instead of using it to work out the problem.

In the technique of "positive ego construction" the therapist is the projective object, taking positive trends in the patient's ego and reflecting them back to the patient as if they were the therapist's own. This is because borderline patients cannot accept good things about themselves or utilize their own constructive thinking without excessive anxiety. Such patients are guilty about their positive trends since they have been taught by their parents to disbelieve them; they have been encouraged to fail in certain ways in order to play the roles consigned to them. Success constitutes a greater threat than failure in specific areas. To reduce their guilt but not to analyze it is one of the purposes of this technique. For instance, if a patient brings in the tale of having applied for a job and having bungled the interview by purposefully saying that he could not qualify because of lack of skills, and if he then reflects back on what happened with the remark, "I should have told him that I know enough about this work to be able to learn the special details rapidly, which is the truth," the therapist may respond in a qualified positive way: "It is definitely *my* opinion that you know enough about this work to able to learn the special details rapidly." Thus the phrases the patient has uttered are repeated as the therapist's own ideas. The phrases may also be reorganized and the same thing said in different words. For example, the patient states: "Probably I feel I don't deserve the job." The therapist does not reply with the conventional, "Why not?" Instead the comment may be, "I've thought of this too. Many people I've worked with feel guilt when a good opportunity

presents itself. They shouldn't have to feel this way, but they do."

Role playing may also be employed to rehearse with the therapist what the patient *might* have said, the patient and therapist interchanging roles of patient and employer. After a certain number of incidents have been "role played," a patient may wonder why he or she acts this way. The therapist then replies, "This is an important thing for us to figure out." The therapist does not give the patient the answers when questioned, "Why?" Rather the therapist indicates that the two must seek answers together; this is a cooperative effort between two people who have come to an agreement on certain points.

After the patient is able to accept responsibility for his or her own actions without developing intense anxiety or manifesting the usual defenses, the treatment may take on a form similar to that of working with a neurotic patient. Should the patient become excessively anxious, projective techniques, as outlined above, should be used.

Avoidant Personality Disorder (DSM-III-R Code 301.82)

The determining feature of avoidant personality disorder is possession of a markedly devaluated self-esteem. This produces a defensive reaction of avoidance of any stimulus that points to this defect. Avoidant individuals safeguard against criticism, rejection, humiliation, failure, and social derogation by withdrawal tendencies and refusal to take chances or to expose themselves to any activities that threaten to bring out their inferiority and personal shortcomings. Ungratified needs for love, acceptance, and recognition sponsor frustration, anger, self-debasement, and other masochistic tendencies. Unlike the schizoid personality, who displays some of the same tendencies, the avoidant personality has not given up desires for success and good social relations, and in fact retains an unquenchable thirst for these bounties.

During psychotherapy, the thrust should be toward encouraging exposure to challenges and to activities that promise self-enhancing rewards. In addition to the baseline interventions, the following are recommended:

    1. Behavioral assertiveness training to enable the patient to accept challenges and

to put his or her best foot forward;

2. In vivo desensitization in situations that are usually avoided;

3. Group therapy and psychodrama to provide a platform for the practice of assertive behavior; and

4. Cognitive therapy to correct false attitudes and inhibiting self-statements.

Histrionic Personality Disorder (DSM-III-R Code 301.50)

The need for histrionic and dramatic displays characterize the histrionic personality disorder. A strong narcissistic tinge colors attitudes and interpersonal relationships. The individual, while evincing a superficial though exaggerated show of affection for and concern with others, is actually self-centered, seeking to impress the immediate audience with his or her charm and talents. Emotional instability with periods of screaming, crying, and explosive carrying-on break out when wishes are not granted or actions are disapproved. The irritability, egocentricity, demandingness, and irresponsibility of such persons result in rejection, which is apt to stimulate retaliatory rage and paranoidal-like recriminations. Such behavior is usually forgiven because of the individual's skilled show of remorse and clever seductiveness, only to be repeated at the next frustrating episode. Dependency patterns are common. The histrionics typically fasten onto hosts whose lives they make a continuing episode of crises. Suicidal threats and abortive attempts at destroying themselves are prominent chapters in the book of theatrical displays.

Therapy is usually sought when a spouse or lover seriously threatens to abandon the person unless the latter begins therapy or analysis. With astonishing rapidity, the therapist becomes the object of the patient's displays, seductiveness, and acting-out, since transference is easily mobilized in these patients. Treatment is usually unsuccessful because motivation to change is shallow and insincere. As long as the patient has another human subject to fasten onto, the referring agency is temporarily relieved of the burden. If a therapeutic relationship can be established and the therapist does not allow countertransference to distort a professional stance, some of these patients may be helped with long-term dynamic psychotherapy.

Antisocial Personality Disorder (DSM-III-R Code 301.70)

Allied to narcissistic character disorders is an antisocial personality manifested by poor frustration tolerance, egocentricity, impulsivity, aggressiveness, antisocial acting-out, an inability to profit from experience, undeveloped capacities for cooperative interpersonal relationships, poorly integrated sexual responses, and urgent pleasure pursuits with an inability to postpone gratification. Many such patients lied, fought, stole, and were truants during childhood and resorted to severe substance abuse during adolescence. Vagrancy, sexual promiscuity, and criminality are hallmarks of the disorder in adults. Because of the indelible warping in ego formation, goals in therapy, as with the narcissistic personality, are geared toward symptomatic relief rather than character change.

Modification of destructive and antisocial behavior is, of course, desirable but usually visionary. Recognition of acting-out, the circumstances and needs that initiate it, and the way that the patient draws other people into his or her maneuvers are not too difficult. Doing something to prevent this behavior is another matter.

Most authorities agree that the management of an antisocial personality is most difficult. All approaches have yielded meager results. In many cases the only thing that can be accomplished is manipulation of the environment to eliminate as many temptations as possible that stimulate the patient into expressing his or her vicarious impulses.

If an antisocial individual can establish a relationship to a person, the latter may be able, as a kind but firm authority, to supervise and somehow restrain the patient's actions. Hypnosis may reinforce this authoritative relationship but the patient will usually continue to test the powers of the therapist who acts as a repressive moral force and as a pillar of support. The patient may get to the point where he or she will turn to the therapist for guidance when temptation threatens. Suggestions are couched in terms so as to convince the patient that he or she is actually wiser and happier for resisting certain activities that, as he or she knows from past experience, are bound to have disastrous results. On the basis of a guidance relationship, the patient may be instructed in the

wisdom of postponing immediate gratifications for those that in the long run will prove more lasting and wholesome. The patient is taught the prudence of tolerating frustration and the need to feel a sense of responsibility and consideration for the rights of others. Not that these lessons will be immediately accepted or acted on, but constant repetition sometimes helps the patient to realize that it is to his or her best interest, ultimately, to observe social amenities and to exercise more self-control.

Experience demonstrates that it is possible to modify to some extent the immature explosive reactions of the patient by an extensive training program, particularly in cooperative group work where the individual participates as a member toward a common objective. Adequate group identifications are lacking in these people, and the realization that ego satisfactions can accrue from group experiences may create a chink in the defensive armor. In cases where the individual comes into conflict with the law and incarceration is necessary, a program organized around building up whatever assets the individual possesses, particularly in a therapeutic community, may, in some instances, bring success. In young patients vocational schools that teach a trade may contribute to self-esteem and provide a means of diverting energies into a profitable channel. Should group therapy be deemed necessary, the constituent members ideally should be antisocial personalities with problems similar to those of the patient. The group leader should ideally be an antisocial personality who has recovered and gained respectability. Even if therapy seems successful, intervals of acting-out are to be expected.

PSYCHOACTIVE SUBSTANCE-INDUCED DISORDERS

Alcoholism (Alcohol Abuse) [DSM-III-R Code 305.00]; Alcohol Dependence [DSM-III-R Code 303.90]

People with alcohol dependence rarely come to psychotherapy because they want to quit drinking of their own accord. They are usually pushed into it because of aversive circumstances that their drunkenness has created. A wife threatens her husband with divorce unless he stops his irresponsible tippling. An employer gives an old employee a last chance to get off the bottle by personally arranging a consultation with a therapist. A

drunken driver is about to lose his license and his lawyer insists that it is a good strategy to be in treatment. A judge suspends sentence on a person who has committed a crime while drunk on the condition that he do something about his alcoholic habit. A physician has frightened the drinker or his family with the announcement that alcoholic liver disease will result in incurable cirrhosis. In many cases the principal reason alcoholics seek help is for symptoms of anxiety, depression, blackouts, and insomnia or for stressful environmental conditions with which they cannot cope even under the influence of alcohol or other abusive substances. Alcoholics will often fail to mention their proclivity to drink until the therapist asks how much they drink. Alcoholics will usually minimize the amount they consume and derogate the idea that they cannot hold their liquor. They do this not because they want to deceive the therapist, but because *they are unable to stop their habit* and want to ensure its continuity without paying the penalty with which they are now confronted. The therapist will then realize that the complaint factor may be a secondary complication and that the basic problem is that the patient is poisoning himself and ruining his life with drink. The therapist will recognize also that unless the alcoholic stops drinking completely psychotherapy will have little effect. If the individual is only psychologically and not physiologically dependent on alcohol, it may be possible with psychotherapeutic help to wean the person from drink. If the pattern has progressed to the point where there is a physical need for alcohol, the problem may be an insuperable one unless motivation is created to achieve complete abstinence. Without this motivation, therapeutic efforts will be useless.

Because motivating drinkers to give up alcohol and other abused substances is so difficult, alcoholism has become, world over, one of the most serious and prevalent problems that threatens society today. The more than 10 million alcoholics in the United States affect the lives of 40 million family members. The economic loss to the nation amounts to $120 billion annually. Alcoholism accounts for a great many illnesses with fatal consequences. It is the fourth leading cause of death. Liver disease, gastritis, an increased risk of acquiring certain cancers, toxic interactions with other drugs, nutritional deficiencies, birth defects, hypertension, sluggishness of the cardiac musculature, interference with hypothalamic and pituitary hormones, and various other calamities

shadow the existence of the indiscreet drinker. In addition, there are the ever-too-abundant psychological ravages that interfere with adaptive functioning which affect work, marriage, family, and social relationships, create accident proneness, and otherwise disrupt one's personal life. These problems are too well known to require elaboration here. In sum, alcoholism is the most commonly abused and most dangerous drug habit today.

The fact that alcoholism has traditionally been regarded as a moral failing rather than a disease with genetic associations has led families to regard it as a stigma and a disgrace. In recent years, however, this attitude has changed. The courageous revelation by First Lady Betty Ford of her struggle with alcoholism has helped enormously to give people a more authentic outlook at this crippling and potentially fatal malady. Recognition that alcoholism can be treated has led to the introduction of a number of regimes that try to approach the illness from a scientific perspective. Acceptance of modern treatments give the alcoholic patient almost a 75 percent chance of returning to productive life. The fact that one-half to three-quarters of all referrals to recently created employee assistance programs are for alcohol misuse has stimulated industry and unions to develop services for alcoholically impaired employees. Many deterrents exist, however, *(JAMA,* 1983). First, there is the matter of confidentiality and the patient's right to privacy. Revealing the nature of the difficulty can threaten advancement if not termination of one's job. Second, follow-up studies on treated alcoholics are thwarted by federal confidentiality regulations. Third, there is difficulty in coordinating the accumulated information so that it can be distributed effectively and utilized in medical curricula and by specialists. Fourth, reliable cost-effective methods of assessing new treatment programs must still be developed.

Aggressive programs, such as one at General Motors Corporation, have proven not only that such programs have economic advantages for a company, but also that they enable the company to retain valued employees and thus minimize staff turnover. Three-to 4-week care in institutions practicing a variety of interventions have proven so popular that freestanding inpatient and residential facilities for alcoholism and substance abuse have multiplied. Medically supervised programs and "Care-Units" now exist that provide

hospital-based medical care, as well as educational and psychological counseling for patients and their families. On some units offering multimodal programs some staff members are themselves recovered alcoholics who, because they have gone through similar experiences and "speak the language" of alcoholics, can often provide better role models than professionals.

A common treatment format includes at the start medical detoxification in a hospital. When the patient is able to do so, he or she attends daily group and individual psychotherapy and counseling sessions as well as recreation therapy. Weekly family seminars with patients and their families are held to discuss mutual problems and to explore changes that are essential in the future. Films are shown, literature distributed, and workshops are held to enrich education about the nature and consequences of alcoholism. An aftercare program acts as a bridge to the community to prepare the individual for the habitual stresses he or she will face without alcohol. These treatment units are located in different parts of the country, and information about them may be obtained from local social service agencies.

Getting off alcohol, it is now recognized, is not the end-all of therapy. It is the beginning. What one must do in addition is maintain sobriety and ideally deal with the sources of the drinking problem. Here we come back to the problem of motivation. It is hard enough to get an alcoholic to want to try to stop drinking and enter a unit that will enable him or her to get off alcohol; it is even more difficult to get the alcoholic to do something about the conditions that have created the drinking problem.

Creating Motivation for Abstinence

As mentioned previously, the first step in therapy is to create a sincere desire to remove from one's life the toxic substances that one uses to subdue anxiety. Initial resistance to the idea of accepting help is common and confounding. It is especially a problem in elderly alcoholics, whose denial mechanisms are abetted by their need to flaunt independence. Motivating an individual to accept that he or she needs to give up alcohol to feel better requires a good deal of patience and skill.

The following points and caveats may be of help:

1. When the average alcoholic applies for therapy, he or she usually expresses or suggests a secret hope of learning to drink normally and to "hold my liquor like anyone else." This may be possible in anxiety drinkers following abatement of their neurosis; it is not possible in the case of real alcoholics.

2. Although some persons believe that alcoholics can be cured by weaning them gradually from the bottle and that they may learn to engage in social drinking without exceeding their capacity, experience has shown that success is possible only where alcohol is completely and absolutely eliminated from an individual's regime. The object in therapy is complete elimination of all alcoholic beverages, including wine and beer.

3. The treatment of alcoholism not only embraces the removal of the desire for alcohol; it also involves restoration of the patient to some adaptational equilibrium. Without such restoration, the person will become pathologically depressed, and tension will drive him or her to drink no matter what pressures are exerted.

4. In the anxiety drinker any attempt to force or shame the person into sobriety will interfere with the therapeutic relationship. A useful rule is not to make the diagnosis of alcoholism for the patient but to give the patient information so that he or she makes the diagnosis or at least genuinely asks for help. It is fruitless to design a treatment program for an alcoholic unless he or she is ready to accept the need for help.

5. Never accuse the patient of being an alcoholic, this will stimulate defiance and denial. The patient will accept any other diagnosis except alcoholism. One may tell the patient that some people are chemically unable to tolerate alcohol and that it acts like a poison to their bodies. Many patients will accept that they are "allergic" to alcohol more easily than that they are psychologically unable to control their drinking.

6. Emphasize that it is difficult to break the habit without professional help because the body has become chemically dependent on alcohol and requires medical and psychological interventions to control the effects of withdrawal.

7. Never pressure a patient into giving up alcohol. Explain its effects on the body

and tell the patient to be the judge of whether he or she wants to try to give it up.

8. If the patient asks what the signs of alcoholic dependency are, one may simply say: "If you can't get through the day without a drink, you may want to do something about it. This indicates that the body is asking for help."

9. Warn the patient that he or she may need some support to stop drinking. The best support is an AA (Alcoholics Anonymous) or similar group. If the patient claims he or she is not an alcoholic and does not see the reason to go to an A A group, tell him or her that people with a wide assortment of problems other than drinking are helped by such groups. Deal with the patient's resistance.

10. You may not be able to do very much with an alcoholic without AA or a similar group as a helping adjunct.

11. Avoid psychoanalytic probing or any other insight therapy until the patient is off alcohol; such treatment will do no good. The triad of confrontation, empathy, and proffered hope is the best technique for breaking down denial mechanisms and other resistances (Whitfield, 1980).

12. A patient may be able to start and continue in psychotherapy without becoming an inpatient in a hospital or treatment unit if he or she has sufficient motivation to join a supportive group such as AA and is able to detoxify himself or herself.

Detoxification

A large number of patients who have no serious physical illness can be detoxified at home or preferably at a local detoxification center, usually without drugs (Whitfield, 1980). A pleasant atmosphere is important. The patient being ambulatory, introductory group sessions are initiated, and distracting group activities are arranged. Drug-free detoxification, if it can be done, has advantages; it is shorter, less expensive, can be executed by non-medical personnel, avoids dependence on drugs, and helps the patient remember the unpleasant withdrawal experience, which acts as an aversive stimulus in the face of temptation. Any medications that are needed except anxiolytics and energizers should be continued. If the patient is uncomfortable, however, benzodiazepines such as

Librium or Ativan may be prescribed during the first few days and then discontinued. A strong multivitamin, 50-100 mg of thiamine, and 1 mg of folate should be given daily. If withdrawal seizures have occurred in the past, 300 mg of phenytoin (Dilantin) should be given daily for 5 days. Where an anxiolytic is deemed necessary for more than a few days BuSpar may be used since this medication produces tranquilization with no apparent abuse liability and no withdrawal syndrome reported at the end of therapy.

Conditioned reflex therapy is not as popular as it was in past years. It requires hospitalization in a special unit when it is used. A popular model is to administer an emetic paired with alcohol. Apomorphine is given for purposes of conditioning if there is no disease of the kidney or liver and the patient has not recently been on Antabuse. The patient then receives several glasses of warm water flavored with his or her favorite alcoholic beverages. Several spasms of vomiting may occur. Suggestions are made that the patient will be able to control his or her drinking by disliking all alcoholic beverages; in this way a person's health is restored. This treatment is repeated on successive or alternate days. Salt should be added to the diet to compensate for the salt lost in vomiting. The conditioning method is expensive, and statistics on its usefulness are still unclear.

Some behavior therapists attempt detoxification by training the patient in behaviors that are incompatible with excessive drinking (Miller, 1977). The patient is taught substitutive behaviors in situations that operate as cues for drinking. Thus assertive training (Alberti & Emmons, 1973) may be instituted to enable the individual to express personal rights and feelings without his or her customary recourse to alcohol. Relaxation training and systematic desensitization teaches the patient to master anxiety-provoking situations that lead to drinking. Because troubled marriages are sometimes at the basis of an alcoholic's drinking, couples may be instructed in the use of mutual positive reinforcing behavior with contingency contracting (Stuart, 1969). A variety of other operant approaches have also been employed (Cohen et al, 1972; Azrin, 1976). "Covert sensitization" utilizes imagery to pair a desire for alcohol with nausea (Elkins, 1980). Hypnosis has also been employed (Katz RC, 1980).

If a patient continues to drink or whatever approach is tried proves only partially effective, he or she should be counseled, best in the presence of the spouse, to take a vacation and go to a treatment unit for help. There are many such units, some good, some not so good. The Yellow Pages of the telephone directory lists them under "Alcohol Information and Treatment," but finding units in this way will require investigating their qualifications. They should be hospital based, state certified, and approved by the Joint Commission for the Accreditation of Hospitals (JCAH). There are more than 100 "care units" around the country. They should have a rounded-out program from detoxification to aftercare. The reason concentrated therapy in a closed unit is necessary is that the alcoholic, despite his or her show of independence, is very dependent and needs people around all the time, as well as activities to divert his or her mind. Boredom easily sends the patient to drink. The alcoholic cannot fill the day with sufficient activities at home or at work. Stresses associated with everyday routines may be too anxiety provoking. A complete change of scene in a well-run unit is needed to get these patients off to a fresh start.

In heavy drinkers, detoxification will precipitate abstinence reactions in 12 to 24 hours. Shaking and agitation may frighten these patients, delirium tremens may kill them unless they get proper treatment. Librium, 50-100 mg intravenously, repeated as necessary in 2 to 4 hours, or Ativan intramuscularly, 0.05 mg/kg up to 4 mg, may be required. Emergency reactions will need special interventions (see Chapter 58, "Handling Emergencies in Psychotherapy"). It usually requires 3 to 5 days to detoxify an alcoholic, and up to 3 weeks if other addictive substances have been taken, which is very common. Coincident with and subsequent to detoxification, a multimodal program of counseling, education, group work, and recreational therapy is implemented. Family counseling and therapy are employed as needed. The patient is prepared to continue in an Alcoholics Anonymous or similar group in the area in which he or she lives, and the spouse and family are referred to Al-Anon (Anthony, 1977). The telephone number for Al-Anon is listed in the telephone directory or may be obtained from Alcoholics Anonymous, also listed in the directory.

A considerable number of alcoholics take abuse substances in addition to alcohol. Among the most popular of these drugs are sedative-hypnotics such as barbiturates (Nembutal, Seconal), nonbarbiturate hypnotics. (Noludar, Placidyl), opiates (heroin, illicit methadone), and stimulants (dexedrine, cocaine). After being detoxified from alcohol, the alcoholic may experience symptoms of withdrawal from the other abused substances, which may also require therapy. In some cases the primary problem was the abuse of substances other than alcohol, and alcohol was taken to reinforce the effects of or to deaden withdrawal symptoms from the drugs. Because of the ease and relatively low cost of alcohol, the drinking continued, resulting in alcoholism.

Not uncommon are manifestations of such syndromes as major or bipolar depression, panic disorder, agoraphobia, impulse control disorder, and psychogenic pain, which appear after detoxification has rendered the patient alcohol free. In many cases the primary problem was the syndrome, whose symptoms the individual has tried to control with alcohol. In such cases corrective interventions will be needed.

Once the patient is free from the mind-befogging effects of alcohol, he or she more easily becomes aware of how drinking has interfered with his or her life and happiness. The patient may still have symptoms of anxiety and depression; stress situations will still exist at home and at work; or a personality problem may continue to interfere with proper adaptation. The patient will continue to need care and psychotherapy for these problems. During the period of hospitalization the therapist will have telephoned the patient once or twice or, better still, if possible, would have visited. In this way, continuity of treatment is maintained.

Post-abstinence Therapy

When the patient returns for psychotherapy, he or she may be able to accept the diagnosis of alcoholism. The patient is told that alcoholism is a treatable disease like diabetes for which one cannot be blamed. However, it must be watched and taken care of the rest of one's life. While the patient is better now, care must be taken not to slip back into old habits. This is best prevented by going regularly to an AA group and by continuing

in psychotherapy. A common question is "Can I ever resume normal drinking?" The answer is a categorical no. Alcoholism like diabetes is a lifelong disease and resuming drinking (even one drink) will activate it again." The patient is told that the recovery rate is high if a person follows a good treatment plan. Doing this is the patient's own responsibility. Nobody else can do it for the patient.

If the patient, in spite of this talk, cannot seem to avoid tippling, he or she should be put on Antabuse (disulfiram) after discussing the urgent need for this helping agent. The average daily dose of the drug is 250 mg (with a range of 125 mg to 500 mg), although sometimes more is needed. The patient must be completely off alcohol when it is started. The patient should be instructed that the drug is harmless unless he or she drinks, and that "going off the wagon" will make him or her violently and even dangerously sick. Antabuse will protect the patient from temptation, so taking it daily is important. Ayerst Laboratories puts out a patient education booklet entitled "Now that You're on Antabuse." After one or two years of abstinence, the patient, in conference with the therapist, spouse, or close family member and A A group leader, may experiment with going off Antabuse, provided the patient is able to cope with life and with crises adequately, is relating well with people, and most important, continues in the AA group. Antabuse is most helpful in older motivated individuals who need to control psychological stressors that invite drinking. Contraindicated for Antabuse use are illnesses such as diabetes, cardiac disease, and cirrhosis of the liver. Antabuse is not suitable for schizophrenics and patients with schizoaffective reactions and markedly unstable impulse disorders. It is best to arrange for a relative or a trusted person at work to supervise the regular and uninterrupted taking of Antabuse to maintain a constant level of the drug in the bloodstream. With too small doses of Antabuse, the patient may be able to override its effect with alcohol resumption.

Psychotherapy

The psychotherapeutic treatment of an alcoholic is vital, since true alcoholics never get over the threat of relapsing into drinking. During the period when they are well, they

become non-drinking alcoholics. For many, attendance at AA is necessary all their lives. Older members eventually become leaders and helpers, ministering to the more vulnerable alcoholics. In this way, by identification, non-drinking alcoholics help themselves. Immediately after detoxification, individual therapy is needed in addition to the supportive AA group experience. The danger of relapse during the first 6 weeks after stopping drinking is real and the patient should be seen as frequently as possible during this period. Vulnerable patients who need supervision may be taken care of in a halfway house.

Designing a treatment program for the non-drinking alcoholic is dependent on what pathogenic links in the patient's behavioral chain require treatment. Basic to any treatment program is, to repeat what has been said before, continuing membership in AA or a similar group. Some alcoholics terminate the group program and are able to remain abstinent. For most, however, a good group is indispensable indefinitely as an anchor to sobriety. Psychotherapy for patients who do not have severe marital, family, or environmental problems can be short term, but group membership should continue without interruption.

Many alcoholics suffer from an underlying depression, which should not be too difficult to diagnose. A major depression may require antidepressant therapy with tricyclics or other drugs. A bipolar depression may need Lithium therapy. A neurotic depression is best helped by cognitive, interpersonal, or other form of verbal therapy. Some borderline cases may need carefully controlled neuroleptic therapy. Panic disorders and agoraphobia should be treated with behavioral approaches and antidepressants; and sedative-hypnotics assiduously avoided. Anxiety and tension are ubiquitous complaints, and the individual may importunately petition for some medications to relieve it. This request should not be treated lightly, but the patient must be reminded that the benzodiazepine drugs may be as harmfully addictive for him or her as alcohol. It is therefore best to use other tension-relieving approaches, such as relaxing exercises (a relaxing tape may be made), biofeedback, hypnosis and meditation, as well as physical exercise. Joining a YMCA or YWCA or other athletic club, running (if it is physically

permissible), and swimming are often helpful. Where an anxiolytic is absolutely necessary, buspirone (BuSpar) may be employed.

Searching out and finding existing causes of stress and anxiety in the patient's work, marital, or family situation will necessitate appropriate interventions. In examining the work situation, a battery of vocational lists may disclose that the patient's interests and aptitudes are in a direction other than the existing work. The patient may then be guided to develop along the lines indicated by the tests. Marital difficulties are best approached with marital therapy and family problems with family therapy. Environmental stress will require counseling and environmental manipulation. Consultations with a social agency for recommendations of suitable resources can save a great deal of time. Any existing remediable elements in the patient's environment that may be creating conflict for the patient should be straightened out with the aid of a social worker if necessary. In spite of expressed optimism, the patient is unable to handle frustration, and any objective source of difficulty may suffice to promote tension that will produce a craving for drink. An inquiry into the patient's daily routine and habits may be expedient. Often one finds a gross defect in the person's diet. Alcoholic overindulgence has been coincident with a depletion in dietary intake and with vitamin deficiency. Bad food habits may persist. Prescribing a well-balanced diet with sufficient calories and with supplementary vitamin B is important. The patient should also be encouraged to appease his or her hunger whenever he or she feels a need for food. Hitherto the patient has propitiated hunger pains by drinking alcohol. He or she may be surprised to observe that eating three square meals a day can remove much of the craving for liquor.

The numerous difficulties a patient has experienced through increasing inability to control drinking, the general condemnation of society, and the disdain of family all contribute toward a depreciation of self-esteem. It is difficult to rebuild self-esteem by reassurance, but an effort must be made to underscore repeatedly that the patient has many residual assets that can be expanded. Because alcoholics become negligent about their appearance, it is essential to rebuild interest in their personal care. Appearing neat and well groomed usually has a bolstering effect upon the person. Alcoholic women may

be directed toward taking care of their complexions and hair by going to a beauty parlor. Whatever interest the patient shows in hobbies or external recreations should be encouraged. Patients must be reminded that they are not hopeless cases and that they have many good qualities that they have neglected. Their guilt may be continuously appeased by showing them that their alcoholic craving is part of an illness and that it will be possible to substitute something much more constructive for it.

Teaching the alcoholic to handle frustration will require considerable effort. The patient must be brought around to a realization that everyone has frustrated feelings and that an important job in life is to exercise control. Because of what has happened, the patient is apt to misinterpret any disappointment as a sign of personal failure. It is mandatory that the patient build up a tolerance of frustration, even though willful effort must be extended in this direction. Behavioral therapy may enable the patient to adjust better to many frustrating situations.

Since frustration is usually accompanied by gastric distress, it may stimulate a desire for drink. The patient, therefore, may be advised to carry, at all times, a piece of chocolate or candy. Whenever he or she feels frustrated or under any circumstances a craving for drink develops, he or she can partake of this nourishment. Hot coffee, cocoa, and milkshakes are also good for the same purpose. As the patient gains more self-respect, greater and greater amounts of frustration may be tolerated.

Many misconceptions and faulty self-statements plague the alcoholic, and clarification, persuasion, as well as cognitive therapy are usually in order. In many cases the basic difficulty is a personality disorder. There is no one predisposing personality problem. The character trait of dependency is often prominent, although the patient may try to conceal it. Dependency makes for a host of difficulties that have been outlined previously. Treating a personality disorder usually necessitates using a modified psychoanalytic approach, which is a long-term procedure (see Personality Disorders). If the patient is motivated and it is done properly, however, the reconstructive effects can be most gratifying.

Other Abused Substances

A miscellaneous group of psychoactive substances other than alcohol are used in all societies for mildly stimulating, tension-relieving, or recreational purposes. Among these are caffeine and tobacco. Only if the incorporation of such substances is beyond the individual's tolerance level, or if they impair social or occupational functioning, or produce abnormal physical and psychological changes, or if habituation upsets the individual or those around the individual, may help be sought from a psychotherapist. When the individual is unable to control the intake of a substance, he or she is suffering from what is commonly called a *substance abuse disorder.* If there is physiological dependence on the drug, it is regarded as a *substance dependence disorder.*

Although noxious substances such as alcohol and tobacco, which are consumed legally by average citizens, can have a pathological impact, minor abuse of these substances is generally disregarded. Serious addictions that lead to lives of crime and other social evils are of much greater concern to society. Prominent disorders encountered other than alcohol abuse and alcohol dependence are cocaine abuse, opioid abuse and opioid dependence, barbiturate and other sedative-hypnotic dependence, amphetamine and other sympathomimetic drug abuse and dependence, hallucinogen abuse (such as with cannabis, phencyclidene, and psychedelic drugs), and tobacco dependence.

The chief objective of this growing stable of substances is to reduce tension, anxiety, and depression and to stimulate feelings of tranquility and euphoria. The search for these rewards has brought forth a host of substances, some of which for years have languished unnoticed in chemical laboratories. Periodically, "revolutionary" drugs appear on the streets which are said to produce heaven on earth. Peace of mind, the ability to love unambivalently, the painless acquisition of deep insights, and other astonishing bounties have never before been promised as they are today. Such a drug was MDMA, dubbed "Ecstacy" by its habitues, who claimed results in minutes never before obtained with other substances. Word travels fast among aspirants looking for lasting euphoria, and before long Ecstacy became the promising gate to a new life. But like other miracle drugs,

disillusionment rode on the wings of reality: changes were short-lived, and episodes of disinhibition and psychosis destroyed the fantasy of harmlessness. Like other hallucinogens, its abuses led to its scientific discreditment and prohibition. Since then, other substances have taken its place. The latest "miracle drug" is "crack," a reincarnation of time-honored cocaine.

Cocaine Abuse (DSM-III-R Code 305.60) and Cocaine Dependence (DSM-III-R Code 304.20)

"The psychic effect of cocaine of .05 to . 1 gram consists of exhilaration and lasting euphoria, which does not differ in any way from the normal euphoria of a healthy person. . . . One senses an increase of self-control and feels more vigorous and more capable of work. . . . One is simply normal and soon finds it difficult to believe that one is under the influence of any drug at all."

These words of Sigmund Freud describe what the founder of psychoanalysis observed during his own dalliance with the champagne of illicit substances, which now has become a public health and safety menace. Cocaine is rapidly becoming the major drug problem in this country because of its intense euphoric impact, ready availability on the street, and ease of administration. Snuffing (snorting) small amounts rapidly produces heightened alertness, feelings of well-being, and self-confidence, which last only a short time. Intravenous injections, ("freebasing") and smoking the concentrated refined drug ("crack") have a strikingly exaggerated effect, but the aftermath of this "high" are uncomfortable physical symptoms. Headache, palpitations, stereotyped movements, confusion, incoherence, rambling, nausea, vomiting, perspiration, chills, tachycardia, skin paresthesias ("insects crawling"), anxiety, trembling, and depression enjoin the addict to dose again. Overactivity, impaired judgment, and other behavioral abnormalities may occur. Recovery within 24 hours is usual unless the individual gets a "fix," initiating a new cycle of exhilaration followed by more unpleasant symptoms. Cocaine addiction is associated with weight loss, insomnia, irritability, and paranoid ideas. It may lead to violent activities and crime. With continued use of large amounts of the drug, psychotic attacks may eventuate, resembling amphetamine psychosis. Serious physical ailments also

intervene, especially when the addict habitually combines cocaine with opiates ("speedballs"). Cardiac abnormalities, brain seizure, and pulmonary dysfunction may be followed by respiratory arrest and even death. The cocaine abuser may try to calm anxiety with Valium, but continued physical suffering soon motivates the addict to search for funds to buy relief, often resulting in thievery. The power of the drug is described by Grinspoon and Bakalar (1985): "Cocaine, along with some amphetamines, is the drug most eagerly self-ad-ministered by experimental animals under restraint; they will kill themselves with voluntary injections." Human beings seem to be no less hedonistic, and cocaine addiction is spreading at an alarming rate. At a national information and treatment referral service, for example, more than 1000 telephone calls (the number is 8OO-COCAINE) are received daily and more than $50 billion for the purchase of cocaine are spent annually by abusers of the drug.

Management of acute symptoms of abstinence is urgent to prevent the individual from dosing again with cocaine. Anxiety and restlessness may yield to 10 to 20 mg of Valium or Librium, repeated as necessary. This, of course, is a temporary measure and as soon as some control is established, more permanent therapeutic measures, including residential care, counseling, and psychotherapy, should be initiated. If an overdose of cocaine has been taken, forced oxygen inhalation and muscle relaxants are given, and for convulsions, sodium pentothal (25-50 mg) is injected intravenously. In the event anxiety and tachycardia are especially strong, 1 mg of Inderal (propanolol) is sometimes injected intravenously every minute for up to 10 times. There is some evidence that bromocriptine (Parlodel), a dopamine agonist, may represent a new adjunctive treatment for cocaine abuse.

Opioid Abuse (DSM-III-R Code 305.50) and Opioid Dependence (DSM-III-R Code 304.00)

An occupational hazard for physicians, and pharmacists because of their easy accessibility, a component of pleasure seeking among psychopaths and sociopaths, a means of proving their masculinity among adolescents belonging to gangs, an unfortunate consequence of their prolonged use for pain or anxiety, opiates (particularly heroin)

constitute a growing menace to the population. Harsh penalties for the possession and sale of these drugs make their cost so high that the average addict must steal and engage in other criminal activities to secure a constant supply. The addict consequently becomes a social menace. Because he or she neglects his or her physical health, the addict suffers from disease and premature aging. Suicide is common as an escape from pain when drugs are not available.

Among the numerous narcotic opioid drugs in use today are heroin, morphine, hydromorphone (Dilaudid), oxycodone (Percodan), nalbuphine (Neubain), meperidine (Demerol), alphaprodine (Nisentil), anileridine (Leritine), methadone (Dolophine), propoxyphene (Darvon), pentazocine (Talwin), propiran (Dirame), levorphanol (Levo-Dromovan) and butorphanol (Stadol). The most frequent abusers of these drugs are teenagers, who are introduced to addiction by their peers.

The action of these drugs mimics the effect of built-in pain relievers released by the brain (endorphins and enkaphalins). Both the artificial and natural analgesics can be neutralized by certain substances such as naloxone, naltrexone, nalorphine, and cyclazocine, which block the effects of the addictive drug.

Generally, narcotic drug addition is not a simple matter of physical dependence. It is a manifestation of a long-standing personality problem that has many forms, addiction being one of the symptoms. It is not only a consequence of social and economic deprivation, although many users of drugs come from areas of poverty and destitution; it also occurs among the wealthier classes. Juvenile drug users are (1) seriously disturbed youngsters with a delinquent orientation to life who, because of a lack of cohesiveness, supervision, and discipline in their homes, drift toward renegade gangs to supply them with a sense of belonging and, through antisocial actions, to bolster up a stunted sense of identity; (2) adolescents in schools, whose peers induce them to experiment or who are depressed, bored, defiant, or simply seeking excitement. Drugs provide them with an answer to the tensions and anxieties of growing up. The pleasure rewards of drug intake followed by the violent discomfort of abstinence make drugs the central interest in the life

of the addict. It requires a good deal of money to satisfy the drug need. This sum is generally obtained through crimes against property and by "pushing" drugs, selling them at profit to other addicts.

The treatment of the drug addict with any of our present methods is frustratingly unsuccessful, principally because the addict traditionally lacks the motivation for cure; the presence of narcissistic, immature, schizoid-like personality patterns that stir up incessant inner conflict and interfere with an adaptation to reality; and the existence of a home environment that imposes burdens for which the addict can find no solution. The following guidelines, nonetheless, may be useful:

1. The treatment of addiction to narcotic drugs is best achieved in a specialized institution where withdrawal symptoms can be handled and there is close supervision to prevent the addict from obtaining drugs. If the financial condition forbids hospitalization in a private institution, it is advisable to ask the patient to apply for voluntary admission or commitment to a U.S. Public Health Service hospital at Lexington, Kentucky, or Forth Worth, Texas (Council on Pharmacy and Chemistry, 1952).

2. Withdrawal or detoxification, which takes 4 to 12 days, is best accomplished with methadone, which may be administered orally (Dole and Nyswander, 1965). According to Fraser and Crider (1953) and H.A. Raskin (1964), 1 mg of methadone is equivalent to 2 mg heroin, 4 mg morphine, 1 mg Dilaudid, 20 to 30 mg Demerol, and 25 mg codeine. The dosage of methadone must be titrated to the tolerance of the patient. Too concentrated a dosage may produce respiratory depression, circulatory depression, shock, and cardiac arrest. Generally, detoxification treatment is administered daily under close supervision, does not exceed 21 days, and may not be repeated earlier than 4 weeks following the preceding course. A single oral dose of 15 to 20 mg of methadone will usually control withdrawal symptoms. This may have to be repeated if symptoms are not suppressed. A usual stabilizing dose is 40 mg per day in single or divided doses. After 2 or 3 days the dosage is decreased at a daily or 2-day interval. Hospitalized patients generally are reduced by 10 to 20 percent each day; ambulatory patients require a slower reduction. In cases of great physical debilitation, a high caloric diet, vitamins, hydrotherapy, massage, and glucose infusions are helpful. It is important

to prevent all visitors and other persons not concerned with treatment from seeing the patient who is hospitalized since drugs may be smuggled in as a result of pitiful pleas to relieve his or her suffering. Patients who have been taking low doses of an opioid and who have a good relationship with the therapist may be given Clonidine, 0.1 to 0.3 mg, three or four times daily for detoxification purposes instead of methadone. Patients must be watched for excessive lowering of blood pressure and for excessive sedation. The relapse rate is high once a patient leaves the hospital. Theoretically, a drug antagonist such as naloxone, cyclazocine, and naltraxone should prevent resumption of the habit. Practically, patients can be induced to start, but they rarely continue on the drug antagonist, and in one study 94 percent gave up the medication within 9 months. Librium, Thorazine, Trilafon, or Sodium Amytal may be taken to alleviate distress. Hypnotherapy has served to make some patients more comfortable. A prolonged period of hospitalization is best. Follow-up studies have shown that a high percentage of addicts released before 4 months become readdicted within 6 months.

3. While many drug addicts do well in a sheltered, drug-free environment, a return to the pressures and conflicts of their everyday world rekindles tensions, escape from which will be sought in drugs. An aftercare program is mandatory. Some authorities advocate legislation to force the addict to obtain aftercare services.

4. Aftercare is best administered in a day-night hospital or halfway house where the addict may spend a good part of his or her time, be exposed to the forces of group dynamics, and obtain a full range of social, rehabilitative, vocational, recreational, and psychotherapeutic services geared to his or her needs. The aftercare of drug-free addicts poses many hazards and disappointments principally because of their immature, hypersensitive personalities, their low level of frustration, and their inability to find adequate ways of dealing with their needs and tensions. A return to drugs is easily initiated by one disturbing experience.

5. An aftercare rehabilitation and guidance center is not enough. Rather, *constant care and supervision* are required, with daily interactions with some person (social worker, minister, rehabilitation worker, or psychotherapist). An adequate drug-control program must be so organized as to meet the individual patient's changing needs. Medical, psychiatric, social, educational, and rehabilitative services are part of this

program; and unless these are closely coordinated, treatment can become both chaotic and ineffective. Methadone maintenance programs by themselves are inadequate without the additional services of counseling, vocational training, and psychotherapy.

Psychotherapy of the opioid addict is usually unsuccessful unless all the measures outlined above supplement the treatment program. In a 12-year follow-up study of addicts who had achieved abstinence, it was found that recovery is possible among delinquent addicts provided there is compulsory supervision and a discovery by the addict of gratifying alternatives to drugs (Vaillant, 1966). Since a considerable number of the patients are borderline or schizophrenic, they must be handled with methods attuned to sicker patients.

Addicts sometimes consult psychiatrists asking that they be given an opiate for renal or gall bladder colic or some other emergent condition that requires temporary narcotic administration. Signs of the addiction include the presence of needle marks on the arms, legs, hands, abdomen, and thighs or physical signs of withdrawal.

Other marks of opioid intoxication are constricted pupils, euphoria, dysphoria, apathy, motor retardation, slurred speech, drowsiness, and memory and attention impairment. Withdrawal symptoms (sweating, diarrhea, tachycardia, insomnia, eye watering, running nose, and yawning) may rapidly be brought on in an addict by injecting naloxone (Narcan) as an antidote to morphine, heroin, and similar narcotics. The presence of an opiate may also be detected from chemical analysis of the urine.

Because it is impractical to treat addition unless the drug intake is completely brought under control, the therapist should insist on hospitalization as a preliminary step in the treatment program. During aftercare, a small number of addicts will have sufficient ego strength to respond to reeducation, behavior therapy, or psychotherapy. But, it must be emphasized, psychotherapy unreinforced by a prolonged, perhaps perpetual program of rehabilitation is, as a rule, unsuccessful. An important deterrent in treating a drug addict by psychological means is countertransferential resentment and strong sympathy with the addict, which interfere with the therapist's capacity to show both tolerance and

firmness when necessary. The addict's acting-out tendencies and low level of frustration will upset the equilibrium of the most stable therapist.

Some authorities, disappointed with the results of all treatment methods, advocate supplying addicts legally with drugs to keep them in balance, in this way eliminating the illegal supply outlets. Other authorities argue against dispensing drugs, saying that the factor of increasing tolerance enjoins the addict to expand the dose required to secure the desired effect. Having obtained the limit prescribed from the physician or clinic, the addict will return to the illegal market and continue to be exploited by drug peddlers, resorting to crime for funds as usual.

For this reason, methadone maintenance therapy has become the most common approach for chronic opioid dependence. Patients come to a methadone maintenance clinic (which is controlled by federal regulations) for their daily (up to 40 mg) methadone and after 3 months are given a supply (100 mg) to take home. Progress is monitored by interviews and urine testing. During the first few months of methadone maintenance some side effects may occur, such as sexual dysfunction, sweating, and constipation. Eventually, tolerance of methadone develops and patients feel more comfortable. We are dealing with a difficult population, however, and violent outbursts may be expected, especially among unstable personalities around such issues as take-home supplies of methadone. Some patients continue to seek opioids in addition to methadone (Maddun & Bowden, 1972; Newman, 1976), and some use alcohol and sedative-hypnotics. But many are helped toward a more productive life; criminality lessens, employability increases, and general adaptation is better (Cushman, 1972; Sharoff, 1966). Even some patients who have complicated psychotic and personality problems are helped with adequate counseling and psychotherapy to stabilize with methadone. A few who are not too ill emotionally may achieve complete abstinence from drugs provided environmental stress can be controlled. The preferred objective, of course, is to render the individual completely free of all abused substances as well as methadone. This may be possible in some cases. In other cases abstinence is obtained by administering an opioid antagonist which the addict continues to take much as some alcoholics rely on Antabuse to help keep

them dry.

Among the newer treatments for heroin control in addition to methadone is methadyl acetate, a synthetic congener of methadone. Methadyl acetate appears to be equal to methadone in its rehabilitative efficacy, but its duration of action is from 48 to 72 hours, so it can be dispensed three times weekly instead of daily. It may be useful for a certain subgroup of the addict population (Senay et al, 1977).

There are some incurable addicts who are "well-adjusted and leading useful, productive and otherwise exemplary lives which would probably be upset by removing their drugs. They are contented with their present states, do not desire treatment and would resist change. The wisdom of disturbing them is to be questioned, for the result socially and economically might be destructive and bad" (NY Academy of Medicine, 1963). This applies also to elderly addicts with healed lesions of various sorts.

Some addicts seem highly motivated to rehabilitate themselves but require a drug other than methadone and a narcotic antagonist to sustain them in resisting narcotics. Neuroleptics are helpful in certain situations, particularly if psychotic symptoms threaten. Roskin (1966) believes that the schizophrenic addict uses narcotics as a tranquilizer in the throes of severe schizophrenic decompensation. The schizophrenic addict, in his opinion, has a better prognosis than the pure acting-out addict. "If a drug addict seeks help on his own volition, it may be suspected that he is a schizophrenic." Neuroleptic drugs, therefore, and the supportive relationship with the therapist are helpful replacements for narcotics in the adjustment of the schizophrenic addict. Patients with primary and bipolar depression will require antidepressants.

As mentioned before, clonidine has been used as a detoxifying agent (Mark et al, 1980; Chamey et al, 1981) to wean addicts completely off opioid substances and methadone. This is followed by administration of a substance like naltrexone (Resnick et al, 1974). Naltrexone (Traxan) is a nonaddicting narcotic antagonist that has fewer side effects than the older cyclazocine (Martin WR et al, 1965; Jaffe and Brill, 1966) and naloxone (Narcan) (Zaks et al, 1971). Blocking the euphoric effects of opioids, naltrexone

acts somewhat in the same way with narcotic addicts as Antabuse does with alcoholics (i.e., by reducing motivation for drugs). The patient must be narcotic free when it is started. After detoxification and the slow reduction of methadone to where it is completely withdrawn and when 7 to 10 days of freedom from all opioids and methadone has been verified (sustained by urine tests), naltraxone (50 mg) is administered daily. Charney et al. (1982) have described use of a combination of naltraxone and clonidine as a "safe, effective, and extremely rapid method for treating the methadone withdrawal syndrome."

Motivated addicts also have been helped in groups by relating themselves to other addicts who have broken the habit. The most successful experiment is that of Synanon under whose care the addict deliberately places him- or herself (Casriel, 1962; Gould, 1965; Walder, 1965). Part of the Synanon idea includes an intensive leaderless form of group therapy—usually three times weekly—during which each member is expected to reveal his or her feelings truthfully, and to lay bare fears and hates. "At Synanon we snatch off all the covers of our dirty little secrets. Then we stand there naked for everybody to see" *(Life Magazine,* 1962). Groups with a leader also exist, ideally consisting of three male and three female addicts and one exaddict ("Synanist"). The Synanist acts as moderator who utilizes insight into himself or herself for interpretations. The Synanist also employs such tactics as ridicule, cross-examination, and hostile attack to stir up involvement and activity. Another device, used with a new addict is the "haircut," in which four of five significant members of the Synanon family structure "take one apart," criticizing actions and performances to date. While the "haircut" may be a verbally brutal experience, it is usually quite effective. "When the word gets around that 'haircuts' are being given, people seem to get in line. . . . Many of the people who have experienced these 'haircuts' reported a change in attitude or a shift in direction almost immediately." Lectures are given daily by one of the more experienced members. The members support each other and come to each other's aid when temptation threatens to disrupt drug abstinence. Each member is also expected to perform household tasks according to ability, which gives the addict a sense of participation. Additionally, "a concerted effort is made by the significant figures of the family structure to implant spiritual concepts and values that will result in self-

reliance. Members are urged to read from the classics and from the great teachers of mankind—Jesus, Lao Tse, Buddha. These efforts have been successful to a rather surprising degree. The concept of an open mind is part of a program to help the addict find himself or herself without the use of drugs" (Dederich, 1958). As soon as the addict is adjusted to the new environment, he or she is encouraged to get a job on the outside, to contribute some salary to the group, and to continue living at the Synanon house. Dropout rates, however, are high.

The Synanon idea, which essentially depends for its force on group dynamics, is being adopted in some correctional institutions. The lack of communication between the inmates of an institution and the authorities who run it has always posed a problem. To circumvent this, the people chosen to work with offenders are themselves ex-offenders who have modified their own deviant behavior. Offenders, alcoholics, and drug addicts seem to respond to a leader who, like themselves, has gone through criminal, alcoholic, or drug addiction experiences, who talks their language, and who, in having achieved resocialization, becomes a model with whom new identifications may be made. Such a leader usually approaches his or her work with an evangelical-like zeal to point out new directions in life from which he or she cannot be outmaneuvered by specious arguments. Another technique that has come into recent use with drug addicts is the "marathon group" of continuous group interaction for 2 or more days with short periods of rest.

Residential treatment centers like Synanon have been developing in different parts of the country. An example is Day-top. Therapeutic communities, such as Odyssey House and Phoenix House (DeLeon et al, 1972; Densen-Gerber, 1973), have provided a refuge for some addicts and beneficial effects are usually maintained for as long as a patient is an active member.

Coincident psychiatric problems found among drug abusers are, in order of frequency, affective disorders, especially major depression; alcoholism; personality disorders, principally antisocial personality; and anxiety disorders. Schizophrenia sometimes may be seen, but paranoidal conditions are more common. Therapy, such as

Doxepin for depression, Antabuse for alcoholism, and neuroleptics for schizophrenia, should be instituted if necessary. About one-quarter of opioid addicts take other substances, such as barbiturates, benzodiazepines, cocaine, cannabis, amphetamines, and alcohol. This accents the need to work with many variables that influence continuance of the drug habit. Therapists looking for an ideal model of therapy should consider detoxification with methadone as a preliminary step toward complete abstinence, the use of an antagonist such as naltrexone as safeguard against resumption of the drug habit, and treatment in therapeutic communities of drug-free day-care centers, with the use of behavioral, cognitive, and, in a few cases, modified analytic therapy according to the needs and aptitudes of the patient.

The following readings on narcotic addiction are recommended: Dole and Nyswander (1965, 1966), A.M. Freedman (1966), A.M. Freedman and Sharoff (1965), Mueller (1964), Nyswander (1956), Ray (1961), Sabath (1964), Seevers (1968), Se-nay (1983), Stimson and Oppenheimer (1982), U.S. Department of Health, Education, and Welfare (nd), Verebey (1982), and Wikler (1980).

Sedative, Hypnotic, or Anxiolytic Dependence (DSM-III-R Code 304.10) and Abuse (DSM-III-R Code 305.40)

Dependence on *barbiturates* was once as serious an addiction problem as dependence on narcotics is now. Barbiturates in overdose are lethal and constitute one of the chief means of suicide. They are especially dangerous when taken with alcohol. Sometimes suicide is unintentional if an individual, because of sluggish thinking or chronic intoxication, forgets he or she took pills and swallows additional ones.

In 1962, a survey by the Food and Drug Administration revealed that more than a million pounds of barbituric acid derivatives were available in the United States (Committee on Alcoholism & Addiction, 1965). This 1-year inventory is enough to supply two dozen 1.5-gm doses to every man, woman, and child in the country. The survey led to the conclusion that "any patient whose psychological dependence on a barbiturate drug has reached a degree sufficient to constitute drug abuse has some form of underlying

psychopathology." He or she is "directly comparable to the opiate-dependent person." There are no specific syndromes involved; practically all diagnostic categories are represented. Since federal restrictions have been placed on the sale of barbiturates, benzodiazepines have largely taken their place.

Short-acting barbiturates (Pentothal, Seconal, Amytal) are particularly addicting "They are as truly addicting as heroin or morphine and give the individual and his physician an even greater problem" (U.S. Department of Health, Education, & Welfare, nd). Like alcohol, they are intoxicating, produce confusion, lack of coordination, and emotional instability. Sudden or complete withdrawal of barbiturates from an addicted person usually results in convulsions and sometimes in a temporary psychosis like delirium tremens. Death may follow.

A sizable class of barbiturate addicts are middle-aged and older people who have been given barbiturates for insomnia and have consumed pills for years. This leads to hazy thinking, poor judgment, memory loss, emotional instability, and diminished motor skills.

The most common barbiturates sold illegitimately are secobarbital (Seconal), known on the street as "reds," pentobarbital (Nembutal), dubbed "yellows" or "nembies," and amobarbital secobarbital (Tuinol), called "double-trouble" or "tooies." Sometimes inveterate addicts, especially alcoholics and amphetamine users ("speed freaks"), inject barbiturates ("downers") intravenously ("pill popping") and use them interchangeably with heroin and amphetamines ("uppers"). Behavior is affected markedly and may include episodes of violent disruptive outbursts.

Any person who has taken an overdose intentionally or unintentionally should be rushed to a hospital for immediate treatment. While waiting for the ambulance, vomiting should be induced and the airways kept clear to prevent strangling. The person should be prevented from slipping into unconsciousness. Withdrawal from the drug is essential, but complete immediate withdrawal is dangerous. The patient must be put back on barbiturates to counteract abstinence symptoms and then phased into withdrawal. No more than 0.1 gm should be withdrawn daily, and physiological signs should be monitored

throughout withdrawal (Ewig, 1966). The daily intake is reduced over a 1- to 3-week period. Librium or Valium may be given temporarily to control agitation, tremor, and insomnia. Supportive restoration of electrolyte balance, vitamins, and intravenous fluids are in order (see Chapter 58 on Emergencies). Hospital admission and proper nursing care are mandatory. Physical dependence on minor tranquilizers (Miltown, Librium, Valium) will also be followed by abstinence symptoms, convulsions, and occasionally even death if withdrawal is abrupt, and emergency measures as for barbiturate overdose should be employed. Continuing aftercare, as with narcotic addiction, will be necessary. Caution in prescribing tranquilizers and sedative drugs with dependence-producing properties is essential in "dependence-prone" persons (Bakewell and Wikler, 1966).

Methaqualone (Quaalude) has had some use in recent years as an agent to counteract insomnia, but it has been abused, especially by young people who take one or two pills, sometimes with wine, to produce relaxation and euphoria. It has a reputation for being an aphrodisiac. Depersonalization and various physical symptoms are common adverse effects. Convulsions, delirium, and death may occur with overdose. Other nonbarbiturates that may be overused are glutethimide (Doriden), ethinamate (Valmid), ethchlorvynol (Placidyl), and methprylon (Noludar). Emergency treatment for overdose is similar to that for barbiturate intoxication. While benzodiazepines (Valium, Librium, Xanax, etc.) are much safer than sedative-hypnotics, addiction can occur when they are taken over an extended period. After a month or so, even therapeutic doses may produce a tolerance. Since withdrawal symptoms are apt to occur, a gradual slow reduction of the medication is necessary. If large doses of benzodiazepines have been taken and withdrawal was abrupt, convulsions are possible and Dilantin (hydantoin) is indicated.

Amphetamine or Similarly Acting Sympathomimetic Abuse (DSM-III-R Code 304.40) and Dependence (DSM-III-R Code 305.70)

Addiction to *amphetamine* and similar-acting sympathomimetic stimulants has been growing in this country. It is used by students to prod them into greater alertness, by pleasure seekers in search of "kicks," and by those who habitually try to suppress their appetites to control overweight. Such addiction results in serious physical effects, the

disorganization of the personality, and can even precipitate outright paranoid psychoses (Lemere, 1966) that resemble paranoid schizophrenia. Other symptoms are impaired judgment, aggressive behavior, and lack of coordination. Tolerance to the drug causes the abuser to increase the dosage for a euphoric effect, sometimes to 20 times the original dose. The intake of large amounts of amphetamine may cause a delirium. Attempts at withdrawal produce a letdown or "crash," with depression, physical symptoms, and aggressive behavior that usually send the addict out for a "fix." Amphetamines have been implicated in increasing numbers of automobile accidents and crimes of violence (Medical Society of the County of New York, 1966). Treatment of the individual who takes only 2 or 3 tablets a day requires quick withdrawal and administration of ammonium chloride to bring the pH to the acid side. Though withdrawal is not as urgent in these cases as in persons who take large amounts, there is always the danger that the intake will be increased. Mandatory withdrawal for persons who consume large quantities of amphetamine substances should be carried out in a hospital. The drug is removed abruptly, and the withdrawal effects are treated with intramuscular neuroleptics such as Haldol and, if necessary, barbiturates at night. These are especially indicated if amphetamine-barbiturate mixtures have been used (Connell, 1966). Depression may need to be treated with antidepressant medication such as tricyclics. Aftercare is as important as it is for narcotic addiction, and psychotherapy may be an essential part of the rehabilitative program.

Cannabis Abuse (DSM-III-R Code 305.20) and Cannabis Dependence (DSM-III-R Code 304.30)

Marijuana (cannabis) continues to be a popular substance, especially among students in school and young people in middle-and upper-income groups. The drug is neither as innocuous as is claimed by its friends nor as destructive as contended by its foes. It is a hallucinogen with varying potentials for toxicity depending on the host and the conditions under which it is taken. Generally, marijuana ("joints," "dope," "pot") is smoked experimentally on only random occasions and the hallucinogenic ingredient is in too low a dose to create any real difficulties. Some authorities say that harmful physical and psychological effects of prolonged marijuana use have not been consistently demonstrated

and are minimal compared with the ravages of alcohol intake. Emotionally disturbed persons will, however, continue to indulge in concentrated efforts to experience euphoria by using the most potent substances such as hashish and purified THC, which can cause greater mischief, including depersonalization, paranoidal ideas, anxiety, depression, tachycardia, and apathy. The abuse potential of marijuana is high. There is, nevertheless, no evidence that the use of marijuana is associated with crimes in the United States (Medical Society of the County of New York, 1966). Nor is there evidence that the drug is a narcotic or that it is truly addicting. Yet, in its usual form, it *is* a mild hallucinogen and may, in some susceptible persons, promote panic and aggressive behavior. Moreover, the impaired judgment under the influence of the drug interferes with skilled activities such as driving. Some people with severely disturbed personality problems may proceed from marijuana intake to a heroin habit, although the exact correlation between marijuana and subsequent heroin addiction has not been established. Pressure to legalize marijuana understandably has brought forth heated debate and controversy. Arguments pro and con related to the harmlessness of marijuana do not suffer from a dearth of misinformation. Research has had little effect on bias and the polarization of opinions.

Phencyclidine (PCP) or Similarly Acting Arycyclohexylamine Abuse (DSM-III-R Code 305.90) and Dependence (DSM-III-R Code 304.50)

Phencyclidine (PCP, "angel dust," "crystal," "Peace Pill") and similar substances such as ketamine (Ketalar) and TCP may be taken orally and intravenously, as well as by smoking and inhalation (Cohen, 1977). Effects are rapid and consist of euphoria, grandiosity, hallucinations of color and sound, and slowing of the time sense. Agitation, vomiting, anxiety, nystagmus, elevated blood pressure, ataxia, muscular twitchings or rigidity, anaesthesia, paranoidal ideas, and other symptoms may follow. Delirium can occur with large doses (20 mg or more). Hospitalization and administration of antipsychotics such as haloperidol (Haldol) may be helpful as an emergency measure.

Indulgence of other hallucinogens has been increasingly reported. The use of dimethyltryptamine, psilocybin, bufotenine, peyote, mescaline, charas, morning glory seeds, and nutmeg sometimes produces variant problems, and glue sniffing among

youngsters of school age can become disturbing (Jacobziner, 1963). LSD, which was popular in the past, was obtained from amateur chemists or from organized criminal groups. Usually 100 to 600 micrograms were ingested by individuals on a sugar cube for the purpose of "taking a trip," which was embarked on once or twice a week. Large doses (more than 700 micrograms) were ingested to produce more intense psychotic experiences. Psychotic episodes persisted for days or weeks and, in schizoid personalities, for months or even years, requiring hospitalization. The use of these hallucinogens has diminished in favor of such drugs as cocaine.

Nicotine Dependence (DSM-III-R Code 305.10)

According to the World Health Organization approximately one million persons die of cigarette-related diseases each year the world over and approximately one-third this number (350,000) in the United States alone. This is not because of misuse or abuse of cigarettes since "no safe use for this product exists; every cigarette smoked is intrinsically harmful to health. . . . even when used normally and as intended" (JAMA, 1986). The National Institute on Drug Abuse has warned that nicotine in tobacco is "a powerful addictive drug. . . . six to eight times more addictive than alcohol." In the United States, medical care and cost productivity associated with cigarette smoking total approximately $65 billion per year.

Promotional advertising linking cigarettes to a healthy and athletic life style nevertheless continue in force. To a large extent, adolescents and children fail to comprehend the dangers of the habit, which they continue as adults. Billions of dollars of profit pour into the coffers of the cigarette companies annually. In the meantime the ravages of cigarette smoking promote heart disease, emphysema, cancer of the lung, cancer of the upper respiratory tract, as well as other debilitating and fatal diseases. These are amply detailed in medical journals, although most of the cigarette-smoking public overlook or minimize medical warnings. But some request help.

Cure of the smoking habit is a difficult task, especially if smoking serves the purpose of alleviating tension. Educational campaigns, psychotherapy, and pharmacological aids

have all yielded limited success (Ford & Ederer, 1965). Mark Twain's comment, "It's easy to quit smoking; I've done it hundreds of times," is tragically the experience of most inveterate smokers who try to force themselves to give up tobacco. Group therapy with smokers, anesthetic lozenges, astringent mouth washes, anticholinergic drugs, vitamins, tranquilizers, stimulants, sensory deprivation, systematic desensitization, aversive conditioning, stimulus control, and lobeline as a nicotine replacement may produce temporary withdrawal from tobacco, but the relapse rate is high—75 to 80 percent. The entire process of smoking becomes for the inveterate user of tobacco an adjustment mechanism serving to satisfy specific needs: appeasing and reducing tension, providing a facade of nonchalance and poise, controlling anger, overcoming embarrassment in upsetting interpersonal situations, providing mouth and oral gratifications, acting as a substitute for overeating. Giving up smoking leaves a hollow in the life of the tobacco addict, mobilizes tension, and deprives the addict of a powerful adaptational tool.

In many cases smokers will openly or indirectly reveal that they are convinced that they will be unable to stop. In one case I was consulted by a professional man with Berger's disease, an illness in which smoking is dangerous. When he was admitted to a hospital for the beginning of gangrene of a toe, he had strapped cigarettes across his back to conceal them from the nurses and attendants, knowing that they would remove any cigarettes on his doctor's orders!

The "I can't" resistance ("I don't have what it takes," "My life is too unsettled now," "I'm not strong enough," etc.) is a means of reducing anxiety stemming from the conflicting desires of wanting to smoke and wanting to maintain one's defensive gratifying prop (Clark R, 1974). The defeatist belief is a way of denying this conflict. In applying for help, there is a forlorn hope that someone other than the patient can control his or her smoking. The resistance if unresolved will defeat any applied therapeutic efforts. The fact that smoking continues in spite of treatment convinces the individual that he or she is hopeless and provides an excuse for continued smoking. The idea that the smoker has exposed himself or herself to therapy appeases the guilt. "I know it's bad for me, but I don't care, it doesn't matter, I'm not going to think about it." In working with any smoker,

therefore, this resistance should be tackled at first. The therapist should verbalize the nature of the resistance and explain its purpose. Smokers should be encouraged to stop pretending that they are doing all they can to overcome the habit. At the same time the therapist should express confidence that they *can* quit smoking if they want to and work toward kindling the patients' faith in themselves.

It is important in treating individuals who want to give up smoking to keep in mind that immediate abstinence is possible with many techniques. As with any other addiction, resumption of the habit will usually follow within the first year unless the needs that led to smoking originally are adequately fulfilled.

The first step in smoking control is to ask the patient why he or she feels he or she should give up tobacco at this time. The patient will probably have been warned by a physician to stop the habit because it is a health risk. Such warning usually has fallen on deaf ears. The habit is compelling and insidious. The patient may be told that he or she, like many others, can succeed by recognizing the *positive* value of abstinence. Some therapists give the patient a typewritten form that says something along the following lines:

Overcoming the tobacco habit may be achieved with a minimal amount of suffering if you follow these principles:

> 1. First, prepare a written or typewritten list of the *benefits* you will gain in giving up tobacco, such as that your health will improve, and that you will feel more vigorous, look better, lose the offensive tobacco odor, save money, and respect yourself more for abandoning a self-destructive habit.

> 2. Choose a time to quit when you are under the least stress or tension. *Then quit completely.* Shred or destroy every cigarette or cigar in your possession. Give away your lighter and ashtrays.

> 3. Discomfort during the next few days is to be expected but will disappear within 2 weeks. Such discomfort may be minimized by (a) reading the list you have prepared once in the morning when you get up and at bedtime and more often if you desire; (b) practicing relaxing exercises at least twice

daily (meditation, self-relaxation, self-hypnosis, listening to a relaxing audiotape); (c) oral substitutes like Nicorette gum or smoke-free cigarettes (Favor) *if you need it* to stop physical reactions. Keep sugarless candies, carrot sticks, and menthol-filled plastic fake cigarettes on hand to take to work or use at social functions; (d) tell your friends that you are quitting smoking for health reasons and ask them, please, if they can, not to smoke in your presence for the next few weeks; (e) during the first 24 hours of abstinence expect to feel some muscle cramps, fatigue, headaches, or nausea as nicotine disappears from your body. Expect periodic cravings for a cigarette. Push your mind away from the thought and busy yourself with some activity; take a long walk, write letters, or do other activities; (f) spend as much time as you can in smokeless surroundings such as libraries and theaters; (g) cultivate a hobby (golf, swimming, tennis, bridge).

4. Your eating habits may need to be changed because in giving up tobacco you are apt to crave sweets and more food. Drink 6 to 8 glasses of water daily; keep water, some fruit juice, or a diet soda near you while watching television and sip it to appease your appetite. Avoid spicy foods, and minimize the intake of alcohol and coffee, which can stimulate a desire for tobacco and increase your appetite. Do not despair if you gain a few pounds; you will lose weight after the craving for cigarettes disappears.

5. In about 2 weeks you will have conquered a good deal of the tobacco desire, but the rest of your life fight off the impulse to take even one puff. When nicotine has completely left your body, the joy and vigor you will feel will more than compensate for the loss of this dangerous habit.

In many cases, these simple suggestions may suffice. If they do not, more extensive measures may be needed. Among the chief methods for getting the smoker off tobacco are behavior modification, hypnosis, and group approaches.

Behavior modification methods are fashioned after the techniques used to overcome overweight and obesity. An investigation is launched into the history of the smoking habit, how many cigarettes are consumed daily and under what circumstances, when the frequency increases, what puffing on a cigarette does for the individual, what efforts have been made to stop in the past, and why the individual wants to give up smoking now. Behavior modification techniques are then devised to replace reaching for a cigarette with

other activities, thus providing a nonsmoking routine for the patient (Bernstein & McAlister, 1976). Holding a sizable sum of money in escrow that is forfeited with the taking of even one puff of a cigarette within 6 months may be effective beyond any other technique.

Therapists acquainted with the hypnotic technique will find hypnosis a useful adjunct. Many ways of employing hypnosis have been described, with varying claims of success (Crasilneck & Hall, 1968; von Dedenroth, 1968; Spiegel H, 1970; Watkins H, 1976). In my own experience I have found that hypnosis can help eliminate sources of tension, especially after the smoking habit has been broken. The initial visits should, if possible, be frequent. Suggestions are made in the trance to the effect that the patient will develop a *desire* to stop smoking and that he or she will grow so strong that neither temptation nor tension, no matter how intense, will deviate him or her from the resolve to give up tobacco. This achievement will be rewarded by a feeling of well-being and strength that will be greater with each day of continued abstinence. It is strongly suggested that the patient will, in relinquishing smoking, be able to control his or her appetite so as not to overeat. Dictated tape recordings, made by the therapist, which the patient plays at home twice daily (see section on Induction of Hypnosis) often help to reinforce suggestions and to reduce tension. They are especially useful if the patient cannot come for frequent reinforcing sessions. Self-hypnosis, facilitated by the recording, will also prove to be of value.

Should the patient inquire about other oral gratifications, such as gum chewing or allowing a hard piece of candy to dissolve in the mouth, "permission" for this may be given if it is not overindulged. Some patients who have a need to defy authority will, rather than return to smoking, engage in these harmless oral activities beyond what they believe is permitted. In this way the tobacco habit may become more readily extinguished. The gum chewing and candy indulgence are gradually given up on their own. Because nicotine addiction drives smokers back into the habit, nicotine in a flavored chewing gum (Nicorette) is sometimes prescribed to ease the physical craving for nicotine. The gum may be helpful during the first few weeks of quitting smoking (Russell et al, 1982). Other

common methods that may be used to get individuals off cigarettes (Schwartz I, 1977) are rapid concentrated smoking inhalation and group approaches (supportive and behavioral). The latter prove especially valuable when behavior modification and self-control methods are combined. Powell and Arnold (1982) have described a multiple-treatment design for coronary-prone men that achieved a 50 percent smoking cessation rate at the end of one year, which is about double the usual reported rate of abstinence. Their "Stop Smoking Program" consisted of four consecutive 1½ hour sessions, Monday through Thursday, composed of highly structured activities along the following lines:

1. Stimulus control (altering the antecedents leading to smoking);

2. Relaxation training (deep breathing with pleasant imagery);

3. Thought stopping to eliminate thoughts about reaching for a cigarette;

4. Eating management (avoiding food and eating situations that stimulate a desire to smoke);

5. Substituting props (such as sugar-free candy);

6. Rehearsal of suitable nonsmoking behaviors;

7. "Cognitive coping" to associate positive thoughts with quitting smoking.

In addition, mild aversive stimulation (pairing smoking with pain stimulation to reduce the appeal of tobacco) was employed in some cases. Three once-weekly meetings were held after the formal 4-day program. A manual containing persuasive "pep" talks was supplied, and a counselor telephoned the patient to inquire about progress and to encourage maintenance of abstinence. At the start of therapy, return of part of the patient's fee is promised (contingency contracting) if abstinence is maintained after three to six months, thus providing further motivation to stop the habit.

Smoking cessation programs have been prepared by the American Cancer Society (1971) and by Dananer and Lichtenstein (1978). An innovative behavior modification program, "Quit-by-Mail," using a home computer has been devised by Schneider (1984).

Participants mail out weekly correspondence detailing their progress and problems, and their questions are addressed in pointed computerized responses. It has shown some promise.

Regardless of the methods employed to produce abstinence, many patients need continuing help to deal with the stress and other factors that promote a craving for cigarettes. The nature of such help will have to be designed for specific problems: environmental factors through environmental manipulation, marital difficulties through marital therapy, family problems through family therapy, faulty attitudes through cognitive therapy, and so on. The continued use of self-relaxation techniques, indulgence in interesting diversions and absorbing hobbies, and graded regular physical exercise are valuable. Should excess tension develop as a result of unusual stress, a minor tranquilizer (Valium, Librium) prescribed for only a short period may be required to ease a patient through the crisis. Patients' feelings of well-being in ridding themselves of the tobacco habit, their enhanced physical stamina as a result of eliminating nicotine from their bodies, and the approval they sense from their therapist and friends for their "courage" will, one hopes, suffice in maintaining abstinence. If smoking persists, more extensive therapy will be needed.

A "nonsmoking kit" of pamphlets written for children, adolescents, and parents m^y be obtained at a small cost from the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C., 20402.

Summary of Treatment Approaches in Substance Abuse

The treatment of substance abuse is a difficult task as attested to by the worldwide pessimism about the prognosis for this disorder. Dropouts from therapy are more the rule than the exception, and noncompliance with therapeutic routines tax the patience of the most empathic therapist. The therapist has to be more active in approaching substance abusers than is customary, especially at the start of treatment. In an attempt to deal with resistance, the therapist should call when the patient misses a session. Continued noncompliance with routines that have been set up and failure to execute homework

assignments may require more aggressive tactics (Marlatt & Gordon, 1985). The maintenance of discipline, so important in acquiring essential nondrinking and nondrug-taking skills, requires that therapists refuse to be lied to or manipulated, since these merely reinforce the patient's self-destructive patterns. The patient does not, however, have the substitutive skills to deal with stress at the beginning of therapy, so the therapist will have to tolerate an occasional relapse at the start. Such relapse provides an opportunity to review what has produced it. The manner of its management by the therapist can be important in consolidating the therapeutic relationship.

Treatment outcomes in substance abuse are dependent on the severity of the psychopathology (McLellan et al, 1983; Woody et al, 1984; Woody et al, 1986). Supportive therapy and drug counseling may suffice for patients who are not too psychiatrically disturbed. Those with a moderate degree of pathology may be helped, often substantially, by additional psychotherapy. But severely psychiatrically handicapped individuals will show a poor outcome whatever the intervention.

A growing problem in the treatment of substance abuse is that more and more people are increasingly using combinations of substances for purposes of recreation, relaxation, control of disturbing psychological and physical symptoms, and the ever-constant search for euphoria ("pharmacodynamic elation"). A recent estimate placed the figure of polydrug use at 84 percent of all substance abusers. The choice of alcohol, tranquilizers, sleeping pills, marijuana, cocaine, amphetamines, opioids, and other substances makes for mixtures whose effects are unpredictable and that pose many health hazards. Detoxification programs will have to deal with the fact that polydrug use can lead to dangerous withdrawal reactions. For this reason, detoxification, which is basic to the start of any organized treatment program, should be done in a hospital or residential center that has adequate facilities. The incidence of withdrawal and abstinence reactions makes mandatory the use of staff members in these units who are experienced in emergency treatments, and the management of problems specific to the substances that are being abused.

Temporary administration of substitute narcotics such as methadone in the opioid addiction, and small doses of barbiturates in barbiturate abuse, can prevent convulsions and other dangerous physical reactions. Thereafter, phased slow withdrawal, while monitoring physiological responses, is mandatory. The use of oxygen, neuroleptics, and, if they exist, specific drug antagonists (e.g., naltraxone in opioid addiction) can also be better controlled in an institutional setting. Most important, abused substances must not be made secretly accessible in institutional surroundings.

Once the patient is detoxified, the next step is to keep him or her off alcohol and drugs. Here, psychosocial treatments are instituted. The largest handicap in using such therapies is lack of cooperation. Most addicts or alcoholics are brought to a psychotherapist by frantic parents, spouses, or friends. The patients, despite verbal declarations, are not fully committed to staying off drugs, or, if they have "hit bottom" and suffered the after affects of a "binge," their commitment soon vanishes when they recover. If the therapist can establish a relationship with the patient, confrontation may be possible and some motivation stimulated. Despite considerable skepticism, it has been shown that *properly* conducted treatment for alcohol and drug abuse can be effective along a wide range of parameters, including, in overcoming the habit, finding employment, reducing criminal behavior, and enhancing psychological functioning (McLellan et al, 1982).

In formulating a proper treatment plan, the therapist should be aware of a number of essential factors:

1. The patient's enthusiasm for therapy, however, sincere, may be short-lived, giving way sooner or later to what seem to be self-destructive impulses. Extreme physical dependence is inescapable with habitual use of opiates, barbiturates, and alcohol. There is some physical dependence and considerable psychological dependence with the long-term use of amphetamines. Psychological dependence is present with marijuana, tobacco, and hallucinogens, but only moderate physical dependence unless dosage has been high. Great tolerance is soon established with opiates, amphetamines, and hallucinogens; somewhat lesser tolerance with the barbiturates, alcohol, and tobacco.

2. The addict is convinced that drug indulgence, better than anything else, enables

him or her to overcome despair, dissatisfaction, depression, and anxiety.

3. Drug abstinence achieved outside of an addict's habitual environment may not last long after the addict returns to his or her customary surroundings.

4. Since single addictions are rare, removal of one substance does not lessen the craving for others. Indeed, it may provoke the addict to try new experiments with other potentially exciting or calming materials.

5. Detoxification and "cure" of the desire for drugs has little effect on underlying pathological personality problems, only one manifestation of which is the thrust toward drug intake. Other manifestations will require psychosocial interventions. These may yield meager results, and prolonged care (1-2 years) in a therapeutic community like Synanon and Phoenix House may be needed to achieve a social adjustment.

6. A support group (Alcoholics Anonymous, Narcotics Anonymous, Cocaine Anonymous) of some kind will be necessary, sometimes for the remainder of the individual's life, as a source of reassurance, education, and companionship and as a "port in the storm" when troubles at home or at work brew or the inevitable cravings for a "fix" or drink return. The best support groups are patterned around the precepts of groups that have proven valuable, such as Alcoholics Anonymous or Synanon, and are composed of peers with similar substance abuse problems. Preferably, some of the leaders have suffered from and conquered similar problems. A professional person should be available for supervision and consultation. Periodic urine and serum drug screens should be employed if possible to detect early defection from abstinence. The choice of a proper group cannot be overemphasized because bad leadership and the presence of too disturbed or offensive members can negate the positive benefits of group participation. In large cities, resources for finding good groups are usually ample. In smaller communities, groups in neighboring towns may need to be explored. The therapist may enlist the assistance of social agencies for this purpose. Other community reinforcement resources—social, athletic, and so on—may be available to provide leisure-time positive reinforcements. Caution is needed in their selection, however, since social (or heavier-than-social) drinking may be the norm in some of these groups. One cannot protect the patient from the presence of alcohol. It is everywhere, being consumed freely in and out of homes. The patient must be able to resist any goading and encouragement to "have a short one." Most patients learn to cope with

this pressure by restricting themselves to plain soda and lime or soft drinks.

7. Marital therapy and family therapy are usually conjunctively needed for marital and family problems, and stress factors in the environment will call for counseling and environmental manipulation.

8. Nondrug management of tension and stress are important because the use of any anxiolytics or hypnotic-sedatives after the first week following detoxification is contraindicated. Here, relaxing exercises, self-hypnosis, and meditation may be taught individually and in groups. Cognitive therapy should be employed to rectify faulty philosophies and attitudes. Proper physical exercise daily and instructions regarding diet to overcome and prevent nutritional deficiencies are necessary. Education in self-care may be needed if there is a pattern of habitual neglect.

9. Depression is one of the most common symptoms of substance abuse, and if it is intense may require antidepressants, such as amitriptyline (Elavil) or sinequan (Doxepin). Psychotic ideation and behavior may necessitate antipsychotic drugs such as haloperidol (Haldol), trifluoperazine (Stelazine), or thiothixene (Navane). Some alcoholics need Antabuse, and some opioid addicts off methadone do well with naltrexone (Trexan) to offset impulsive drug use.

10. Once abstinence is sustained by faithful attendance at a support group, and environmental stresses have been mediated through counseling, the therapist should consider whether individual psychotherapy would be valuable. Depth therapy, focused on unconscious conflict and the acquisition of insight into early conditionings, has failed notoriously with this class of patients. Some analysts believe that this is because substance abusers possess an arrested personality and are so handicapped by infantile omnipotence that they cannot make a proper transference to the therapist. Any transferences that do develop are bound to reflect distortions that developed in the original family that are now ego-syntonically indelible. Their revival will prove antitherapeutic. Treatment programs that have proven successful have taken into account the patient's disturbed character structure but have dealt with it in ways other than through insight. They have approached the need on the part of the patient to engage masochistically in unrewarding behaviors by reconditioning responses through a social learning paradigm. The model of treatment described below (12 to 15) can be adapted to both alcohol

and substance abuse (McGrady 1983, 1985; Miller WR et al, 1980; Miller PM, 1982).

11. Preaching the evils of drug and alcohol intake, and its effects on oneself or one's family, does not work. What the patient must achieve is the conviction that he or she can be happier over a longer period without the abused substances than with them. One hopes that through positive reinforcements the patient will acquire this conviction during the early stages of abstinence. Every satisfactory experience of social and vocational adjustment should be rewarded by praise or other reinforcer to encourage a better life style. Designed programs will vary because of differences in personal needs and environmental opportunities, as well as specific responses to reinforcers. What is universally important is a job, occupation, or diversion to engross the individual a good part of the day; boredom is a leading source of stress. If the patient is unemployed, involvement in a hobby (music, art work, occupational therapy, etc.) or organized work-adjustment or volunteer program may have to precede finding paid work. Some substance abusers, especially adolescents, turn with vigor to religion or esoteric philosophies (Zen, Yoga, etc.), which supply them with a meaning for existence that they have sought through spurious chemically induced "insights." This should not be discouraged unless it is overdone and counterproductive.

12. The actual treatment process starts with identification of the stimuli that initiate alcohol or drug intake. This necessitates consideration of all the disturbing factors in the patient's personal, marital, family, and social life. Elements that further reinforce or that punish the drinking or drug response in the present situation are examined. This intensive study of external and internal stimuli that inspire the taking of drugs or alcohol is done with the object of determining ways of modifying or eliminating these stimuli or of finding better modes of dealing with them, cognitively, emotionally, and behaviorally. The treatment interventions that will be used will depend on the resources available, the readiness of the patient to accept them, and the skill of the therapist in implementing them.

13. Vital to the success of any program is motivation to stop the bad habit of resorting to the abused substance. If the patient does not have adequate coping skills, the best resolve will go down the drain as soon as he or she experiences strong anxieties or stress. Further, depression may have been masked by alcohol or drug intake. Insidious also are the ubiquitous desires for pleasure, and need to escape from responsibilities in living

and from the pressures of inner conflicts. Because the patient minimizes the bad consequences of his or her habit and exaggerates his or her ability to control it, efforts toward abstinence may be minimal. The therapist may work on the patient's false assumptions through cognitive therapy, by providing reasons why the patient will be better off dealing with pressures and problems in more suitable ways. Some therapists hand the patient a list of the negative consequences of drinking that the patient has previously identified and ask the patient to read the list several times a day as homework. Training in self-relaxation techniques and a relaxing ego-building audio cassette tape may be valuable. Some patients will require assertiveness training over a period of many months.

14. The therapist must keep searching for stimuli that provoke the patient. Dealing with such mischief mongers directly is an important part of treatment. A prime source of stress here is a family member or spouse who nags, attacks, criticizes, and acts-out his or her problems through the medium of the patient. Counseling of the spouse on an individual or group basis may be important. Marital therapy or family therapy may be indicated, and self-help organizations such as Al-Anon should be sought out. Family members who have been battered by the patient's substance abuse may discover in these group settings better ways of dealing with the patient's difficulties.

Help in the acquisition of new stress-resolving skills and strategies is an important part of the therapy program. The patient is enjoined to search for "triggers" that initiate drinking or drug taking (e.g., an invitation to have a drink, fatigue, stressful events, receiving bad news, perceiving good news, engaging in "happy hour," etc.) and to explore nonalcoholic and nondrug responses to these triggers. The effects of a drink or other substances are then discussed in depth: talking too much, acting foolishly or brashly, guilt, self-disgust, feeling bad physically, a hangover, and so on. Instead of stopping the desire for drugs or drink, these aversive consequences may be shown to act as stressful triggers that initiate more substance abuse. So a chain reaction ties the patient into his or her destructive habit. One strategy to break the chain is to teach the patient to think *immediately* of the negative consequences the moment an impulse, invitation, or other trigger brings up the desire for a drug or drink. Some therapists ask the patient to prepare and carry around a card for each day of the week and to write down the cues that stimulate a desire for indulgence as well as what the patient did about it. Honesty in

recording is stressed, and if a slip occurs the exact amount of drug or drink that was taken must be written down.

Alternative ways of dealing with triggers are encouraged. Insofar as doing something about the environments that tempt the habit, two ways of management are possible. The first consists of reducing environmental temptation, such as avoiding parties where conviviality demands imbibing alcohol, marijuana, or cocaine for good cheer. The second way is deliberate exposure, necessitating in vivo desensitization practice in some situations. Actually, alcohol and recreational drug taking are so much a part of the subculture that one cannot avoid exposure. Patients are constantly confronted with temptation, and it is best to deal with such challenges while in therapy.

Even with all the skills, the therapist will need dedication and concern to deal with substance abusers. Some patients will fail to achieve complete abstinence. Recourse to alcohol and drugs may constitute a preferred way of life. There seems to be little one can do with these patients to stimulate the motivation essential for sobriety or drug abstinence. In these cases, the therapist can perhaps act as a good friend and counselor who is available when the patient needs help with a crisis, to arrange for detoxification if necessary, and to get the patient back to work and acceptable functioning. The therapist need not consider himself or herself a failure in such cases but instead recognize that for some patients neither God nor man can do more than the patient wills.

15. It may be possible with a certain number of patients who have been off abused substances for a while to approach underlying personality conflicts, being aware that such probings may produce untoward transference reactions that will serve as stress stimuli. There are, however, a few patients who have the curiosity and the residual ego strength needed to reach for reconstructive goals.

SEXUAL DISORDERS

A complex aggregate of physiological, psychological, and environmental factors enter into the sexual reaction. The capacity or incapacity for responsiveness to sexual needs and the distorted or perverted forms of their expression are largely products of past conditionings. Interfering emotions may relate to defects in early training and education (e.g., prohibition of masturbation), to transferential projections (e.g., incestuous feelings toward parental figures), to carryovers of later childhood experiences (e.g., fearsome and humiliating seductions), and to unsatisfactory adult human relationships (e.g., a hostile or nonresponsive partner). Resulting anger and fear are anathema to proper sexual functioning. These affects are not always clearly perceived by the individual suffering from sexual difficulties. Indeed, their existence may be completely denied, and even if the early initiating circumstances are remembered, the emotions relating to them may be shielded under a coat of non-feelingness. This anesthesia influences sexual behavior, distorting the perception of sexual stimuli or altering the manifestations of the sexual drive. Joining this conspiracy are defects in the self-image prompted by disturbances in personality development and by prolonged exposure to humiliating happenings.

The most common phenomena influencing sexual behavior are premature ejaculation and impotence in the male and non-orgasmic response, frigidity, dyspareunia, vaginismus, and conflicts about infertility in the female (Practitioners Conference, 1957; Kleegman, 1959; Geijerstam, 1960; Hastings DW, 1960; Mann EC, 1960; Nichols, 1961). The degree of failure of response may range from total disinterest in sex and inability to derive any sensation from autoerotic stimulation, to prurience under special circumstances (e.g., singular dreams, fantasies, and fetishes), to orgasmic response to

certain acts (e.g., rape, "bondage," humiliation, pain, or sadistic acting-out), to selective reaction to the embraces of a specific love object, to excited behavior with a variety of sexual objects, to constant preoccupation with sexuality (e.g., nymphomania and satyriasis). People are "turned on" by a host of stimuli that are unique to their personalities and early conditioning experiences. Objects and circumstances accompanying the first sexual arousal may be indelibly imprinted and may motivate actual or symbolic revival for sexual feeling thereafter. Later sexual expression may host consequences dependent on the significance of guilt-ridden experiences (e.g., relaxation and exhilaration or self-punitive mechanisms, like anxiety, migraine, and gastrointestinal symptoms). It is understandable that with the complex array of operative contingencies, a vast assortment of patterns will be displayed by different people and at different times prior to, during, and after the sexual act. The degree of orgasmic reaction will also vary individually, from mild release to violent, ecstatic excitement and even unconsciousness.

Sexual Dysfunctions (DSM-III-R Codes for Hypoactive Sexual Desire, 302.71; Sexual Aversion Disorder, 302.79; Female Sexual Arousal Disorder, 302.72; Male Erectile Disorder, 302.72; Inhibited Female Orgasm, 302.73; Inhibited Male Orgasm, 302.74; Premature Ejaculation, 302.75; Dyspareunia, 302.76; Vaginismus, 306.51)

A diagnostic assessment of any sexual problem is vital to determine what kind of treatment is necessary. It is important to determine which of four phases of sexual response is implicated. Is the disorder one of inhibited desire or inability to maintain excitement and genital tumescence, to control or achieve orgasm, or to achieve postorgasmic relaxation and well-being? (Kaplan & Moodie, 1984; Lief 1981). Distinguishing these phases of sexual response is important because different mechanisms and neural pathways are operative in each and different therapeutic interventions may be called for. For example, inhibited sexual desire may be the product of guilt about and repression of sexuality produced by over-moralistic promptings in childhood with consequent fantasies or needs for self-punishment, indulgence in rape or bondage fantasies, and sexual masochism as a condition for the release of sexual feeling. Conquest of these developmentally sexual inhibitions may inspire the individual to imagine or act-out violently and sometimes sadistically (sexual sadism) and to use

antisocial behavior as a way of subduing or symbolically destroying the conscience or projected guilt representations. Guilt feelings and masochistic self-punishment usually follow these releases but rarely eliminate them. Treatment when sought will require psychotherapy, preferably dynamically oriented, and behavioral approaches later should sexual functioning continue to fail. Inhibited sexual desire may also be associated with the release triggers that open the gates to sexual feeling, such as fetishism, transvestism, zoophilia, pedophilia, exhibitionism, and voyeurism, which must be approached psychotherapeutically, although prognosis for recovery in these ailments is guarded. Sexual desire can be deadened by ailments such as depression, as well as by antihypertensive, antidepressant, tranquilizing and other medications. These interferences require specific correction. Finally, one's relationship with a marital partner may be pathological (e.g., incestuous) or so seeped in ongoing hostility as to deaden all thoughts of sex. Here marital therapy and dynamic psychotherapy may be essential. Appropriate treatment for all these conditions requires accurate diagnosis. In the case of inhibited sexual excitement with frigidity and impotence, once organic (endo-crinopathics, diabetes, arteriosclerosis, etc.) and medical factors (antihypertensive and beta-adrenergic drugs, alcohol, tranquilizers, etc.) have been ruled out, behavioral sex therapy may be effective in itself, especially if the onset of the dysfunction has been recent or the causes minor. If personality difficulties exist or anxieties and phobias are strong, however, coordinate psychotherapy may be necessary. The same may be said for inhibited female and male orgasm, premature ejaculation, dyspareunia, and functional vaginismus. If postorgasmic relaxation and well-being are a concern, such treatment as cognitive therapy to alter meaning systems and dynamic psychotherapy to explore conflicts may be useful (Wasserman et al, 1980). If an antidepressant is found necessary for depression, bupropion (Wellbutron) has been found less associated with sexual dysfunction than other antidepressants.

Unfortunately, there has been a tendency on the part of some professionals to project their own experiences into their opinions of what constitutes "normal" sexuality instead of dealing with it as a broad spectrum of behavioral repertoires that cannot rigidly be circumscribed in terms of "healthy" and "pathological." Thus, there are writers who

insist that oral contacts are abnormal, that manual genital stimulation is immature, and that orgasm derived in any other way than through penetration of the penis in the vagina is aberrant if not perverse. These injunctions reinforce any prevailing misconceptions that a patient may be harboring and add to guilt feelings.

Brief sex therapy may be eminently successful in modifying or curing some milder sexual disturbances. In an inspired setting, away from everyday problems and pressures, a couple has the best opportunity for loosening up their inhibitions, relaxing their defenses, and under the prompting of new permissive authorities acquiring better habits of sexual response. Interpersonal hostilities are quietly subdued under these circumstances, and new and more constructive communicative patterns are set up. After therapy is terminated, the real test occurs. Can the improved functioning be sustained in the couple's habitual setting? There is always a possibility that reinstitution of customary pressures and responsibilities may restore tensions and break down the new communication patterns. It would, therefore, seem vital to continue to see the couple after the instruction period is over to help resolve developing problems.

The key to successful sexual therapy is the therapist. One's personality, one's casualness, one's flexibility, one's empathy, one's understanding, one's sense of humor, and one's capacity to communicate all influence the techniques. In many couples the strong defenses and resistances to the directives of the therapeutic authority are apt to create frustration and anger in the therapist. The therapist has to know how to deal with the patient's reactions in an easy-going way without taking offense. The therapist actually needs the skills of a good communicator. It is not possible to adopt a passive analytic stance with this type of treatment.

The short period of therapy can provide a biopsy of the prevailing pathology between the two people. If the pathology is not too severe, if healthy defenses are present, if reasonable flexibility of adaptation prevails, new sexual habits may be maintained. On the other hand, if the sexual difficulty is a reflection of a personality problem, there may still be some improvement sexually but the personality difficulties will have to be dealt

with by more intensive methods.

For example, an impotent single man comes to therapy harboring deep hostile feelings toward women, stemming from a high level of dependency that one may historically trace to his being overprotected by a dominant mother figure—by no means an uncommon condition in problems of impotency. The immediate precipitating factor for the impotency in our present patient, let us imagine, was sexual association with a dominant, demanding woman who somehow undermined his confidence in himself. Let us also hypothesize that, through behavior therapy and in relationship with a cooperative and non-dominant woman, the patient is restored to potency. Lacking recognition of his inner drives and needs, however, he may soon lose interest in what he would consider "uninteresting weak females" and seek out domineering women with whom he could act out his dependency and hostility. Without speculating too much, we would probably witness in a new relationship with a controlling woman a revival of his symptom. A thorough understanding of the problem, however, may help him not only to try to desensitize himself to domineering women, but also to manage more assertively their specific domineering traits. By seeing that he was projecting attitudes toward his mother into his contemporary relationships, he might better be able to deal with "strong" women. The evolvement of firmer controls may enable him to relate even to manipulating women without fear. Or, realizing his choice of women as a weakness he must overcome, he may decide to restrict his sexual contacts to more passive types, while handling his impulse to goad them into domineering roles.

A complicating factor in many patients is that the sexual function in the human being is often employed as a vehicle for the expression of varied strivings, interpersonal attitudes, and needs. Thus, sexual behavior may embrace, among other things, impulses to hurt or to be hurt, to humiliate or to be humiliated, and to display or to mutilate oneself.

When impotence results from vascular surgical procedures, an implant or a recently developed surgical procedure may be effective (Zorgniotti, 1987).

Paraphilias (DSM-III-R Codes for Exhibitionism, 302.40; Pedophilia, 302.20; Sexual

Masochism, 302.83; Sexual Sadism, 302.84; Transvestist Fetishism, 302.81; Voyeurism, 302.82)

Among the more serious and less prevalent sexual disorders are those that relate to gender identity and the paraphilias. An assorted group of problems are embraced under the term *transsexualism.* Here there is conflict about one's anatomic sex and a desire to exchange it for genitals of the opposite sex. Assumption of a role consonant with the desired sex identity are compelling, and occasionally submission to surgery to amputate the undesired sex organs is yielded to. The cross-dressing here is distinguished from transvestism in that in the latter there is no desire to rid oneself of one's genitals. The cross-dressing appears to act as a stimulus for sexual excitement, which in most cases is expressed heterosexually. A *gender disorder of childhood* is characterized by a repudiation of one's sexual identity and a frantic need to act like a member of the opposite sex. The little boy plays with dolls and desires to dress like a girl; the little girl engages in male activities and may deny not having a penis. In the paraphilias there is a compulsive need to utilize imagery or to engage in unusual acts in order to stimulate sexual desire, such as specific items of clothing *(fetishism)* or animals (*zoophilia*); to be humiliated, bound, and beaten (*sexual masochism)-,* to inflict pain or humiliation on the sexual object (*sexual sadism*); to exhibit one's genitals to strangers (*exhibitionism*); to spy upon and observe people in situations of undress or intercourse (*voyeurism*); and to engage in sex (usually mingled with aggression) with a child *(pedophilia).* Neurotic and personality disorders often coexist with these sexual distortions.

These conditions are among the most difficult of all syndromes to treat. Because of the intense pleasure values inherent in the exercise of the perversions and the fact that they fulfill deep needs other than sexual, the patient is usually reluctant to give them up. Although there may be a desire to overcome certain disagreeable symptoms, such as anxiety or tension, the motivation to abandon the coveted sexual expression may be lacking. Because of the lack of incentive, resistance often becomes so intense as to interfere with the therapeutic process.

There is, nevertheless, a growing conviction that sexual deviations are pathological

conditions that sometimes may be helped by psychotherapy. The specific approach to perversions will vary with the theoretical orientation of the therapist (Bieber I, 1962; Bychowski, 1961; Deutsch H, 1965; Fried, 1962, Lorand, 1956; Marmor, 1965; Nunberg, 1955; Ovesey, 1954, 1955a & b; Ovesey et al, 1963; Saul & Beck, 1961; Stark, 1963).

Some authorities speculate that a genetic defect complicated by conditionings in childhood makes certain preliminary fantasies or acts mandatory for sexual feeling and performance in adult life. The origin of many of these conditionings are forgotten, repudiated, and repressed, although the individual is mercilessly bound to special stimuli (fetishistic, masochistic, sadistic, etc.) to release his or her sexuality. In many instances the sexual disturbance reflects improper identity. If normal masculine identification is lacking (an overly possessive controlling mother, intimidation by an overwhelming father, passive indulgence by a weak father) tendencies toward effeminacy may develop in a male. Lack of a feminine and motherly mother who can act as a feminine model may divert a girl from female identification. Under these circumstances, the sexual direction may be altered.

Whether all forms of homosexuality should be classified as abnormal is a moot point about which there are differences in opinion among professionals. Under pressure of some groups, the trustees of the American Psychiatric Association (amidst considerable controversy) officially ruled that the term "homosexuality" be replaced in the Statistical Manual of Mental Disorders by the phrase "ego-syntonic homosexuality" to avoid the stigma of being classified as a disorder. Ego-dystonic homosexuality was a diagnosis applied only to those homosexuals who were in conflict with their sexuality. In justification of this move, we do find many homosexuals who are happy and adjusted, and some studies reveal that symptoms and behavioral disorders among this group are no more frequent than among heterosexuals.

Under these circumstances, it is argued, homosexuality might for some individuals be regarded as a manifestation of a preferred normal life style rather than as a distortion of sexuality. On the other hand, there are those who continue to accent the point that analysis of even so-called well-adjusted homosexuals indicates without question that they

have a developmental block in the evolution of the sexual drive. In appraising the pathological nature of homosexuality, we do have to consider the fact that many homosexuals suffer from the abuse and discrimination heaped on them by society, without which they would probably be able to make a better adjustment.

Homosexuals who apply for therapy are in a special category when they are ostensibly disturbed and upset about their sexual behavior. They may seek therapy for their symptoms, but they may not be motivated to change their sexual orientation. A therapist's forceful attempts to induce change under these circumstances will usually fail. If there are strong conflicts about homosexuality and a sustained and powerful desire for heterosexuality, dynamic psychotherapy or psychoanalysis may succeed in a certain number of cases (Bieber I, 1962) in changing their sexual orientation. Adolescents disturbed about homosexuality may well benefit from some brief counseling along the lines suggested by Gadpaille (1973), which may help lessen their identity problems.

Sometimes homosexual preoccupations in a conflicted individual become so uncontrollably compulsive as to cause the person to act out impulses in a destructive and dangerous manner. Masochistic and sadistic drives are usually operative here. The problem is that the person can easily jeopardize one's safety by becoming involved with psychopathic individuals or by getting into trouble with the law. Such a person may seek from psychotherapy not so much stoppage of homosexual activity as the opportunity to direct one's behavior into less dangerous channels.

Traditional psychotherapy, unfortunately, has had little to offer such applicants; neither insight nor appeals to common sense influence the driving determination to involve themselves in exciting trouble. A form of therapy still in the experimental state is aversive behavioral treatment. Some behavior therapists recommend that if patients are insistent on being forced to stop their behavior, and if sufficiently motivated, they may be able to endure exposure to a series of slides that are sexually stimulating to them but are rewarded with a painful electric shock through electrodes attached to the fingertips (Feldman & MacCulloch, 1965). In a technique evolved by McConaghy (1972) the male

patient selects 10 slides each of a nude adolescent and of young men and women to which he feels some sexual response. At each session three male slides are shown for 10 seconds. A 2-second shock is delivered during the last second of exposure, with the level of shock as unpleasant as the patient can stand. Following this, a slide of a woman is turned on for 20 seconds without accompanying shock. Variable intervals between 3 to 5 minutes pass between showing the three sets of male and female slides. Sessions are given three or more times the first week and are gradually reduced in frequency over the following few months. In female patients the shocks would be delivered with the slides of women, and no shocks would be delivered with the male slides. Again, unless the incentive to control one's homosexual activities is high, this treatment is doomed to failure.

The treatment of sexual perversions, such as sadism, masochism, voyeurism, and exhibitionism, must be organized around removing blocks to personality development in order to correct the immature strivings that are being expressed through the sexual perversion. Fears of adult genitality and of relating intimately and lovingly to persons of the opposite sex must be resolved before adequate sexual functioning is possible. The only rational approach is, therefore, reconstructive in nature. Lack of motivation may, however, inhibit the patient from entering into reconstructive treatment. Additionally, ego weakness and disintegrative tendencies are often present in sexual perversions and act as further blocks to deep therapy. For these reasons the therapeutic objective may have to be confined to the mere control of the perversion and to its possible sublimation. Behavior modification has been utilized here. The therapist may have to function as a supportive, guiding authority who helps the patient to lead a more restrained life.

In treating perversions, the therapist must be prepared for a long struggle. Resistances are, as has been mentioned, usually intense, and the patient will repeatedly relapse into the sexual deviation. The patient should not be blamed, reproved, or made to feel guilty for this. Rather, he or she must be helped to see the purposes served by the perversion and to appreciate why the need to express it becomes more overwhelming at some times than at others. While the ultimate outlook is not as favorable as in some other problems, there is no reason why patients who become motivated for, and who can

tolerate reconstructive therapy, cannot achieve satisfactory results.

SPEECH DISORDERS

(Developmental Articulation Disorder (DSM-III-R Code 315.39), Expressive Language Disorder (DSM-III-R Code 315.31), Receptive Language Disorder (DSM-III-R Code 315.31); Cluttering 307.00; Stuttering, 307.00)

Functional speech problems, which are sometimes arbitrarily called "stuttering" or "stammering," are the consequence of the lack of coordination of various parts of speech wherein the speech rhythm becomes inhibited or interrupted. Associated are vasomotor disturbances, spasm, and incoordination of muscle groups involving other parts of the body. The speech difficulty is initiated and exaggerated by certain social situations, so that the individual is capable of articulating better under some circumstances than others. This is confirmed by the fact that the person is usually able to sing and to talk without difficulty to himself or herself and to animals. Some authorities insist that since there is no actual pathology of the speech apparatus, it may be a grave misnomer to label stuttering a speech disorder. Rather it might be conceived of as a manifestation of total adaptive dysfunction.

Martin F. Schwartz (1974) of Temple University has presented evidence that stuttering is produced by an inappropriate vigorous tightening of the larynx (contraction of the posterior cricoarytenoid) triggered off by subglottal air pressures required for speech. Psychological stress reduces the action of the usual supramedullary inhibiting controls of the involved muscle. To correct this, the patient must place the larynx in an open and relaxed position, which helps keep the air pressure in the voice box low. One-way mirrors and videotape equipment are used to coach the patient. The therapy is still in the experimental stage but a "reasonable expectation of perhaps a 90 percent success rate with stutterers given the proper therapeutic implementation" may be expected within 2 or 3 months (Pellegrino, 1974). Should the therapy prove itself to be this successful, it will undoubtedly replace the traditional treatment methods.

The counseling of parents of a stuttering child is important in the total treatment plan. Generally, parents react with dismay, frustration, and guilt feelings in relation to

their child, many assuming that they are responsible for the problem. At the onset of counseling the parents should be told that we are still unsure of what produces a stuttering child and that worry about complicity in it is not as important as doing something about it. There are, however, things they can do that may help the problem. Constant emphasis on mistakes and subjecting the child to drilling helps aggravate the nonfluency by making the child more self-conscious and aware of his or her failings. The stuttering child requires a great deal of demonstrated love and affection, and the parents must be enjoined to go out of their way to give these. It is essential also that they encourage the child to express feelings openly no matter how badly the child enunciates these and that they control themselves if the child bumbles along in front of friends and relatives. This does not mean that proper discipline should not be imposed, even punitive measures for outrageous behavior, since discipline is an important learning tool for healthy growth. There is in some families a tendency to infantalize and to overprotect a stuttering child. This must be avoided, and the child should be expected to manage whatever responsibilities one of his or her age must assume. The role of the father is important in providing proper guidance and companionship. Since tension in the home contributes to the child's disturbance, it may be necessary to institute marital therapy or family therapy before appreciable improvement can be expected.

Therapy with a child therapist, particularly one experienced in speech difficulties, may have to be prescribed for the manifestly disturbed child or one who has been undermined by the speech problem. These children are exposed to ridicule, teasing, and social ostracism by their classmates. They shy away from talking and presentations in class, resulting in an undermining of self-esteem.

The usual treatment of adult stuttering proceeds on two different levels: correction of the improper speech habit and the handling of the deeper emotional problem that originally initiated and now sustains the difficulty. A guidance approach and social skills training are used toward achieving the first objective (Brady, 1984).

The second goal is obtained through a persuasive, reeducative and, where possible,

reconstructive approach. Therapy involves correcting patent difficulties in the environment that stir up the person's insecurity, and dealing with disturbing inner conflicts. Since the character disturbance in stutterers is usually extensive, therapy is bound to be difficult, prolonged, and, in many cases, unsuccessful insofar as alteration of the underlying personality disorder is concerned. The most that can be done for many stutterers is symptomatic relief in the form of speech correction.

Speech training may do as much harm as good. It is valuable only as a means of building up confidence in the individual's powers to articulate. Unfortunately, it may psychologically have the opposite effect since it overemphasizes will power and control and concentrates the stutterer's attention on the mechanics of speech rather than on what is being said. Instead of becoming less conscious about the speech difficulty, the person becomes more involved with it, thus intensifying the problem. This is not to say that proper exercises in diaphragmatic breathing, phonetics, and articulation are of no value in certain patients. Sometimes, with these methods, a symptomatic recovery may take place in mild cases. In severe cases, however, they are relatively ineffectual, and, especially if the person makes a voluntary effort to stop stuttering, the severity of the speech problem may increase. Rhythmics and eukinetics are sometimes helpful. Training methods, when used, should be employed by a therapist experienced in speech techniques.

In supportive approaches with stuttering adults certain evasions and defenses are sometimes taught to tide the stutterer over situations in which he or she must talk. Drawling, speaking in a rhythmic manner or in a sing-song tone, utilizing distracting sounds like "ah" or a sigh prior to articulation, employing a gesture or engaging in some motor act like pacing or rubbing a watch chain, purposeful pauses, and a variety of other tricks are used. These are entirely palliative and must be considered escapes rather than therapeutic devices.

A persuasive approach is sometimes helpful. The first step in therapy consists of convincing the patient that because of disappointing experiences, he or she has come to overemphasize the speech function. To the stutterer it constitutes an insignia of

aggrandizement and defamation. Self-esteem has become linked with the performance of speech. Because of this the stutterer concentrates attention on the manner of talking more than the content of what is being said. While the speech problem is understandably disturbing, it is probably not regarded with the same emphasis by others. People suffering from stuttering overcome it more easily when they stop running away from acknowledging it. The best tactic is to face the situation and even admit it. As soon as this is done the person will be more at ease and the speech will improve.

A talk such as the following may be indicated:

> *Th.* There is nothing disgraceful about stuttering. Avoiding social situations because of fear of ridicule merely serves to exaggerate the sense of defeat. It is necessary to regard stuttering in the same light as any other physical problem. If you stop being ashamed of it, and do not concern yourself with embarrassing others, people will notice your speech less and less. As you become more unconcerned about *how* you talk, you will concentrate on *what* you say. Keep concentrating on what you say, and pay no attention to how it sounds. Fear and embarrassment exaggerate your speech difficulty, so make yourself act calm and you will feel calm, and your speech will improve.

The next stage of therapy draws on some reeducative techniques and consists of demonstrating to the patient how he or she becomes upset and loses the sense of calmness in some situations. There will be no lack of material since the patient will bring to the therapist's attention many instances in which his or her stuttering becomes exaggerated. Examining the patient's emotional reactions to these situations as well as his or her fantasies give the therapist clues as to the dynamic elements involved in the patient's speech disorder. These may be pointed out to the patient in terms that conform with his or her existing capacities for understanding. The aim is to show the patient that the speech difficulty appears when he or she loses the capacity to remain relaxed and when, for any reason whatsoever, emotional instability develops.

In some cases it will be advisable to refer the patient to a good speech therapist. The therapeutic approach that appears most successful comes from the work of Van Riper (1971), and Wendell Johnson (1946). This aims at the elimination of anxieties about stuttering, which is considered a learned reaction to conscious fears of speech or fluency failure. Patients are enjoined to adopt an "objective attitude" by facing the fact squarely

and, instead of avoiding displaying their stuttering, talking about the speech handicap to others, deliberately meeting all fearful and difficult speaking situations, and articulating in the best way they can, utilizing, if necessary, the evasions, defenses, and tricks that are so often employed by stutterers. Exposure to various speaking challenges while maintaining as objective an attitude as possible is also advised.

Specifically, patients are taught to open up, in as casual and objective and even humorous a way as possible, the speech problem with others, even if the listeners do not know that they have a speech problem. Clearing the atmosphere in this way will put both the listeners and themselves at ease. They are asked to observe how others falter and make mistakes in speaking and by this to realize that normal fluency is imperfect and quite variable. They are requested to observe how certain listeners react to what they say and to check their observation with those of others present. In this way they will discover that they project their personal fears and prejudices onto other people. Most important they are requested to give up running away from fearsome words that cause stuttering and to utter them deliberately, particularly in situations in which they have stumbled over them while remaining emotionally detached and not caring how the listener reacts. Role playing may be used here to prepare the patients for such stints. They are requested to discuss their experiences with the therapist at the next session. The patient is reminded to try to cultivate a calm, unemotional tone of voice. They may practice this with a friend or with members of the family. One-half hour each day is devoted to reading aloud from a book, jotting down those words that are difficult to pronounce. They may then practice enunciating words several times during the day. Some persons find it helpful to talk for a short time daily in front of a mirror, watching their facial movements as they utter sounds. Along with these reconditioning techniques, environmental therapy may be used, geared toward an expansion of the assets of the individuals and a remedying of liabilities in themselves and their situations.

If these techniques do not yield desired results, patients may be taught ways of postponing word attempts, of starting difficult words or of releasing themselves from blockages. They may also be taught a substitutive stuttering pattern, deliberately

prolonging or repeating themselves in an unhurried, tenseless way. For instance, Van Riper's cancellation technique enjoins stutterers to pause immediately after they experience a stuttering block and to ask themselves what they did (pressed their lips together? pushed the tongue against the roof of their mouth? felt panic? diverted their gaze from the listener?). They are then to cancel their failure by "stuttering" on the same word deliberately in a new way with prolonged relaxation, maintaining eye contact with the listener. This starts a reconditioning process so that the stutterers may begin to change their behavior during the fist attempt and then to manipulate preparatory sets prior to the attempt "to facilitate the production of a 'fluent' pattern of stuttering" (Bloodstein, 1966; Van Riper, 1971).

Three important adjuncts in speech therapy are behavior therapy, self-hypnosis, and group therapy. Assertiveness training may be extremely important. Other behavioral approaches can be quite valuable (Brady, 1968) particularly utilizing a metronome. In metronome-conditioned speech retraining (MCSR) a miniaturized electronic metronome is worn behind the ear like a metronome (Brady, 1971, 1972). This may be especially helpful when patients are confronted with a speaking engagement. The metronome allows the speaker to pace the speech. Prior to the use of the ear metronome, the therapist may expose the patients to an ordinary desk metronome, such as used in piano practice. At first as few as 40 beats per minute may have to be used, the patient pronouncing one syllable for each beat. As soon as the patients are fluent in pronouncing several syllables at this speed, the rate is gradually increased to 90 to 100 per minute. A metronome should be procured for practice at home, at first alone, then when feeling confident, with a friend or parent in the room; then with more than one person present. Pauses are introduced to some beats and then more than one word to each beat. What can be helpful is practicing while fantasizing progressively more anxiety-provoking scenes. When reaching a satisfactory fluency, the patients practice with the miniature metronome and then utilize the fluency outside the home, at first in low-stress situations and then in high-stress situations. Should difficulty be experienced under some conditions, they may reduce the speed of the metronome and speak more slowly. Gradually, as the patients gain confidence, they may practice speaking without turning on the metronome, first in low

then higher stress situations.

Another method is to listen to a transistor radio, using earphones while talking to a cassette tape recorder. The radio is played so loudly that one's voice is not heard. At first this is done after practicing relaxation. Then situations of increasing anxiety are imagined. The patient articulates feelings and thoughts at the same time and particularly pronounces his or her name and the words over with which difficulties have been experienced. As the stutterer gains confidence in speaking, he or she may turn the radio off while speaking, turning it back on should nonfluency return.

Persuasive autosuggestions in a self-induced trance reinforce the patient's desires for self-confidence and assertiveness. Group therapy in which the patient comes into contact with other persons suffering from speech problems removes the sense of isolation. The fact that companions experience the same trepidations as the patient does help the patient reevaluate his or her reaction. An opportunity is provided to speak and to recite in a permissive setting. The identification with the group, along with the growing confidence in the ability to speak fluently, may have a most positive .effect on speech performance.

As the patient begins to experience improvement in his or her interpersonal relationships, the speech problem will plague the patient less and less. Utilizing the speech group as a bridge, one may be able to integrate with other groups and to consider oneself on an equal plane with its constituent members. In some cases reconstructive therapy may be possible to deal correctively with the personality disorder (Barbara, 1954, 1957, 1958, 1963). This, however, is associated with many vicissitudes as Glauber (1952) has pointed out.

In situations of strong anxiety, such as speaking before a group, some therapists advise taking 40 mg of Inderal shortly before the assignment, which will cut down on the anxiety without impairing cognition.

SLEEP DISORDERS (DYSSOMIAS)

Among the sleep disorders are the *Dyssomias,* which include primary insomnia, hypersomnias, and sleep-wake schedule disorders, and the *Parasomnias* identified as dream anxiety disorders (nightmare disorder), sleep terror disorder and sleepwalking disorder. By far, Primary Insomnia DSM-III-R Code 307.42 is the most common sleep disorder encountered in practice.

Insomnia is a ubiquitous symptom which more than one-third of the population experiences periodically. In most cases episodic sleeplessness is accepted philosophically, especially if it does not interfere too much with everyday functioning. In some persons, however, it is a persistent phenomenon for which help may be sought. Causes are heterogeneous, ranging from physical ailments, to depression, to environmental crises, to psychiatric stress. Sometimes insomnia is a consequence of prolonged consumption of hypnotics and sedatives, in which case the buildup of tolerance inspires wakefulness.

Patterns of insomnia are individual: (1) some people find it difficult to fall asleep but once slumber occurs do not awake until morning; (2) some fall asleep easily but awake in a few hours, fall asleep again, and go through the sleep-awakening cycle several times during the night; (3) some doze off readily but awaken at 4 to 6 a.m. and then cannot return to sleep; (4) others sleep throughout the day lightly, fitfully, restlessly, and get up in the morning as exhausted and tired as when they went to bed.

In recent years, research in sleep laboratories and clinical experience has yielded important information that is valuable in treatment planning (Kales, 1984). The following points are important to consider:

1. Insomnia is not as ruinous to health as the victim imagines. People can go without sleep for even several days without being damaged physically or becoming psychotic.

2. The amount of sleep required for optimal alertness the next day varies with the individual. Not everybody needs 8 or 9 hours; some persons do well with *4½* or 5 or 6 hours. Aging lowers the requirements to as little as 4 hours in some people, and older people normally sleep lightly.

3. People generally underestimate the hours of true sleep they get. Thus, many subjects on testing in sleep laboratories will show no sleep disturbance yet will complain of insomnia.

4. Insomnia is only a symptom. Its causes can be diverse. In all cases, treating the causes if possible is primary: Physical ailments such as coronary artery disease, which produces nocturnal anginal pain; duodenal ulcer, which stimulates gastric acid especially at night, driving the person to seek antacids; prostatic enlargement, which produces arousal because of the frequency of urination; bronchial asthma; hypothyroidism, sleep apnea, myoclonus, and other physical conditions that cause discomfort and pain requiring proper medical or surgical help. Depression may need antidepressive medications; anxiety reactions often do well with simple relaxation therapy; environmental disturbances may be helped with counseling and milieu therapy; and psychiatric stress necessitates psychotherapy and behavior therapy.

5. Certain medications such as beta blockers and tranquilizers can make a person feel sleepy and fatigued during the day, which may falsely lead a person to think he or she is not getting enough sleep. Other substances may actually cause insomnia. These include Dexedrine, Ritalin, Tenuate, Proludin, and coffee, tea, soft drinks containing caffeine, and alcohol taken late in the day or evening. Steroids, Inderal, and other beta blockers, may also create problems.

6. Once insomnia develops for any reason an added deterrent to sleeping well is anticipating being awake during the night and suffering fatigue and exhaustion as a consequence. This whips the person into a state of self-defeating alertness.

7. Markedly irregular hours of retiring interfere with the bodies built-in time clock. People who go to bed late at night usually, often to their dismay, wake up at their regular morning hour.

8. Hypnotic drugs used over a long period lose their effectiveness and therefore are for short-term (no longer than 3 to 4 weeks) or periodic use. Continued employment creates tolerance and addiction without added benefits. Withdrawal of these drugs, taken over a period, produces a "surge" of dreaming, jitteriness, and more insomnia. Such withdrawal must be done slowly and in some cases may require hospitalization to deal with unpleasant sequelae.

9. Over-the-counter sleep medications contain methapyrilene and/or scopolamine. Prolonged use is neither safe nor effective at current dosage levels.

The treatment of insomnia will depend upon whether or not it is acute, the provocative factors that keep the patient awake, and the degree of addiction to hypnotic drugs.

Acute temporary periods of insomnia produced by situational stress are usually readily handled by reassuring the patient that sleeping less than his or her usual quota will not cause damage, by permitting the patient to verbalize his or her fears and resentments, and perhaps by prescribing a hypnotic substance for 1 to 3 nights if necessary. Short-term insomnia due to work and family problems, bereavement, or illness requires education about insomnia, helping the development of proper sleeping habits, and, if necessary, prescription of a benzodiazepine hypnotic for no more than 3 weeks.

The treatment of chronic insomnia is a more difficult matter, largely because the patient has established faulty habits and has probably incorporated the insomnia into his or her neurotic superstructure. The primary treatment is behavioral (Hauri, 1979), and hypnotics should be avoided if possible.

The therapy for established insomnia starts with exploring its history and manifestations, the patient's attitudes toward it, what he or she has done about it in the past, and what is maintaining it in the present. In many cases the demoralization of the patient will have to be dealt with by supplying scientific facts about insomnia to displace as much as possible unfounded myths and fears. If the patient has not had a good physical examination in the past, he or she should be asked to get one to rule out any organic causes. The patient should also be asked to keep a diary of his or her sleeping habits and working schedule for at least 24 hours, including bedtime routines, use of medications, sleep disruptions, and daytime fatigue, which may or may not yield important clues.

The next procedure is to instruct the patient in proper sleeping habits. These can serve as effective alternatives to drugs. Among measures to be recommended are the

following:

1. Rearranging sleeping habits.

2. Reassuring the patient about sleep needs.

3. Getting the patient to accept insomnia.

4. Teaching the patient relaxing exercises.

5. Treating hypnotic drug dependence.

6. Prescribing medication.

Rearranging Sleeping Habits

(1) The patient should attempt to establish a regular bedtime, avoiding naps during the day. If sleep does not come easily, one may try relaxing exercises (or deep breathing, audiotapes, self-hypnosis, or meditation) or imagery with object counting ("counting sheep"). Should sleep not follow, one should go to another room to read or watch television until drowsiness develops instead of tossing around. (2) excessive smoking and drinking should be eliminated. (3) In some patients a change of mattresses should be made from hard to soft or vice versa, attention being paid to the bedcovers so that the patient is neither over- nor underheated, to the wearing of more comfortable night apparel, and to the regulation of the room temperature. Simple as this may sound, it may be all that is required. (4) A change in position during sleep may be indicated if the patient is in an uncomfortable repose. Superstitions such as that one must not sleep on the left side because the heart may be damaged, should, if this position is a preferred one, be corrected. Patients with asthma or orthopnea are more comfortable propped up in bed rather than lying prone. An elevation of the head and upper trunk is sometimes a preferred position. In married persons a change from a double to twin beds, or the reverse, may be considered. (5) A bedtime snack (warm milk, sandwich, cocoa) is reassuring to some people, as is a glass of beer or ale or a small tumbler of sherry, port, or an aperitif. (6) Tea or coffee should be excluded from the evening meal and not taken before going to bed. (7) Reading in bed concentrates the attention away from inner

concerns. Television programs selected before bedtime should not be too stimulating. (8) Daily exercise and a brisk walk in the evening followed by a hot bath are recommended by some. (9) Should the patient desire to experiment with it, an oscillating mattress is available in "sleep shops" or department stores that rhythmically rocks some people to sleep. (10) Ear plugs, antisnore masks, and eye shades may be used to control situations disturbing to sleep. If necessary, one may sleep in a separate room away from a snoring partner. (11) Making up for lost sleep during weekdays by sleeping longer over weekends or on holidays can be disruptive to establishing proper sleeping patterns. Regular wake-up times should be observed even after a poor night's sleep.

Reassuring the Patient About Sleep Needs

The individual's estimate of how much sleep he or she must have for health reasons is usually far above his or her true physiological requirements. As people get older, sleep needs decrease. A reduction of deep sleep stages (III and IV) is normal. Because lighter stages (I and II) occur, older people get the feeling they do not sleep a wink. They also awaken several times during the night and fall asleep again, which is normal. If the patient can be convinced that merely reposing in bed and not forcing oneself to sleep is not damaging to one's health and if the patient can develop the philosophy "If I sleep, so much the better; if not, it doesn't matter," he or she may be able to stop worrying himself or herself into wakefulness. The patient may be told that merely lying in bed and relaxing are usually sufficient to take care of the physiological needs. If the patient does not sleep as much as he or she believes is necessary, no real harm will befall the patient. Of course, he or she may be driven to distraction by worrying about not sleeping. Worry will actually cause the insomniac more difficulty than not sleeping.

Relaxing Exercises

Progressive muscle relaxation with deep breathing exercises and self-hypnosis are valuable adjuncts in insomnia. The techniques of relaxation and self-hypnosis have been outlined previously in this volume *(q.v.)*. They may advantageously be taught to the patient. Repeated suggestions are made that he or she will be able to "turn one's mind off,"

to focus on a pleasant scene, and to feel himself or herself getting more and more drowsy and relaxed. This may reestablish the sleep rhythm more effectively than any other measure. A useful pamphlet on ways to approach sleep may be prescribed for the patient *(Better Sleep,* 1963). An interesting article called "The science of sleep," by Joan Arehart-Treichel (1977) in *Science News,* may be recommended, as may the book by Coates and Thoresen (1979).

Acceptance of Insomnia

Several unusual methods of controlling sleep have emerged that may be suited for certain patients. One technique deliberately restricts the hours spent in bed fruitlessly attempting to fall asleep. Persons appear to "sleep better if they spend fewer, rather than more hours, in bed" *(JAMA,* 1985). Subjects are enjoined to stay awake later but to arise at their customary times. They are not permitted to nap during the daytime. Another method that has been employed with patients who drive themselves frantic during the day with the fear that they will not be able to sleep that night is paradoxical intention (Ascher and Efran, 1978, Ascher et al. 1980). Here suggestions are given that the person "try to remain awake as long as possible, rather than attempt to fall asleep." A rapid reduction of sleep onset latency can result.

Should insomnia continue to be distressing, referral to a sleep disorder clinic may be considered. Such may be the case in phase-shift sleep-wake (in which the patient seems to be able to sleep only during the daytime and is awake at night). Chronotherapy, a specialized procedure, is best done in such clinics.

Some therapists try to get insomniacs to accept their insomnia as something with which they can learn to live. Indeed, insomniacs may, as Modell (1955) has pointed out, successfully exploit their symptom. Once they are convinced they need less sleep physiologically than their mind dictates, patients may be encouraged to accomplish something useful during their waking hours at night. Instead of tossing about fitfully in bed and brooding about problems, they may read or write in bed. Or they may get up, take a shower, and, for an hour or two, apply themselves to useful work, particularly work that

worries them if it goes undone. They may then return to bed.

Drug Treatment

Prescription of a hypnotic should be given only when behavioral or psychosocial therapy fails to relieve sleeplessness. In cases of depression, antidepressants may eliminate the insomnia. If stress exists, the only logical intervention is to deal with its sources. Hypnotics temporarily given for no more than 3 weeks, and preferably less, may be of great help. If there is a history of alcohol or drug abuse, hypnotics should not be prescribed because the patient will almost invariably refuse to give them up or, worse still, will take them with alcohol or other depressants, which may be fatal. When hypnotics have been used for more than 2 weeks, withdrawal should be gradual to avoid rebound sleeplessness or such neurological symptoms as twitching.

Many substances have been used, abused, and then discarded in humans' quest for a harmless substance that can hasten and sustain sleep. We still do not have such a substance, but currently the benzodiazepines, the least harmful, though still not perfect, solution, have replaced alcohol, bromides, opiates, barbiturates, ethclorvynol, glutethimide, and methaqualone as the most frequently prescribed drug for insomnia. Chloral hydrate is still employed by some as a safe and effective hypnotic.

Taken occasionally when stress distracts the normal sleep tendency, hypnotic benzodiazepines are useful aids. When taken regularly as sleep insurance, all hypnotics eventually betray their purpose by fostering cognitive and psychomotor impairments. Without a pharmacological "straight jacket," the individual anticipates a sleepless night with the feared consequence of not being able to function well or at all the next day. On the other hand, if benzodiazepines are not prescribed, a stressed individual may resort to alcohol or more dangerous drugs that cannot be monitored.

The most popular benzodiazepines employed as hypnotics are the long-acting flurazepam (Dalmane), with a half-life of about 100 hours, the short-acting temazepam (Restoril), with a half-life of 9.5 to 12.5 hours, and the ultra short-acting triazolam

(Halcion), with a half-life of only 1.6 to 5.4 hours. Diazepam (Valium), 2 to 5 mg (and up to 10 mg), is an old standby; it has a half-life of several days. Lorazepam (Ativan), 2 to 4 mg, is also popular and has a shorter half-life of up to 18 hours. Doxepin (Sinequan), 25 to 50 mg, is another choice. It is a dibenzoxepin tricycle compound used in depression and hence less prescribed for insomnia although it may be effective in some cases.

The drug to use will depend on the type of insomnia the patient is suffering. In transient situational stress with a carry over of anxiety during the day, Valium (2 to 5 mg) is a good alternative, especially if one wants its anxiety-reducing effects (with its accompanying slight hangover) to continue through the daytime. Dalmane has its advocates. Its sedative effects continue in the daytime because of its long half-life. Here one starts with a 15-mg dose but informs the patient that it is more effective on the second, third, or fourth night of consecutive use than on the first night. Should 15 mg fail to work after a week, 30 mg may then be given. In severe chronic insomnia one may start initially with the 30-mg dosage. Elderly persons who require daytime alertness and good psychomotor performance are best given 0.125 mg of Halcion, which may be increased to a limit of 0.25 to 0.5 mg. Halcion (0.25 to 0.5 mg) is also valuable for persons with jet lag or who awaken in the middle of the night and need a short boost to fall back to sleep. Restoril (15 to 30 mg) is also tolerated well by young and old and is especially suited to those who anticipate sleep difficulties. For early-morning awakening, doxepin (25 to 50 mg) is sometimes quite effective. The amino acid L-tryptophane has been shown to reduce sleep latency without distortions of psychological sleep (Hartmann, 1977), but it has not been consistently used as a hypnotic because of its mild effect.

Should these medications fail and it is judged that the patient truly needs a stronger temporary hypnotic, the choice of drug will depend upon whether short action is desired (i.e., 3-4 hours), in which case pentobarbital (Nembutal) 1.5 grains (100 mg) is prescribed; intermediate action (i.e., 4-6 hours) will require butabarbital (Butisol); 1.5 grains or long action (i.e., 6-8 hours) for which 1.5 grains of phenobarbital will be necessary. Sometimes a combination drug is used such as Tuinol (1.5 grains), which contains Seconal and Amytal, for short and intermediate action. Should a "hangover" result the next morning,

the doses should be halved. Under no circumstances should a stimulant such as amphetamine be prescribed to alert the patient the next day since a vicious sedating-stimulating habit may be established. The non-barbiturates are also popular. Among these chloral hydrate is preferred (7.5-15 grains). This is available in capsule form (Noctec), which consists of 3 or 7.5 grains of chloral hydrate and is taken in doses of one to two capsules nightly; or in syrup form, which contains 7.5 grains of chloral hydrate per teaspoonful. Other non-barbiturates are also occasionally employed but must be used with caution. These include Placidyl (500 mg), Doriden (500 mg), and Noludar (300 mg).

The use of hypnotics should be confined to at most 3 weeks because beyond this time habituation is likely. If long-term use is anticipated, the patient may be enjoined to skip medication several times during the week. Many patients are comfortable with a hypnotic every 3 days, which enables them to catch up on their desired quota of sleep. In spite of everything that can be done to deal with the causes of insomnia, it may be impossible to stop it. This is especially the case if the patient has an intractable medical condition with pain and debility. In these cases, the therapist may have to prescribe long-term periodic hypnotic medication as adjunctive therapy.

When hypnotic drugs have been used over a long period, they usually become less effective and REM sleep is markedly reduced. Therapy is much more difficult since the patient will resist going off hypnotics. Should drugs be abruptly withdrawn, disturbing rebound insomnia will eventuate. The brief snatches of sleep that do occur are interrupted by a rebound in REM sleep, upsetting dreams, and nightmares. Consequently, slow withdrawal is necessary (a good rule is reducing by one nightly dose every 5 or 6 days). The patient should be warned about the possibility of a temporary increase in insomnia, vivid dreams, and nightmares. Relaxation exercises or self-hypnosis are prescribed or biofeedback employed if the therapist has the apparatus. Other principles outlined above should be followed.

In absolutely refractory insomnia, multidimensional treatment in an inpatient psychiatric unit may be most helpful.

EATING DISORDERS

Overweight and Obesity (Psychological Factors Affecting Physical Condition, DSM-III-R Code 316.00)

The pursuit of thinness has become an obsession, especially in prosperous societies, but often it is a futile gesture. Obesity is a refractory condition whose cure rate is less than for many kinds of cancer. If grossly excessive, overweight leads to many physical disabilities, but even more important to untold hours of self-reproach and suffering on the part of even its less overweight victims. Recent studies have shown that such physiological factors as fat cells that are enlarged in size and number and a low metabolic rate are prominent among some obese persons. These factors, probably genetically determined, make it difficult and for some individuals impossible to lose weight even on a prescribed low-calorie diet. There is also a small group of persons who have serious personality problems dating back to infancy and early childhood associated with an overvaluing of oral activities, in whom overeating becomes a compulsive mechanism that defies all methods of control except long-term psychotherapy (Bruch 1957, 1961, 1973; Caldwell, 1965). Even here the food compulsion may defy correction. Most overweight persons do not fit into these sub-types of obesity, however, and may be helped by modern methods of treatment to lose weight for cosmetic if not health reasons.

The basic therapy that has been commonly employed is behavior modification that takes into consideration the prevailing eating patterns of the patient (Stunkard 1972, 1985, Craighead et al, 1981). Detailed questioning is essential regarding not only the kinds and preparation of foods the patient prefers to eat, but also the time of day when overeating occurs, the availability of the food, the exact circumstances under which the appetite is stimulated, propensity for sweets, late-evening snacking, social pressures, and so on. What is essential is control of environmental eating cues that excite temptation. Once these factors are identified, the patient is instructed in how to rearrange eating routines and given homework assignments to practice the new orientation.

Standard forms of therapy involve (1) following a diet of around 800 to 1000

calories daily, carefully recording the food consumed, (2) keeping a chart, daily or weekly, of one's weight, (3) eating meals preferably at home with no distractions such as radio, television, or reading, (4) chewing each mouthful of food very slowly and spending at least 20 minutes at each meal, (5) forbidding snacking between meals, (6) food shopping from a list of essential items and no more, (7) exercising daily and walking rather than riding, and (8) being rewarded with money or gifts for losing weight and being penalized by a fine for gaining weight. Such programs are often executed in groups for a number of sessions, among which Weight Watchers and Overeaters Anonymous are especially popular.

Except for a small group of physiologically and psychologically handicapped persons, overweight individuals who follow the principles of these programs will lose considerable poundage. The real problem is maintenance, because most people are constantly plagued with temptation and sooner or later will abandon their new eating styles. Fantasies of the good life—the tinkle of beautiful crystal, the feel of fine silver, and the smell and taste of gourmet cooking will haunt the most dedicated soul. And, in an incredibly short time, to the great consternation of the dieter, the old weight has been restored. Anyone who operates under the illusion that weight loss is simply a matter of discipline and diet and that a few behavioral strategies can dissolve fat and ensure permanent weight loss will be subject to disappointment.

For many people, food is a pacifier. It alleviates tension and acts as a means not only of gratifying hunger and securing great pleasure but of quelling anger and restoring one's adaptive equilibrium. The driving impact of hunger is kept alive by inner forces of which the individual may not be entirely aware. This fact has led to a broadening of behavioral strategies to include cognitive elements. We are interested not only in what the patient does but in the thoughts and impulses that stir up the craving for food and especially for those foodstuffs that are fattening.

In some cases, particularly if physiological factors exist and constant dietary attempts have led to failure, the individual should not be forced to reduce. The lesser of two evils is to accept one's body size and try to lessen the overconcern with achieving

thinness. Society does discriminate against overweight people, and even those who are mildly plump get to hate their bodies and to despise themselves for loss of willpower. Psychotherapy may not be able, especially with short-term methods, to get to the provocative psychological factors responsible, and the most we will be able to accomplish is to help people to stop tormenting themselves with their obsessional dieting preoccupations.

If a patient comes to therapy principally for help for emotional and adjustment problems and obesity is a secondary concern, the focus at first will be on the primary complaint factor. In the course of therapy, the patient may bring up the matter of overweight, in which case techniques may be used similar to those used when obesity is the initial complaint. Generally the patients will already have experimented with weight-loss measures on their own. The therapist may inquire about those that have proven temporarily successful. In some cases no more has to be done than to encourage the patient to continue on these diets and to join Weight Watchers, Overeaters Anonymous, or similar groups. Commercial weight-loss clinics must be selected carefully since some employ potentially dangerous drugs, have minimal medical supervision, and neglect essential exercise, which is an important ingredient in a good program. In treating the average adult who is less than 40 percent overweight and who probably does not possess serious psychological problems, some clarification about diets will usually be necessary. Though the patient has been exposed to years of dietary information and may profess to know all about dieting, there are usually large gaps in knowledge that have been filled with old wives' tales about food and feeding as well as faddist whimsies extracted from magazines and newspapers. Information on what constitutes a good dietary regime (7 calories per pound of ideal weight with proper protein, mineral, and vitamin content) that can act as the basis of a living diet to be followed faithfully may have to be supplied. In some patients alcohol, taken to appease tension, constitutes a block to dieting. One ounce of drink of any spirit contains about 135 calories. An average martini has as many calories as three slices of bread! Considering that several highballs or cocktails supply 500 to 750 calories and that the appetite is in addition stimulated by alcohol, food control for the drinker becomes a nonexistent entity. The matter of exercise will also require explanation.

A 250-pound man climbing 20 flights of stairs will lose the equivalent of one slice of bread. Exercise firms up muscles, but it cannot take off sufficient poundage without strict dieting. When suggesting a proper diet, the therapist may have to give the patient a basic nutritional list of essential daily foods. This consists of a helping of fresh fruit twice daily; a small helping of cooked vegetables; a salad; lean broiled meat, fish, or fowl twice daily; a glass of milk or cheese twice daily; 2 to 3 eggs weekly; and little or no alcoholic beverages (Tullis, 1973). Fats, nuts, candy, cake, and all desserts are to be avoided. Low-calorie salad dressings, low-calorie sweeteners, and sugar-free drinks may be permitted.

A report released by researchers in a study supported by the National Institutes of Health has lauded the substitution of fats in the diet with 60 mg of sucrose polyester per day. This reduces caloric intake by 23 percent (*JAMA*, 1982) and contributes to weight loss. Meals should be taken at regular hours with no snacking allowed.

In most cases, however, the lack of success with these routine methods will necessitate an aggressive therapeutic program on either an individual or group basis. Assessment should include an evaluation of the patient's goals. Sometimes these are unrealistic, for example, if the patient expects to lose 20 pounds in 4 weeks. The patient's dietary and eating habits should be recorded as well as any stress factors of which the patient is aware. Many patients believe that they can lose weight by having little or no breakfast and skimping on lunch. In this case, most of the eating occurs at nighttime, when a ravenous appetite is set loose. Some patients desire medications that will act as appetite suppressants. Information should be supplied that experience with these chemical adjuncts has been disappointing. Their effect is temporary at best, and when they are discontinued, the patient is worse off than at the beginning.

An evaluation of social support systems is vital since many tensions are the product of social isolation and lack of family and group contacts. Because the relationship with the spouse is especially important, the spouse should become a vital part of the treatment program from the start. As the patient loses or fails to lose weight, the attitudes of the spouse will influence what happens, and the spouse's relationship with the patient may

change for the better or worse. Not infrequently, the spouse will subtly encourage the patient to go off the diet as body changes in the latter occur. Obesity may be a way of locking the patient into a neurotic relationship that the spouse needs for his or her personal stability. There may be fear that greater physical attractiveness will motivate the patient to abandon the spouse or make the spouse attractive sexually to others or seek activities away from home. Some men find obese wives more sexually stimulative and thus may discourage weight loss in their wives. These additional reasons for sabotage of the patient's therapy make the husband's presence at some of the sessions a desirable part of the treatment program.

It is obvious that motivation to lose weight is crucial to the success of any treatment program for obesity. Certain patients come to therapy with the expectation that some miracle will happen and that their appetites for food will somehow disappear as a result of magical tactics like hypnosis (Krogar, 1970; Stanton, 1975). Because motivation to participate actively in the assigned program is essential, an initial screening process may be used. Patients are told that unless they are ready to follow the routines prescribed, they are not ready for the program. They are then given a few routines to follow during the first and second session, such as keeping a record of their weight and their food intake each week.

Simple tactics such as chewing food very slowly, putting the fork down between bites, sitting in the same place for each meal, and avoiding distractions like television while eating may be advised. Should the patients fail to do these simple things nor be disciplined enough to lose at least 2 pounds during the first 2 weeks of therapy, it is doubtful that the more burdensome tasks that come later will be executed. Such reluctant patients may be told bluntly that they are not yet ready for the program the therapist has to offer. Motivation may sometimes be helped by imposing financial penalties for non-attendance at sessions (Brownell & Foreyt, 1985). At the University of Philadelphia and Baylor College of Medicine, for example, patients are required to deposit $100 in addition to a treatment fee of $200. If the patient attends at least 80 percent of the sessions, the deposit is returned.

Included in the weight-reducing directives are definite instructions regarding routine exercise. Physical exercise is prescribed not so much for its weight-reducing potential, which is low, but for its general effect on the well-being of the patient, which reflects back on the patient's ability to follow a sensible weight-loss maintenance regime. Morever, exercise helps prevent the loss of essential muscle tissue and the lowering of the basal metabolic rate as dieting proceeds. The therapist must be firm about insisting that graded exercises be carried out daily. Most obese patients will resist exercising for many reasons, including shame of exposing their bulky bodies to others and the torpor that excessive poundage imposes on them.

According to some authorities on obesity (Stunkard, 1984; Garrow, 1981), different degrees of obesity call for different approaches. Mildly obese people (30-40 percent overweight) are best helped with behavioral methods. Moderately obese people (40-100 percent overweight) require a very low-calorie diet as well as behavior modification. Severely obese people (more than 100 percent overweight), which is rare, may need an intestinal bypass operation after having failed with a very low-calorie diet and behavior modification. Such intractable cases usually display a combination of basic defects in metabolism and poor motivation, which results in lack of cooperation. A "short-circuit" procedure (ileal bypass) results in a reduction of the length of the small bowel lowering the absorptive surface for nutrients. While weight loss occurs, serious malabsorption, diarrhea, gallstones, and susceptibility to infections may impair health. The operation is consequently done as a last resort.

It is important to remember that weight will rapidly be regained if a reducing diet is markedly different from the diet the individual will return to later. Some nutritionists therefore advise patterning a diet around the patient's customary one but substituting nonfattening for fattening items, eliminating high-calorie foods, and introducing more vegetables, fruits, and cereals. It is essential that the organization of a dietary regime take into account the need for the person to continue to eat healthful foods to maintain his or her ideal weight. How fast one should lose weight is also important. Obese people want to reduce rapidly. They have previously tried to do this with crash diets. This has not worked

because returning to previous food habits nullified their accomplishment. The rate of weight loss during the active period of dieting is best maintained at a low level, perhaps no more than 1 to 1 i pounds weekly, which gives the individual a chance to reorganize food habits. If however, obesity is pronounced, if morale demands it, and especially if the metabolism of the individual is sluggish, a drastic reduction of food intake (to 400 to 700 calories) or outright semistarvation (Genuth et al, 1974) *under medical supervision* may be undertaken to foster the loss of 3 to 5 pounds weekly. Naturally, there is great danger here of rapid return to the original weight once professional supervision if terminated.

In recent years a very low-calorie diet mainly of protein (lean meat, fish and fowl, vitamins and minerals) has been popularized for patients who are at least 40 pounds overweight. Patients have initial physical examinations and are seen regularly by their physicians for checkups and laboratory tests. Supervision is essential, and if the patient adheres to the diet, and in addition receives behavior modification, impressive weight loss is possible in most cases. Unless a continuing maintenance program exists, however, relapses are the rule. Satisfactory maintenance may often be achieved when patients are continuously supervised, preferably in a group setting. An interesting treatment manual describing a behavioral approach to obesity has been prepared by Brownell. Information on it may be obtained by writing to Dr. Kelly D. Brownell, Department of Psychiatry, University of Pennsylvania, 133 South 36th Street, Philadelphia, PA 19104.

Weight-loss maintenance is a key issue and, as has been mentioned, the involvement of a spouse at the point when the patient has lost enough weight to make a difference in appearance may spell the difference between a successful and poor outcome. Most patients will require personal individual or group therapy for a year. Thereafter, some patients do better in a continuing group, but this is not always the case. The patient should be forewarned to contact the therapist should there be danger of slipping back into the old habits. Any stress situations are apt to cause a patient to overeat to appease tensions. Often fantasies of gourmet foods may tempt or upset the patient. Patients who have irreverent thoughts about luscious foods must be taught to correct self-statements that keep undermining their resolve. The emphasis in such a cognitive approach must be on

their strengths not weaknesses. Hunger may be explained as a good sign, indicating that the patient is consuming excess body fat. Mastering hunger then becomes a virtuous act of caring about themselves and safeguarding health, longevity, and appearance.

One should not overlook the damaging psychological consequences of having been overweight. Obese people often have a depreciated self-image and believe their bodies to be misshapen, grotesque, and contemptible. They sustain a loathsome hatred of themselves. This is most often the case in juvenile obesity in which extraordinary efforts may be made to conceal body fat. Some of these residues remain even after weight loss. Or an attractive body may confront the individual with new challenges, for example, coping with sexual gestures from members of the opposite sex which they are not equipped to handle. Continued psychotherapy may then be in order.

Psychoanalysis and psychoanalytic therapy have little impact on the isolated symptom of obesity. Correcting disturbed personality factors may, however, have an impact on overeating patterns. When successful, they can significantly improve the quality of life of their beneficiaries in a broad spectrum of behaviors.

Anorexia Nervosa (DSM-III-R Code 307.10)

Anorexia Nervosa usually invites desperate expediencies. In their anger, anguish, and dismay, patients and therapists may take recourse in such measures as cajolery, bribes, tube feedings, and even electroconvulsive therapy. These may have an immediate ameliorative effect, but since they circumvent the core problems they ultimately aggravate self-starvation. Anorexia nervosa mainly affects young adolescent girls of well-to-do families who defend their avoidance of food with a captious logic that does not yield to common-sense arguments. Even though they are emaciated, they still insist on losing weight by restricting food intake, forcing themselves to vomit, and driving themselves mercilessly in forced exercise. Sometimes obsessive-compulsive behavior takes place. Interludes of binge eating (bulimia) and vomiting are followed by self-hatred. If some motivation exists, behavior therapy by itself sometimes brings temporary benefits (White JG, 1964). Follow-up studies, however, have been discouraging, with relapse and alarming

substitutive symptoms being the rule rather than the exception (Bruch, 1973). The malady appears to be on the increase throughout the world, as the pursuit of thinness remains a chief obsessive concern.

Theories of its cause range from genetic predisposition, to hypothalamic dysregulation, to exaggerated dopamine activity, to an affective disorder, to reaction to psychosexual conflict, to an extraordinary stressful experience. Psychological studies often reveal an erstwhile "perfect" child struggling to maintain her stature with abstemious relentlessness. Basic is the search for identity and a struggle for independence and control. Paradoxically, short-lived bouts of uncontrollable eating binges further undermine the anorexic's self-esteem and incite an exaggerated refusal to eat. A pathological distortion of the body image is universal.

Therapy is thus understandably difficult. It hinges on two objectives: (1) improving nutrition (the use of high-calorie diet is sometimes helpful but must not be forced (Maxmen et al, 1974); and (2) rectifying the instrumental psychological causes. In mild cases, where the family warfare is not too extreme, treatment may be achieved at home. In most instances, separation from the home environment (usually with hospitalization) is mandatory in order to remove the patient from the highly charged family situation and from the aversive entourage surrounding the prevailing eating atmosphere. The relationship with the therapist is primary, with a minimum of pressure employed. Focus on food stuffs and calories is avoided.

Certain medications have a positive effect on anorectic patients. The most important of these is the antidepressant group, such as amitryptiline (Elavil), which is started in a low dose and worked up to 150 mg daily. Another drug with antidepressant qualities is cyproheptadine (Periactin). Chlorpromazine (Thorazine) has also been used with good results in some cases. Behavior modification is used freely to reinforce corrective eating patterns. If family difficulties are prominent, family therapy can be helpful. Psychoanalysis in the classical from has not been found to be too useful, one reason being the lack of motivation for depth therapy. A modified form of dynamic therapy reinforced by family

therapy (Liebman et al, 1974) and supportive measures has yielded the most encouraging results and has helped to rectify identity problems, temper cognitive distortions, and expand autonomy and self-control in relation to eating habits. Continuing psychotherapy with the patient, and perhaps family therapy, is required after hospitalization (Bruch, 1973, 1975).

Bulimia Nervosa (DSM-III-R Code 307.51)

The episodic unrestrained incorporation of large quantities of food, which sometimes occurs along with anorexia nervosa, is also an isolated pattern that is increasingly being encountered in adolescent girls of normal weight. Occasionally it occurs in obese people who seemingly resent the strictures of dietary control, and periodically indulge themselves in compulsive eating. A recent survey of tenth-grade students has also revealed an alarming number of children who engage in binge-purge activities (Killen et al, 1986). The activity is usually followed by guilt feelings, self-recrimination, and forced vomiting. Laxatives and diuretics are taken for the purpose of trying to regulate weight. A good deal of secrecy may accompany the habit, spasms of wild food intake being confined to stealthy visits to the refrigerator or to the privacy of one's room, where sweets and other goodies have been stowed away. Depression accompanies the disorder either as a primary or secondary factor. Indulgence in such substances as barbiturates and amphetamines may sometimes occur. Periods of frantic dieting are often pursued. Concern with one's body and appearance mingled with distortions of the body image make for a peculiar picture, although in all other respects the individual appears normal. Most victims of this illness do not spontaneously seek therapy, but they may be referred by concerned parents or friends.

The association of bulimia and depression is an interesting one. A disproportionate number of bulimics have a positive dexamethasone suppression text, reflecting a relationship between bulimia and major affective disorder (Hudson et al, 1983a). A number of reports have detailed the successful treatment of bulimia with tricyclic antidepressants such as imipramine (Hudson et al, 1983b) and MAO inhibitors, such as

phenelzine (60-90 mg daily) (Walsh et al, 1982).

The fact that binge eating may be controlled by antidepressants does not reduce the impulse to engage in this abnormal food activity. For this reason, individual therapy plus short-term therapy groups should be held with a focus on nutrition, expanding self-esteem, and finding alternatives to binge eating and purging. Indeed, some studies show that a multifaceted group approach produces results equivalent to the taking of antidepressants. Connors et al. (1984) has shown that utilization of a treatment approach incorporating education, self-monitoring, goal setting, assertiveness training, relaxation, and cognitive restructuring can lead to significant attitudinal and behavioral change. Following the initial improvements with antidepressants and with brief group therapy, prolonged dynamic psychotherapy may be needed if personality disorders require restructuring.

HABIT DISORDERS

A number of symptomatic complaints are commonly encountered among patients that serve either as a prime reason for seeking therapy or become so distracting that they obstruct the therapeutic effort. Their resolution consequently will concern the psychotherapist, who, having satisfactorily managed to overcome them, may proceed with any underlying personality problems of which the symptoms are a surface manifestation. Many of the techniques for habit modification come from the behavioral field. The effectiveness of reinforcement therapy has been validated even with chronic psychotic patients (Gottfried & Verdicchio, 1974).

Functional Enuresis (DSM-III-R Code 307.60)

Once urologic or general causes for enuresis (a good physical examination is a necessity) are eliminated (for instance, local irritation around the meatal or urethral area, phimosis, adherent clitoris, balanitis, cystitis, urinary tract infections, pinworms, diabetes, cerebral dysrhythmia, and systemic diseases), its sources in psychological conflict may be explored. If the patient is not mentally defective or of borderline intelligence, the presence

of enuresis probably indicates improper habit training, emotional immaturity, or conflicts related to sexuality or aggression (Bakwin, 1961). Frequently enuresis has positive values for the individual as a masturbatory equivalent. In some instances it represents a form of aggression against the parents or against the world in general. Often it signifies an appeal for dependence on the basis of being a childish, passive, helpless person. In this context, enuresis may symbolize for the boy castration and the achieving of feminity. In girls it may connote aggressive masculinity and symbolic functioning with a penis.

For children a record is kept of dry and wet nights, the former being rewarded by praise and the record marked with a star. Rewards like ice cream may also be used. When the child wets, he or she should be responsible for changing the bed clothes and for seeing that they are washed. One-third of the children presenting with enuresis may be cured by this regimen alone (McGregor HG, 1937).

Strong emotional stress sometimes produces enuresis in persons who are ordinarily continent. This was brought out during World War II when certain soldiers subjected to the rigors of induction or warfare displayed the regressive symptom of bedwetting. Most soldiers who showed this symptom had a history of early bedwetting or of periodic attacks of the disorder prior to induction.

In treating enuretic children, they may first be requested to empty their bladder at bedtime; then awakened 2 hours later and induced to urinate again. This interval may gradually be prolonged, and, if enuresis stops, the evening awakening may be discontinued after 6 months. Positive praise and encouragement are given the children when they control their bladder; however, there should be no scolding or punishment for wetting. Exciting play or activity prior to bedtime is best curtailed, and fluids restricted after four o-clock. Coffee, tea, cocoa, sweets, salts, and spices should be avoided. Sedatives, amphetamine, methyl testosterone, anticonvulsants, belladonna, and other substances have been administered with varying results. Imipramine (Tofranil) has been used (Poussaint & Ditman, 1964; Stewart MA, 1975) one-half hour before bedtime and the results have been promising. The dose is 25 mg for children of 4 to 7 years, 35 mg for

children of 8 to 11 years, and 50 mg for children older than 11 years. Countering improvement are side effects in certain cases. Friedell (1927) obtained an 80 percent cure rate with intramuscular injections of sterile water. W. A. Stewart (1963) described how Zulliger cured a young man of 19 with lifelong enuresis in one session by convincing the patient that he, the therapist, sided with the patient against his father. The fact that so many treatments have yielded positive results indicates the presence of a strong suggestive and placebo element in the management of enuresis (English OS & Pearson, 1937; *Hospital Focus,* 1964).

Enuresis developing in an adult is usually a regressive phenomenon connoting a desire to return to a childish adaptation and a defiance of the adult world.

The treatment of enuresis will depend upon whether one wishes to deal with the symptom as an entity, disregarding the emotional undercurrents, or to work with the intrapsychic structure in hopes that the symptom will eventually resolve itself (Pierce, 1975). Focusing on the symptom as preliminary to working with more fundamental dynamic factors is preferred by many since the symptom is an undermining element that robs the individual of self-confidence and vitiates interest in searching for conflictual sources. Accordingly, concomitant counseling and carefully conducted psychotherapy should, if possible, be employed.

A rapid effective conditioning technique, which, according to the British journal *Lancet* (1964), brings a relief yield of 75 percent, involves a buzzer or bell which sounds off when there is wetting of the bed (Mowrer & Mowrer, 1938). There are advocates and critics of this method. Sidetracking the issue of whether symptom removal is rational or irrational (Winnicott, 1953; Eysenck, 1959) or whether the buzzer treatment is a form of classical or operant conditioning (Lovibond, 1963), this approach to enuresis in controlled studies has been shown to be superior to other therapies (Werry, 1966). While the relapse rate is about 30 percent, relapses respond rapidly to a second course of treatment. There is little evidence that symptom substitution or precipitation of a neurosis develops with the removal of enuresis; on the contrary, the emotional well-being seems benefited (Bailer

& Schalock, 1956; Behrle et al, 1956; Bostock & Schackleton, 1957; Gillison & Skinner, 1958; Lovibond, 1963; Werry, 1966). The apparatus consists of two foil electrodes separated by thin gauze placed under the child. The covering over the electrodes should be as thin as possible. Parents and child are reassured there will be no shock, and the child is to prepare the bed and set the alarm. Should the alarm go off, he or she must get up and go to the bathroom. On return the child is to remake the bed and reset the alarm. Eventually the child will awaken before the alarm goes off. Should the child fail to awaken when the alarm sounds, the parents should awaken the child and see to it that he or she goes to the bathroom. A 90 percent cure is reported in 6 months (Dische, 1971). An improved form of apparatus is the Mozes Detector invented and used in Canada and tested at the Toronto Hospital for Sick Children with impressive results *(Medical World News,* 1972). Another conducting apparatus consists of a moisture pad worn inside the underwear (jockey pants or stretch-type bikini). The reported success rate is more than placebo. It may be obtained through Nite Train'r Enterprises, P.O. Box 282, Newberry, Oregon 97132.

Hypnotherapy is sometimes a useful adjunct (Stanton, 1979). Elsewhere (Wolberg LR, 1948), a full recording of the hypnotic treatment of enuresis is described. Actually, there is no single hypnotic method suitable for all patients; the specific suggestions and stratagems will depend upon the problems and personality characteristics of the patient. One method is to train the patient to enter as deep a trance state as possible. In the trance, an attempt is made to show the patient that he or she is able to produce various phenomena, such as paralysis and muscle spasm, and that he or she can shift or remove these by self-suggestions. Fantasies related to the most pleasurable thing that can happen to a person are obtained for the purpose of reinforcing the conditioning process later on. The patient is then requested to experience a sensation of slight bladder pressure such as occurs immediately prior to urination. As soon as he or she feels this sensation, it will inspire a dream or will make his or her hand rise to the face, which will cause the patient's eyes to open and to awaken. Even though no dream or hand levitation occurs, it is suggested that the patient's eyes will open, nevertheless. At that moment he or she will experience an urgency to get out of bed. Going to the bathroom will be associated with a

feeling similar to that accompanying the fantasy of the best thing that can happen to a person. These suggestions are repeated a number of times.

The next stage in therapy is teaching the patient to control sensations that arise inside the bladder so that urine can be retained without needing to awaken until morning. Suggestions to this effect are given the patient as soon as he or she establishes a habit of getting out of bed and going to the bathroom. The positive relationship with the therapist may be utilized as a reinforcing agent in reconditioning, praise and reassurance being offered when suggestions are followed.

In patients who have expressed a willingness to undergo dynamic psychotherapy, conditioning procedures may be delayed until they are deemed absolutely necessary. This is because the symptom may disappear as the origins of bedwetting are explored, and the unconscious fantasies associated with it clarified. There is, however, no reason why psychotherapy cannot be combined with a conditioning approach.

Nail Biting and Hair Plucking

Nail biting and finger sucking are common outlets for tension in preadolescence and adolescence and may persist as a neurotic symptom into adult life. Among other things,, nail biting serves as a substitutive release for masochistic, sadistic, and repressed masturbatory needs. If no other serious emotional problems coexist, the treatment may be symptomatic (Pierce, 1975), or therapy may be focused on outer emotional factors that generate tension, particularly environmental family problems. Most nail biters have little motivation for real psychotherapy, seeking mere measures of control because of embarrassment about their habit. They are usually unaware that the nail-biting symptom has a meaning, and they are often puzzled by the persistence of the urge to chew their fingertips.

If psychotherapy is resisted, the therapist may have no alternative but to treat the symptom. Hypnosis may be useful here. In hypnosis, strong authoritarian suggestions are made to the effect that the patient will have a desire that grows stronger and stronger to

give up the childish habit of nail biting. Patients who put their fingers into their mouths will discover that their fingernails taste disgustingly bitter. They may even develop nausea with the mere desire to bite the nails. Daily hypnotic sessions are best, but since this is usually impractical, a tape recording may be made that the patient may use twice daily (see Induction of Hypnosis, Chapter 56). Some therapists teach the parents of nail biters to activate the machine while the child is asleep to reinforce suggestions through sleep conditioning. Self-hypnosis may be employed in an adult. If these tactics fail, aversive conditioning *(q.v.),* a small shocking apparatus or a heavy rubber band around the wrist that can be painfully snapped may be tried (Bucher, 1968). A strong desire to control the symptom must be expressed by the patient and cooperation secured.

An assessment of the patient's problems will determine whether further reeducative or reconstructive therapy is indicated after the nail biting is brought under control.

Hair plucking (trichotillomania) (DSM-III-R Code 312.39) of the head, eyelashes, eyebrows is often a manifestation of a severe personality problem, often of an obsessive-compulsive or schizoid nature. It may serve as an outlet for revenge and self-punishment, and it is often accompanied by frustration, guilt feelings, and remorse. Psychotherapy is notoriously ineffective in dealing with this symptom. Hypnosis and particularly aversive conditioning may score some successes.

AFFECTIVE DISORDERS (MOOD DISORDERS)

BIPOLAR DISORDERS: bipolar disorder manic [296.4X]; bipolar disorder depressed [296.5X]; bipolar disorder mixed [296.6X]; cyclothymia [301.13]; DEPRESSIVE DISORDERS: major depression, single episode (296.2X); major depression recurrent [296.3X]; dysthymia *[or depressive neurosis]* 300.40; Atypical Disorders: *Bipolar Disorder* not otherwise specified [296.70]; Depressive disorder not otherwise specified [311.00]).

Depression is a generic term that embraces a variety of syndromes ranging from normal grief at the passing of a loved one, to reactions of prolonged distress out of proportion to the intensity of the traumatic stimulus, to paralyzing inhibition and retardation arising spontaneously from endogenous sources, to psychotic manifestations

with intense melancholia and nihilistic, somatic, or paranoid delusions or hallucinations. A number of syndromes are classified under the category of affective disorders. At the top of the scale in intensity are *major depressive disorder* and *bipolar disorder.* The latter is characterized by alternating moods of elation and depression and is constituted by three subtypes: (1) *bipolar disorder, manic,* in which expansiveness and overactivity are dominant; (2) *bipolar disorder, depressed,* in which sadness and retardation are prominent; and (3) *bipolar disorder, mixed,* in which one or the other mood occurs within a short span. *Cyclothymic disorder* is a mixed affective disorder of lesser intensity. Depressive reactions that often follow psychosocial stress and promote sleep disturbance, fatiguability, social withdrawal, and ahedonia are classified as *dysthymic disorder* (depressive neuroses, reactive depression). Atypical features of a mixed reaction merit the diagnosis of *atypical bipolar disorder;* or if the mood is primarily depression without the usual characteristics of a major depression or dysthymic disorder, they are regarded as signs of an *atypical depression.* Shadings of depression with schizophrenic symptoms have been called *schizoaffective disorder.*

According to some researchers, bipolar and unipolar disorders are two distinct entities. There is some controversy about the precipitating factors that activate a bipolar disorder. In some cases, stress seems to initiate an attack. In other cases, endogenous causes are implicated that appear to have little relation to environmental or inner conflictual sources. Typical of the manic phase are euphoria, irritability, grandiosity, hyperactivity, pressure of speech, and flight of ideas. After recovery and a varying interval of relative calm, a depressive phase may intervene, marked by sluggishness, retardation, loss of appetite, insomnia, and somatic distress. Symptoms vary in intensity from being so mild and under control that the illness is overlooked to being floridly psychotic. It is important to distinguish major depressive disorder from bipolar disorder. To establish the unipolar diagnosis, there must be at least three episodes of depression without a manic episode. Atypical symptoms may confuse the diagnosis, such as when mania masks itself as a personality problem in spurts of creative overactivity and productiveness and depression is concealed by dry humor and a smiling countenance. The search for biological markers goes on, but the Dexamethasone Suppression Test (DST), the TRH

Stimulation Test, catecholamine metabolite levels, urinary phenylacetic acid levels, and sleep EEG studies are still inconclusive.

Depressive Reactions

Depression is one of the most common syndromes encountered in psychotherapeutic practice. Approximately 20 to 26 percent of women and 8 to 12 percent of men will be affected by at least one episode of depression in their lifetimes. Symptoms of this illness vary, but most often it is manifested by listlessness, fatiguability, loss of interest in practically all activities, diminution of the sexual drive, disturbances in appetite and sleep, feelings of worthlessness, self-reproach, and, in severe cases, psychomotor agitation or retardation and suicidal ideas or impulses. Bipolar depressions are characterized by periodic manic phases with swings toward hyperactivity. In most severe depressions, psychotic ideation is not uncommon. Once a depression occurs, there is a 40 to 50 percent likelihood of a second attack, and in the majority of these cases, subsequent attacks are possible. The person may then be plagued by recurrent depressions throughout his or her life. Some depressions seem to persist over a period of years with varying degrees of intensity; others apparently disappear; still others disappear only to recur at some time later.

Depression is a common reaction to separation and bereavement. It may become especially intense after the loss of an important person, such as a spouse, parent, child, or love object, inspiring grief and mourning. In most people the depression, after a period, is resolved. Its continuance or appearance and persistence when there is no adequate stimulus to account for it has a pathological significance and may require clinical intervention. Sometimes depression accompanies a severe physical illness, particularly if its chronic quality makes the person feel hopeless or proper functioning is impaired. Thus cancer, crippling arthritis, Parkinson's disease, cardiac failure, and other enduring medical and neurological ailments may sustain a prolonged depression. Aging, with its effect upon one's health, appearance, memory, and work capacities, is an especially provocative depressive stimulus. Substance abuse and detoxification (alcohol, amphetamines,

barbiturates, narcotics, etc.) are frequently followed by a spell of depression that drives the person to more drinking or drug indulgence. The intake of certain medicinal agents such as antihypertensives (Reserpine, Diuril, Hygroton, etc.) and beta blockers (Inderal, Corgard, etc.) may also produce depression.

Depression sometimes merges with anxiety, making it difficult to distinguish the two. Confusing also is "masked depression" that is camouflaged by such somatic symptoms as headache, backache, facial and limb pains, dysuria, dyspareunia, dysmenorrhea, and sundry other complaints. A puzzling relationship exists between certain psychiatric syndromes and depression. Some observers consider conditions such as anorexia nervosa, bulimia, panic attacks, and obsessive-compulsive neurosis to be manifestations of neurotransmitter abnormalities akin to those of depressive illness, and, most important, they are relieved by antidepressants. Depression in childhood often takes the form of somatic illnesses such as headaches and abdominal pain mingled with a dysphoric mood. Aggressive and hyperactive children may also actually be suffering from depression. Depression among the elderly is common and is accompanied by relatively frequent somatic concerns, memory and cognitive deficits, and occasional paranoid delusions.

The diagnosis of depression is not difficult to make with a good clinical interview. Some physical ailments, however, mask themselves as depression. Gianninni et al. (1978) list 91 such ailments, and Hall (1980) lists almost as many. Consequently, a physical examination and laboratory tests should be done on all depressed patients. Similarly, substance abuse may produce depressive symptomatology and if suspected will justify urine and blood drug abuse screens. Some clinicians recommend the Dexamethasone Suppression Test if there is a problem in differential diagnosis. The DST can identify at least 50 percent of severe depressions (major depressive disorder) but is less accurate in detecting mild to moderate depressions. Certain medical problems, commonly prescribed medications, and some psychiatric disorders can distort DST results, and a negative DST does not rule out severe depression. At this stage, therefore, the test should not be employed as a routine diagnostic procedure although it still has some utility in research.

In reactive or neurotic depression (dysthymic disorder) some ostensible blow to security or self-esteem seems to set off the depressive pattern. The stress stimulus may be loss of a love object, of status, or of worldly goods. The meaning to the individual of the traumatic incident is the key to whether or not depression will result. The depressed patient organizes his or her thinking around the precipitating incident. If a love object has died or abandoned the patient, he or she is preoccupied with the image of the departed one. If status is impaired, the patient considers that he or she is "a nothing." Loss of worldly goods sparks off a poverty complex. The question is still not completely answered as to why some people respond with depression to a crisis in their lives, whereas others marshal their adaptive resources and overcome the vacuum created by the incident. Dynamically, reactive depression is related to (1) feelings of loss of a love object (expressed as feelings of isolation and emptiness), (2) a feedback of hostility blocked from external expression (expressed in self-deprecatory comments) in a masochistic maneuver, and (3) a converted form of anxiety (here anxiety and depression may alternate, depression apparently serving as a means of dealing with anxiety).

Major depressive disorder and bipolar disorder spring from biological disturbances presumably hereditary in nature and can develop periodically without identifiable exogenous or internal conflictual provocations. Social and psychological disruptions consequent to such biological depressions in turn can aggravate the symptoms. Depression in such conditions is often ushered in by feelings of loss of self-confidence, the absence of initiative, and fatiguability. The depressive mood itself may not be apparent; it is often covered by an overlay of hollow humor in what has been called the "smiling depressions." As the depression deepens, loss of appetite, insomnia, diminution of the sexual drive, and a general anhedonia (lack of gratification in the pursuit of pleasure strivings) follow. There are difficulties in attention and concentration and variations in mood, the intense depression during the morning lifting as the evening approaches. Interference with work and interpersonal relationships follow. Extreme suffering and regression to early dependency with masochistic behavior then develops in the course of which suicidal thoughts, impulses, and acts may erupt.

Principal goals in therapy consist of the following:

1. Removal of symptoms and a relief of suffering.

2. Revival of the level of adaptive functioning that the patient possessed prior to the outbreak of the illness.

3. Promotion, if possible, of an understanding of the most obvious patterns that sabotage functioning and interfere with a more complete enjoyment of life.

4. In motivated patients, recognition of conflictual patterns and exploration of their meaning, origins, and consequences.

5. Provision of some way of dealing with such patterns and their effects in line with a more productive integration.

Unfortunately, depressions are singularly resistive to treatment in that the mood change imposes a barrier to three of the most important elements in therapy: faith, hope, and trust. Lost is the expectancy of getting well that so often powers the machinery of cure. Gone is the feeling that someone cares, so essential in establishing a therapeutic relationship. Yet beneath the isolation and hopelessness, the depressed individual seeks a restoration of his or her ties with humanity. The person resists relationships, and then credits the feelings of isolation to the fact that he or she is unloved.

Among the therapeutic measures that are most effective are the following:

1. *Establish as rapidly as possible a relationship with the patient.* This is precarious as has been mentioned before. Yet winning the patient over in spite of inertia, gloom, sluggishness, despair, hostility, and self-recriminations is urgent. Depressed patients are insatiable in their demands for help and love. No matter how painstaking are the therapist's attempts to supply their demands, they will respond with rage and aggression, often accusing the therapist of incompetence or ill will. The patients should, nevertheless, be approached with the attitude that the therapist understands and sympathizes with their suffering. Such measures as active guidance and externalization of interests may be attempted. The basis of treatment is a warm relationship between the patient and the therapist. The relationship that the patient establishes with the therapist

will, however, be extremely vulnerable. Much leniency and tolerance are needed, and an attempt must be made to show that the therapist realizes the depth of the patient's fears and misgivings. This, however, is more easily said than done, since the depressed patient has a distrustful nature.

Distrust springs from the fusion of hate with love. Hostile feelings generate guilt that may be so disabling that the person will want to discontinue treatment. The slightest frustration during therapy, such as the unavoidable changing or canceling of an appointment, may be equivalent to rejection and will mobilize a tremendous amount of anxiety. Under the surface there is always fear of abandonment, and there is a tendency to misinterpret casual actions. The patient seeks reassurance but may resent its being called psychotherapy.

The aim in treatment is to develop and reinforce all positive elements in the relationship. This will involve much work, since the attitudes of the patient are so ambivalent that he or she will feel rejected no matter what the therapist does. It is best to let the positive relationship take root in any way it can without attempting to analyze its sources.

One of the means of maintaining the relationship on a positive level is by communicating empathy and by avoiding arguments. It is essential to convey to the patient nonverbally the idea that he or she is liked and that the therapist is a friend in spite of anything that happens. An attitude of belittling, harshness, ridicule, or irritation must be avoided. The therapist must maintain an optimistic outlook and express the sentiment that although the patient may not believe it now, he or she *will* get over the depression in a while.

Hypnosis may be of help for some of the milder depressions as a means of establishing a relationship primarily as an avenue toward inducing relaxation and toward giving persuasive suggestions to stabilize the person. A number of depressed patients appear to thrive under hypnotic therapy, probably because it appeals to their dependency needs.

2. *Use drug therapy when necessary.* Benzodiazepines such as Valium and Xanax may be of help in patients with mild depressions, especially those associated with anxiety, in elevating the mood and supplying energy. Simple mild depression occasionally is helped by methylphenidate (Ritalin) but should be taken for no more than 3 weeks. More severe

inhibited depressions may be approached with imipramine (Tofranil) (100-200 mg daily), while agitated depressions appear to respond better to amitriptyline (Elavil) (100-200 mg daily) combined, if anxiety is especially strong, with Librium (30-40 mg). In very severe anxiety 20-25 mg 3 or 4 times daily may be given. The effects of the latter drugs may not be felt for several weeks. The MAO inhibitors (Nardil, Parnate) are also of some value, especially for atypical or neurotic depressions. Bupropion (Wellbutrin) is an antidepressant with a minimal effect on sexual functioning. Some experimental drugs for depression are being tested, which have low side effect profiles. These include idazoxan and S-adenosylmethionine.

If side effects are intolerable, some of the newer depressive agents may be tried, such as trazodone (Desyrel) and maprotiline (Ludiomil). Mellaril has been employed for depressions of the schizoaffective type. If a schizoid element is present, a phenothiazine drug (Trilafon, Stelazine) may be combined with Tofranil and Elavil. In bipolar depressions, lithium has been given, but in almost one-third of cases it is ineffective or produces bad side effects or sparks of manic attacks. Alternative therapies have been tried, including anticonvulsants such as carbamazepine (Tegretol), valproic acid, (Depakene), tryptophan, thyroid medications, calcium channel blocking agents, and propanolol. Carbamazepine has been increasingly employed because, unlike combined tricyclic-lithium and neuroleptic-lithium treatments, it does not encourage more rapid cycling. Haldol and Navane are often used for psychotic depressions. Depression during medical illness often responds well to triglycerides. (See also Chapter 56, Somatic Therapy for a detailed description of antidepressant medications.)

If drugs are used, patients should be told about the side effects to encourage the continuation of the medications in spite of them. Side effects are the chief reason why antidepressants are discontinued. The need for sleep may be reduced without harmful effect, and the patient may, if not forewarned, take excessive hypnotics. Constipation and weight gain may occur and require remedial measures. Mouth dryness may be counteracted partly by chewing gum or glycerin-based cough drops. Postural hypotension of a severe nature may be handled by advising the patient not to arise suddenly, to avoid standing unmoving in one place, and for women to wear elastic stockings and a girdle. Neuralgias or jactitation of the muscles may require 50 mg vitamin B_6 and 100 micrograms of vitamin B_{12} twice daily. Coffee intake should also be reduced. The troublesome

insomnia in depression is best handled by chloral hydrate (Noctec, 1½ gm) or the benzodiazepine hypnotics (see Insomnia). The patient may be given a mimeographed form about the side effects of drugs (see Appendix T). In older people, antidepressants such as Elavil may be effective, but the dose after the age of 60 must be cut down to 25-100 mg daily. Tetracyclic antidepressants are useful in this group because of the minor anticholinergic and cardiovascular effects. Maprotiline, for example, may be started with 25 mg to 50 mg daily, increasing by 25 mg every third day until 75 to 100 mg is reached, which can then be given in a single-evening dose. Some drugs have been introduced to reduce intolerable anticholinergic effects, e.g. bethanechol, and cyclic tremor, e.g. propranolol.

3. *Administer electroconvulsive treatments immediately in severe depressions, or if there is any danger of suicide.* Electroconvulsive treatments are superior to any of the present-day drugs. (See section on Electroconvulsive Therapy in Chapter 58.) The effect is rapid, 8 ECTs generally eliminating the depression; however, more treatments may be required. In very severe agitated depression, 2 ECTs daily for 2 or 3 days may be followed by 1 ECT daily, and then by treatments twice or three times weekly. Following ECT, energizing drug therapy may be instituted (Tofranil, Elavil) and, if agitation continues, Thorazine or Trilafon can be prescribed. Unilateral ECT may be employed if even temporary memory loss cannot be countenanced. The superiority of ECT over drug therapy for psychotic depression is without question.

4. *Hospitalize patients with severe depression.* Mild depression may be treated at home, preferably under the supervision of a psychiatrically trained attendant or nurse, or, better still, and especially if family problems exist, the patient should be admitted to a rest home. Isolation from parents and friends, bed rest, and constant care by a motherly attendant may prove very beneficial. Because of anorexia, efforts should be made to bolster the diet with high caloric and high vitamin intake in the form of small but frequent feedings. In severe cases of malnutrition, a few units of insulin before meals may be helpful. If the depression is more than mild, hospitalization is advisable. Suicidal attempts in depression are made in almost one-third of the cases, and deaths resulting from these attempts occur with great frequency. The patient's complete loss of interest in himself or herself makes mandatory the establishment of definite daily routines, such as a hospital can best supply. Electroconvulsive therapy, the treatment of choice, can best be instituted in a hospital setting, and, if

the patient requires tube feeding, nursing care is available.

5. *Institute psychotherapy as soon as feasible.* Psychotherapy is usually ineffective during extremely depressed phases. The only thing that can be done is to keep up the patient's morale. Patients should not be forced to engage in activities that they resist because this may merely convince them of their helplessness and inability to do anything constructive. If there is little suicidal risk, patients should be encouraged to continue their work, if they feel at all capable of managing it, since inactivity merely directs their thinking to their misery. In many cases, contact should be regulated with the patient's family and environment. This is necessary since the family of depressed patients often chides them for "not snapping out of it" and constantly reminds them that they must make up their mind to get well. The family members may be told that recovery is more than a matter of will power, and they must be urged to avoid a nagging and critical attitude.

6. Sleep deprivation therapy is still in an experimental state with varied reports attesting to its efficacy (King 1980), uncertainty of benefit (Pflug 1976), and possible worsening of the depression (Vogel et al, 1973). Different procedures have been employed, including sleep deprivation for only one night totally, one night weekly, several nights weekly, and partial sleep deprivation in which the patient is awakened repeatedly during sleep.

Exactly how to conduct psychotherapy is difficult to say. Much depends on the training and skill of the therapist and his or her ability to establish a therapeutic alliance (Arieti, 1978). In general, during the acute depressed stage a supportive, reassuring manner is best, shying away from probing for unconscious material, which may increase anxiety and heighten the possibility of suicide. The patient is given an opportunity to verbalize his or her fears and feelings. Guidance, support, reassurance, and persuasion are used. The patient is told that no matter how bad things seem and how depressed he or she feels, patients with depression recover. There are, however, steps that can be taken to speed recovery: It is essential that the patient get involved in his or her usual activities to the extent that available energy will allow, but not beyond this. Because initiative may be lacking, the patient may require a daily routine for retiring, arising, meals, working, and social and recreational contacts. One difficulty encountered is dealing with the tendency for denial regarding the severity of the problem and the need for treatment. Regardless of

the therapy employed, the countertransferences of the therapist are apt to be brought into play and will have to be handled appropriately. The tendency of the patient to employ the therapist as a replacement for an object of loss has to be handled with tact and understanding, avoiding rejecting the patient without supporting too enthusiastically a dependency relationship and without draining oneself too much with givingness and empathy.

Dealing with the depressed patient calls for a good deal of optimism, support graded to the patient's requirements, and need to control the tendency to be overprotective and overly reassuring. The patient must be made to feel that the therapist understands him or her and will do everything possible to help. The self-limited nature of depression should be repeatedly pointed out and the patient reminded that eventually he or she will feel much better, as others before have. Depressive ideas should never be ridiculed or accepted at face value. The therapist should point out that the situation is not as hopeless as it seems. If the patient harbors suicidal thoughts, a frank aeration of these feelings should be encouraged. It may be essential to extract a promise from the patient that he or she will not try suicide. If suicide is more than a passing fancy immediate ECT is necessary. A physical basis (biochemical, for example) for the depression may be presented and the patient told that there are medications that can help. "When an emotion of depression develops everything seems gloomy, but this will pass." Much of the benefit from psychotherapy is due to the relationship with the therapist. Appreciation of the therapist as a person who cares is important in securing cooperation. Family therapy may be indicated to manage guilt feelings in the members and to educate them regarding factors that can create a more harmonious relationship with the patient. Marital therapy can also be important, as may group therapy and behavioral therapy. Termination of therapy will have to be managed carefully because of the depressed person's sensitivity to loss. Adequate time must be given prior to terminating psychotherapy to allow for the working through of grief and rage reactions, which if neglected may spark off another round of depression. If a transfer to another therapist has to be made, the therapist must be careful not to give the patient the impression he or she is being rejected and pushed off into the hands of substitutes, which may be interpreted as another object loss and precipitate a

deeper depression.

In depressions that have followed in the wake of actual or fantasied loss of a love object we may expect a rapid, positive transference as a means of object replacement. The substitution, however, is often rooted in magical expectations with desires for a giving, loving, nurturing, and omnipotent object reincarnation. The immediate reaction may be a temporary lifting of one's spirits, an overidealization of the therapist, and a stimulation of hope and anticipation that all will be well.

Inevitably, as the relationship with the therapist develops, the patient becomes aware of some failings in the therapist, a realization that the therapist is not the all-giving, all-powerful figure he or she imagined. What will emerge then is hostility and a feeling that the therapist has failed in anticipated obligations. The patient may try to vanquish his or her hopelessness by repressing doubts about the therapist, and passively submitting to the therapist with a sadomasochistic dependency. The hostility is usually suppressed by guilt feelings or in response to disapproving or attacking maneuvers on the part of the therapist. Depression may then return in full force or even become greater than before. Yet the patient will cling desperately to the therapist out of fear of undergoing another object loss.

The countertransference of the therapist will determine the fate of these transferential shifts, the proper handling of which will enable the patient to work through the termination phase of therapy. This involves resolution of the separation and grief reactions associated with loss of the love object that had initiated the depression. Some impact may also be scored on the original separation traumas sustained during the developmental years that sensitized the patient to later object loss.

Klerman has described a brief interpersonal psychotherapy (IPT) (12-16 weeks) for ambulatory, nonbipolar, nonpsychotic depressed patients aimed at symptom relief and enhanced interpersonal adjustment, rather than at personality change. The treatment is organized around the premise "that clarifying and renegotiating the (interpersonal) context associated with the onset of symptoms is important to the person's recovery and

possibly to the prevention of further episodes" (Klerman et al, 1984b). A procedural manual (Klerman et al, 1984a) designating the rationale and techniques has been prepared and the method tested against some other treatments for depression. IPT rests on the assumption that depression issues out of stress induced by life events, especially social adjustment and interpersonal relations. Predisposing to the depressive reaction are personality factors, especially those involving self-esteem and the handling of guilt and anger. Therapy consists of exploring immediate interpersonal difficulties and then clarifying and modifying them. Alteration of maladaptive perceptions is attempted without delving into unconscious conflict or childhood antecedents or developing and exploring transference. Four interpersonal precipitants are particularly dealt with, namely, grief, role disputes, role transitions, and interpersonal deficits. Controlled studies have shown that IPT significantly lessens symptoms and after 6 to 8 months, social impairments. The final appraisal of IPT awaits further replication studies.

Cognitive therapy for depression can also be helpful and in some cases is superior to drug therapy. In cognitive therapy an attempt is made to rectify conceptual distortions in order to correct the ways that reality is being experienced. Interviewing techniques analyze defects in a patient's views of the world (cognitive assumptions or "schema"), methods of stimuli screening and differentiation, and the erroneous ideas that mediate destructive response patterns. Homework assignments reinforce the patient's ability to deal constructively and confidently with adaptive tasks. The treatment is short term, consisting of approximately 20 sessions on a twice-a-week basis. Cognitive therapy for depression is organized around a number of assumptions (Rush & Beck, 1978; Rush et al, 1977). As a consequence of early events, the patient retains a "schema" that makes him or her vulnerable to depression. Among such events is the death of a parent or other important person. What results is a "predepressive cognitive organization." Operative here is a global negative attitude on the part of the patient. Thus the patient misconstrues situations to a point where "he has tailored facts to fit preconceived negative conclusions" (Rush, 1978).

Depressed patients regard themselves as unworthy and assume this is because they

lack essential attributes to merit worthiness. They assume their difficulties will continue indefinitely in the future, that failure is their destiny. These characteristics constitute the "cognitive triad" in depression. In treatment these patients are enjoined to keep a record of aspects of their negative thinking whenever this occurs and to connect these episodes with any associated environmental events that trigger them off. The simple quantifying of any symptoms—in this instance negative thinking— tends to reduce them. Whenever the patient during a session brings up a negative thought, the therapist asks the patient to reality-test it and then to do this away from therapy. Through this means patients are helped to see how they make unjustified assumptions ("arbitrary inferences"), how they magnify the significance of selected events ("magnification,") and how they use insignificant situations to justify their point of view ("overgeneralization"). Other "cognitive errors" are identified, such as how offensive details are used out of context while ignoring more important constructive facts ("selective abstraction"), how circumstances and thoughts that do not fit in with negative "schemas" are bypassed ("minimization"); how unrelated events are unjustifiably appropriated to substantiate their ideas ("personalization"). The patient is encouraged to review his or her record of thoughts, to identify past events that support his or her faulty schemas. Point by point, the therapist offers alternative interpretations of these past events. By so doing, the therapist hopes that sufficient doubt will develop in the patient so that he or she will engage in experimental behaviors, recognizing the fallaciousness of his or her hypotheses, and arrive at different, less destructive explanations for events. A marital partner or family may also be involved in cognitive therapy to reinforce correction of distorted negative meanings.

Step by step the patient is encouraged to undertake tasks that he or she hitherto had considered difficult ("graded task assignment") and to keep a record of his or her activities ("activity scheduling") and the degree of satisfaction and sense of mastery achieved ("recording a mood graph"). Discussions in therapy focus on the patient's reactions to his or her tasks and tendencies at minimization of pleasure and success. Homework assignments are crucial. These range from behaviorally oriented tasks in severe depression to more abstract tasks in less severe cases oriented around correcting existing

schemas. Should negative transference occur, it is handled in the manner of a biased cognition.

The material elicited during the periods of active depression, both as to mental content and as to the character of the relationship with the therapist, may yield important clues to the inner conflicts of the patient. Although notes may be made for later reference, all confrontive interpretations during the active period should be suspended. Only during a remission can interpretive work of any depth be helpful. In most cases interpersonal and cognitive therapies are useful, but depth therapy is avoided in patients with major depressive disorder. Some patients with dysthymic disorder spontaneously express a desire to know more about their illness. Here, a dynamic insight approach may be used. Many patients, however, show an unwillingness to go into their difficulties and resist insight therapy. Having recovered, they are convinced they are well, and they desire no further contact with the therapist. Without the "wish" to get well, little can be accomplished in the way of reconstructive psychotherapy.

Following recovery, the patient should be guided regarding the possibility of further depressions. If the patient has been on medications, half to two-thirds of the effective dose should be continued for at least 4 months. An excellent discussion on therapies helpful for severely depressed suicidal patients may be found in the paper by Lesse (1975). Insofar as prophylaxis is concerned lithium presents promise. Controlled studies have shown that lithium can substantially reduce the long-term morbidity of both unipolar and bipolar disorders. Unipolar patients with endogenous and psychotic features, a family history of depression, and minor disturbance in personality respond well. Prophylactic treatment should be started after 3 episodes in unipolar depression and after the second episode in bipolar depression. Lower lithium plasma levels (0.45-0.6 mEq/l) are maintained best to reduce side effects.

Manic Reactions

The immediate objective in manic reactions is to quiet the patient. This is best achieved with neuroleptics, such as chlorpromazine (Thorazine), which must be

administered in ample dose (up to 1600 mg daily or more). In wild excitements, intramuscular injections (25-50 mg repeated in an hour if necessary) are indicated, followed by oral administration. (See also Chapter 58 on Emergencies.) Dangerous overactivity may call for electroconvulsive therapy (ECT). This may be given twice daily for 3 or 4 days, followed by a treatment every other day. Following this, Thorazine or other neuroleptics may be substituted. Lithium carbonate (see Chapter 56 on Pharmacotherapy) has been employed with considerable success for recurrent manic states. The most effective treatment for mania is reported by Black et al., (1987) to be ECT. Almost 70 percent of patients who did not respond to lithium had marked improvement with ECT.

Psychotherapy is usually ineffective in most manic conditions. The patient's attention is too easily diverted; acting-out is too unrestrained; emotions are too explosive. Because of this, hypomanic and manic patients are extremely difficult to manage in the office. They will seek to involve the therapist in all of their fantastic plans. They will make demands which, when unfulfilled, will release great hostility or aggression. They will try to overwhelm and dominate those around them, and they may become uncontrollable when their wishes are not gratified.

One of the chief reasons for hospitalizing overexcited manic patients is to prevent them from involving themselves and other people in projects that issue out of their overconfidence. Because they are inclined to be erotic, they must be protected from sexual indiscretions and from a hasty marriage that they may contract on the crest of an ecstatic wave. Another reason for early hospitalization is that some manic cases will go into a state of delirium when they are not treated intensively at the start. These delirious attacks may be fatal if they give rise to exhaustion, dehydration, and hypochloremia. Sedation, tranquilization, and electroconvulsive therapy are most easily administered in a hospital setup.

SCHIZOPHRENIC DISORDERS

(Types and DSM-III-R Codes: Catatonic 295.2X, Disorganized 295.1X, Paranoid 295.3X,

Undifferentiated 295.9X, Residual 295.6X)

Schizophrenia, in spite of the massive amount of accumulated data, remains psychiatry's greatest challenge (Bleuler E, 1950; Bleuler M, 1984; Arieti, 1959, 1974; Redlich & Freedman, 1966; Cancro, 1985). The question of whether it is a special disease entity or a unique way of experiencing is still being debated. Although it affects less than 1 percent of the population, its devastating influence on the patients and its cost to society are astronomical. Efforts to understand it along neurophysiological, biochemical, genetic, psychosocial, epidemiological, psychoanalytic, existential, anthropological, cultural, and communicative lines have been heroic. But many aspects of the illness are still unclear. Neither biochemical nor analytic-psychological investigations have brought us closer to its real essence.

While we do not have a complete picture regarding the etiology and pathology of schizophrenia, it is reasonable to assume from all the available evidence that a genetic factor exists. For one thing, the fact that the concordance ratio for schizophrenia is three times greater in monozygotic than in dizygotic twins suggests a hereditary component. But the finding that in 50 to 75 percent of monozygotic twins one member *does not* become schizophrenic when the other twin develops the disease indicates that a genetic deficit is not enough to produce schizophrenia. Nongenetic constitutional factors must also be considered, for example, flaws through damage to the brain during intrauterine life or as a result of birth trauma. In short, while schizophrenia appears to be a genetically determined disease, its phenotypical expression is, at least in part, influenced by life experience.

Among the life experiences that have a destructive impact is the use of the child by the parents as a foil for their own neuroses. When parents are themselves emotionally unstable and mentally confused, they are unable to provide sensible and temperate learnings. The child thus receives training in irrationality, as Lidz (1973) has remarked. Communication patterns are distorted and the child is exposed to contradictory messages. There is defective gender identity and a crushing of the child's efforts at autonomy. The parents offer poor role models for the child. The consequence of the personality deficits

that eventuate out of these conditionings is a deficiency in ways of interpreting reality and of handling and resolving stressful life events.

Of all speculations advanced to account for the outbreak of schizophrenia, the stress hypothesis seems to many to be the most feasible. Postulated here is the idea that stress activates in the schizophrenic individual anomalous biochemical and neurophysiological mechanisms as a result of faulty enzyme action. It is avowed that the end product of this action is hyperactivity of catecholamines, especially dopamine, as well as the release of pathological psychotogenic metabolites, resulting in a disorganization of brain function. Some authorities have also conjectured the existence of increased numbers of dopamine brain receptors to account for dopamine hyperactivity. In some cases, computed tomography shows ventricular enlargement in the brain, which has been correlated with such negative symptoms as emotional flattening, social withdrawal, and lack of energy.

When we search for stress sources that may have precipitated a schizophrenic breakdown we often find it to be environmental events that have a special traumatic meaning for the individual. Perhaps the most powerful sources of stress are disturbed family interactions, and there is ample evidence of difficulties in families of schizophrenic patients. A provocative question is why all members of a family in which there is a schizophrenic member are not affected with schizophrenia. The answer is that there is no such thing as the same environment for all family members, even for identical twins. Some are more protected than others; some are chosen for projective identification by a mother or father; some are scapegoated, or subjected to contradictory demands, or exposed to discriminatively defective communication signals. The consequence is an interference in the character organization, making for conflicts that in themselves become sources of tension. The stresses that impose themselves on the individual therefore are environmental difficulties from without and disturbances from within (biochemical and cognitive). Such stresses may become critical at certain periods in the developmental cycle (as during adolescence) and when pressures and demands both from without and within exceed the individual's coping capacities.

Many schizophrenic patients were exposed to *selective illogic* in early development, which made for irrational thinking around specific areas. The consequence is that the patient can think seriously about certain subjects and disjointedly about other subjects. He or she can deal better with selected stresses and be completely unable to manage other stresses to which he or she is singularly sensitive.

Among the deficits that emerge from a difficult childhood are an overwhelming sense of helplessness, a defective self-image, and overpowering hostilities. These impulses are handled by defenses organized around different levels of reasonableness. Helplessness may be managed by either a dependent clinging to some magical protective figure or movement, or by denial manifested in compulsive independence. Ambivalence toward objects will make for varied responses to people and be so disturbing to the individual that he or she will become apathetic and detached from people to avoid being rejected, hurt, or completely engulfed in a relationship. A defective self-image gives rise to a host of coping devices, ranging from inferiority feelings on one end to grandiosity on the other. The hostility may be turned outward in sadistic attitudes and aggression, or turned inward in the form of masochistic self-punishment. In part, reactions are the product of a massive biochemical upset set off by stressful stimuli with which the individual cannot cope. Impulses are fed through neurophysiological channels disorganized by these biochemical alterations. This produces changes in the transmission messages in the subcortex, ultimately influencing thought processes. Because of the existing pockets of irrationality, the manifestations of these impulses and the defenses that control them may in cases of extreme distortion become highly and even psychotically symbolized and distorted. Thus dependency may be expressed by feelings of being influenced and manipulated by powerful or protective or malevolent agencies or machines. A devalued self-image may take the form of being accused by voices of emitting a foul odor or of having changed into an animal. Or it may be neutralized by the defense of a grandiose delusion. Hostility may be acted out directly in terms of paranoidal delusions and of violence toward persecutory enemies. Periods of rationality may alternate with those of irrationality, and the nature of the symbols may vary. When emotional stability is restored, pathological manifestations may temporarily vanish, only to reappear under the

further impact of stress.

Most people who are able physiologically to deal with stress are threatened with periodic irrationalities but are able to process these cognitively and to control them without distorting reality. Yet psychotic-like impulses may appear in fantasy or in dreams. Other persons maintain their stability by circumscribing and isolating areas of psychotic or psychotic-like thinking or behavior, for example, by paranoidal ideation which serves as an outlet for hostility. This defense permits them to function and to maintain some adaptive capacity. Still other persons decompensate temporarily under the impact of stress and show overt psychotic behavior from which they rapidly recover *(schizophreniform disorder).* If there is a specific genetic vulnerability, however, the cognitive distortion may be extensive and prolonged, resulting in the syndrome of schizophrenia.

The onset of schizophrenia varies. Often it is insidious, becoming apparent only in late adolescence or in early adult life. The individual shows behavioral changes such as isolation and withdrawal and may drop out of school or quit work. Emotionally the schizophrenic may be unstable and depressed and resort to drugs or alcohol for relief. Unhappy at home, the schizophrenic may run away, seeking out groups of other isolated children or young adults with whom he or she may establish an unstable affinity. Affiliations are shallow, ideation more or less fragmented, the self-image devalued, and the boundaries between reality and fantasy blurred. The expression of needs is chaotic, and often fulfilled only in fantasy. Omnipotent, grandiose, and paranoidal ideas prevail. There is constant moving about as the person seeks some refuge in relationships that eventually are distrusted and abandoned. There is repeated experimenting with disorganized ways of regaining control, solving problems, bolstering security, and enhancing self-esteem.

Once a genetic vulnerability exists, the individual always is at high risk. The avoidance, removal, or palliation of environmental situations that have a stress potential for the person, the identification and mediation of faulty behaviors through

psychotherapy, the building of self-esteem through positive achievements and productive work, the presence of accepting role models with whom the patient can identify, the utilization of support systems where necessary, and the administration of neuroleptics when a breakdown threatens may bring the individual back to his or her customary equilibrium.

The big problem for the therapist at this early stage is that the patient has little or no motivation for treatment. He or she distrusts people and resists any kind of close relationship, the vehicle through which psychotherapy is done. If treatment is attempted, it will take all the tact and resourcefulness a therapist can muster to keep a patient coming for sessions in the face of his or her detachment, suspiciousness, fear, and hostility. The therapist should try to avoid giving commands and orders because the patient will resist them. Nor should any mention be made of the need for or direction of change. Clues as to focus are gathered from what the patient is interested in and wants to deal with. No judgments should be expressed about the patient's behavior or dynamics except when the patient asks. Even then, interpretation must be carefully and reassuringly made. Attempts to alter the patient's attitudes, to plan goals, and to offer suggestions on how best to manage one's personal affairs will usually be resisted. Breaking of and lateness in coming for appointments call for great flexibility in time arrangements. The therapist concentrates on ways of solidifying the relationship with the patient and on introducing some reality into the patient's perceptions of what is happening to him or her. In spite of remedial interventions, the schizophrenic process may proceed to an adaptive breakdown that defies all efforts at resolution. An external precipitating factor may or may not be apparent, but a search for it should be instituted.

Removing the Stress Source: Hospitalization

If the patient's psychosis has been precipitated by an *overwhelming* external traumatic situation, simple environmental manipulation may help, if not suffice, to bring the patient back to his or her prepsychotic level of adaptation. Most schizophrenic reactions, however, are associated with such great weakness of the ego that the person is

unable to withstand even average pressures. There is variation in the degree of stress that can be tolerated. In some, ordinary responsibilities of living and relating to people cannot be mediated. Environmental manipulation may not suffice to restore the patient because he or she senses menace everywhere, even in the most obviously congenial atmosphere. There is faulty information processing.

Fears rooted in past inimical conditionings and damaging conflicts seem to generate anxiety continuously and prevent the ego from emerging from its regressed level. The patient erects a wall of detachment and isolation as a protection from further hurt; it is this wall that interferes so drastically with any attempted therapy.

If the patient feels threatened in his or her present environment in spite of efforts at regulation, if his or her responses constitute a potential source of danger to the patient and others, and if the patient cannot be treated satisfactorily in the existing milieu, temporary hospitalization may be inevitable. The employment of psychotropic drugs and consultation with the patient's family in an effort to get them to be less critical, hostile, demanding, and demonstratively emotional toward the patient may enable the patient to adapt outside of an institutional setting. There will still be acute emergencies, however, for which no other alternative is available than hospitalization, either on the psychiatric ward of a general hospital or in a mental institution.

On the other hand, there are certain disadvantages to hospitalization. The most insidious feature of "institutionalization" is that the patient's tendencies to regress will be reinforced enormously by any lack of stimulation in the hospital. As one of a large group of patients, the individual may lose his or her identity. The patient becomes dilapidated in appearance and oblivious to customary habit routines. There may be little in the environment to encourage latent desires for growth and development. This unfortunate feature is due, to a large extent, to the overcrowding of institutions and to the lack of enlightenment and education of the personnel. The motives governing an employee's choice in working in an institution may not be those helpful to restoring the patient to active participation in society.

That hospitalization can prove to be a stimulating rather than a retarding influence is illustrated in institutions with a progressive administration and well-trained personnel. Selected occupational therapy and crafts, carefully chosen to meet the patient's interests and aptitudes, can help prevent the abandonment of reality. Exercises, games, entertainment, dancing, music, social affairs, and group discussions can also be of inestimable benefit. When it is practiced in an empathic setting, group therapy of a short-term nonpsychoanalytic nature (Parloff, 1986) may be helpful. The benefits of such therapy help convince the patient that he or she is not considered hopeless, in this way building up a feeling of confidence in the therapist and in oneself. It is probable that the old-time Aschner treatment for schizophrenia, with its emphasis on detoxification, stimulation, exercise, baths, sweats, venesection, catharsis, emesis, and hormone therapy, was mostly psychological in effect. At any rate, hospitalization should be regarded as a temporary measure, and the patient should be moved back into the community as soon as possible.

Milieu Therapy

Regulation of the environment so that it is therapeutically constructive, meaning that it provides stress relief and gratifying experiences, is important in treating schizophrenia. Occupational, recreational, and social therapy may be gainfully instituted in a hospital or outpatient setting. The atmosphere of a day-and-night hospital, halfway house, or community rehabilitation or recreational center also lends itself to environmental control and social skills training. A total therapeutic community program (e.g., with a suitable group) may prove rewarding. Settlement in the community and encouragement to engage in productive work is much better for the patient than assignment to the barren hinterlands of a mental hospital ward.

As part of a milieu therapy program, family therapy and individual psychotherapy with other members of the family may put a halt to many destructive stimuli within the household. Schizophrenia, more and more, is being regarded as a manifestation of family pathology. Relationship distortions are not only with the mother, but also with the father

and other significant persons in the family constellation (Wynne et al, 1958; Bowen, 1960; Lidz & Fleck, 1960). The importance of the "double bind" as a basis for schizophrenia has been underscored by Bateson, Jackson, Haley, and Weakland (1956). These authors, describing the family interactions in schizophrenia, contend that the "victim" who succumbs to schizophrenia is exposed to (1) a repetition of prescriptive themes or experiences, (2) conflicting injunctions in relation to these "themes" with threats of punishment for disobedience, and (3) further restricting "commands" that prevent the "victim" from escaping the field of communication.

The "victim" arrives at a perception of his or her life as based on a number of key double-bind interactions with family members. For example, a mother's reaction of hostility to her boy may be concealed by overprotecting him. The child may be aware of this deception, but to retain her love, he cannot communicate this knowledge to her. "The child is punished for discriminating accurately what she is expressing, and he is punished for discriminating inaccurately—he is caught in a doublebind." Incongruence between what is said and what is intended is the essence of the faulty communicative process: " . . . the more a person tries to avoid being governed or governing others, the more helpless he becomes and so governs others by forcing them to take care of him" (Haley, 1959a & b, 1961). Family relationships alternate between overcloseness and overdistance; the members become intrapsychically "fused" so that differentiation of one from the other is often impossible. A psychosis may constitute a mirror image of the patient's unconscious. These factors have focused attention on family therapy as a preferred approach in schizophrenia (Midelfort, 1957; Boszormenyi-Nagy & Framo, 1965). Family psychotherapy increases the chances of breaking the schizophrenic's communication "code" (Jackson J, 1962).

Psychotherapy

Psychotherapy with schizophrenics is an art that graces few therapists. In the face of the patient's stubborn resistance, suspiciousness, withdrawal tendencies, and inability to communicate appropriately, most therapists are apt to throw their hands up in surrender.

Yet there are a few experiences as gratifying to a therapist as providing an empathic bridge to reality for a withdrawn patient. It is difficult to define the qualities a therapist must possess for such a successful eventuality. I once asked Frieda Fromm-Reichmann what she considered the most desirable characteristic for work with schizophrenics. She replied, "Humility, persistence, sensitivity, compassion, and *[she added drolly]* a good deal of masochism." It is only human to respond with frustration at repeated therapeutic efforts that slide off the patient with little or no apparent effect. But I am convinced that when such efforts are sustained, with warmth and sincerity, they ultimately will be rewarded.

In my training as a psychiatrist I spent 13 years of my early career working in a state hospital, principally with schizophrenics. Those were the days before psychotropic drugs, and the only tools available to the therapist (other than wet packs and hydrotherapy) were his or her skills in establishing a meaningful relationship with patients. No matter how severely withdrawn the patients were from external stimuli (and sometimes our catatonic citizens retained their frozen, statue-like behavior for years), it seemed obvious to me that they craved and needed consistent and kindly communication, even though this seemed to register no impact on them. When some of the patients "spontaneously" emerged from their deathlike repose, it astonished me to hear them recount in minutest detail some of the things they had observed going on around them, with virtual playbacks of my one-way conversations with them. They particularly recalled the little kindnesses bestowed upon them by the nursing staff and myself, which I am now convinced had a more penetrating effect on them than the most mighty of miracle drugs.

Even wild paranoidal individuals seemed to respond to quiet sympathy and lack of retaliation for their abuses. I remember one of the most disturbed patients I had ever encountered, a middle-aged, distraught and disheveled, hallucinating woman, who accosted me the first day I was put in charge of the disturbed ward on which she had been sequestered for more than 10 years. Blood-curdling shrieks and cries for the police came from her at the first sight of me as 1 walked through the ward protected by a bodyguard of nurses and attendants. She identified me positively as her tormentor—the man who had

for years been making indecent proposals to her and who had been sending electrical impulses up her rectum and genitals. It was all my bodyguard could do to keep her from assaulting me.

Despite the daily indignities that she heaped on me, I took pains each day briefly to talk quietly to her, expressing my concern at her upset and assuring her that if there were anything I could do to help her, I would be happy to do it. Her response was stereotyped— anger, vilification, and occasionally expectoration. On one occasion as I left her, she managed to find a flower pot, which she hurled at me, barely missing my head. Slowly, after many months, her response to my consistent reassurances became more attenuated, although she daily repeated her resentment that I had the temerity to persist in talking to her when I was the last person on earth she wanted to see.

And then something dramatic happened. On one occasion I was in a hurry to get ward rounds over with to attend a special meeting, and I breezed through the ward without talking to her. Her reaction was electric. She became more highly disturbed than before, upbraiding the nurses for their neglect in directing me away from her, and accusing me of having no respect for her and her feelings. The next morning, for the first time, I was able to talk to her without fear of bodily harm. We spoke quietly about matter-of-fact subjects, and although she was still psychotic and hallucinating, she spoke calmly and with good sense about many matters, apparently enjoying her exchanges with me. Shortly thereafter, the patient became ill with lobar pneumonia and was transferred to the acute medical unit. Sick as she was, she refused to allow anyone except myself to treat her. With persuasion, I convinced her that she could trust the regular staff members of the unit. Upon her recovery from pneumonia, she returned to her old building and was transferred to a quiet, open ward.

My final victory occurred when the patient requested that I cut her toenails! Since her admission she had not trusted anyone to get near her feet. Her nails had become thickened like horns, and I had to borrow special shears from the tool shop to do a half-decent job. To my delight and surprise, the patient recovered from her psychosis and was

able to leave the hospital. I am not certain what other forces were responsible for the patient's improvement, but I am convinced that the relationship I developed with her was a prime vehicle in bringing her back to a reasonable contact with the world.

The ability to enter into the patient's life and to share his or her anguish and dis-pair, to refrain from making demands that would ordinarily seem justified, to persist in showing friendship and respect in the face of outrageous and irresponsible behavior may ultimately win out. To carry out this formidable task, a therapist needs to possess a good deal of stamina and an undaunted optimism that the healthy elements in a sick human being will eventually bubble through. Obviously, the average custodial unit and the average therapist are not equipped to render ideal psychotherapeutic care for these vulnerable human beings. Because some therapists can engage effectively with schizophrenics and others cannot, the literature on psychotherapy in schizophrenia is ambivalent. For example, May's 1968 research indicates that psychotherapy had little to offer schizophrenics in comparison with medication. The Massachusetts Mental Health Center study by Grinspoon, Ewalt, and Shader (1972) also cast doubts on the value of psychotherapy. The studies by Rogers et al. (1967) and case reports of Vaillant, Semrad, and Ewalt (1964), Kayton (1975), and McGlashan (1983) are more optimistic. May's research was flawed, however, by the use of only inexperienced therapists and supervisors who were dubious about the use of psychotherapy with schizophrenics. The other studies could also be criticized for faulty design and controls.

There are many pitfalls in working psychotherapeutically with schizophrenics, not the least of which is provoking and nurturing a hostile dependency that cannot be resolved. Transference is frequently a problem, and if it is not dealt with in the early stages, it may evolve into a disturbing transference neurosis or transference psychosis. No less troublesome are the therapist's irritation and anger at the patient, which is understandable considering the vexations inherent in dealing with the patient's obstinacy, querulousness, uncooperativeness, contentiousness, belligerence, and detachment. Such emotions on the part of the therapist must be controlled. Countertransference mismanaged can interfere with the therapist's objectivity and ability to provide an

empathic relationship.

While there may be some advantage to working exclusively with psychotherapy in the few instances when the psychotherapist is especially dedicated and skilled in working with schizophrenics (Laing, 1960, 1967; Arieti, 1974), the vast majority of therapists find antipsychotic drugs most helpful, if not indispensable if a thinking disorder exists. Drugs are capable of keeping many chronic schizophrenics operating so that they can reasonably maintain their responsibilities, of preventing them from regressing to a state of work disability, and of restoring their capacity to communicate. The disadvantages that drugs impose by masking defenses are more than offset in many cases by their ability to make hospitalization unnecessary and to foster better cooperation with the therapist. Nevertheless, one must keep in mind the possibility, of untoward side effects and sequelae such as tardive dyskinesia.

The immediate objective of psychotherapy in schizophrenia is to enhance the adaptive reserves of the patients so that they will be able to come to a rapid equilibrium, to discern their chief sources of stress, and either to help resolve or remove themselves from them as expeditiously as possible. While the schizophrenic's vulnerability will not be eradicated, the patient may be strengthened so that he or she does not shatter so readily upon exposure to stressful stimuli. In extremely uncooperative and withdrawn patients, behavior therapy, employing operant conditioning, has been used with some success (see Chapter 51). When the patient becomes accessible, formal psychotherapy may begin. Sometimes supportive and reeducative group therapy is utilized adjunctively with individual therapy; at times, it constitutes the sole psychotherapeutic modality.

The key to the treatment of schizophrenia lies in the ability to establish some sort of contact with the patient. Most schizophrenics desperately fear relationships with people and erect various obstacles to any interpersonal threat. The withdrawal from reality and the archaic type of thinking and symbolism enhance the individual's isolation, since there is no common means of communication. Yet, beneath the surface, the patient yearns for a friendly and loving relationship. The patient wards it off, however, because he or she has

been injured by past interpersonal contacts. He or she does not wish to encounter further rebuffs. The patient's apathy, detachment, and expressed hostility and aggression are means of protection from the desire for a closer union with people. Establishing rapport with the patient is in line with two objectives: first, to reintegrate the patient in more intimate relationships with people to where he or she can obtain at least partial gratification of personal needs without fear of abandonment or injury and, second, to bring the patient back to the realistic world by proving that reality can be a source of pleasure rather than pain.

The technique of developing rapport varies with the patient. A great deal of activity is essential. In very sick patients whose productions are seemingly irrelevant and incoherent, a careful analysis of the productions will disclose a language that is very meaningful to the patient. The ability to show the patient that his or her words and gestures are understood may be the first constructive step. Sullivan (1931) has stressed the need to communicate understanding of the patient's language and gestures as a means of solidifying the interpersonal relationship. To do this, it may be necessary to talk to the patient on his or her own regressed level. J. M. Rosen (1947, 1962) has interpreted the utterances of the patient in terms of their symbolic meaning and has been able to develop a relationship with some of his patients through this method. Entering into the psychotic world of the patient, Rosen and his followers attempt to make contact by intensive daylong sessions, overwhelming the patient with direct interpretations of his or her unconscious. How valid these interpretations are may be challenged, but the fact that the patient is showered with attention and is shocked with statements coached in harshly frank and sometimes sexually explicit terms may in a relatively short time bring the patient out of his or her regressed state. This approach has been practiced in foster homes, where the patient is provided with a therapeutic environment throughout the day and night. It is, consequently, an expensive form of therapy and one that can be indulged by a limited clientele. Moreover, follow-up studies are not encouraging.

Employing symbolic objects, Sechehaye (1951) evolved a nonverbal method of communicating with a regressed schizophrenic girl. This was necessary, Sechehaye

believed, because the primary trauma occurred before the stage of verbal language. For example, only by realizing that apples symbolized mother's milk was it possible to offer the patient love through drinking "the good milk from Mummy's apples." In ways similar to this, the therapist may gather clues to essential needs and conflicts from the bizarre symbolic thought content, translating it the same way as if it were a dream. Cryptic as these utterances may be, they contain important messages that may well be heeded by the sensitive therapist, who will answer them in ways that indicate to the patient that his or her plaints are recognized and acknowledged.

Using an existential approach as well as family therapy, Laing (1960) and Laing and Esterson (1971) have explored the despair of patients, siding with them against their families and the environment and, in this way, establishing intimate contact. The relationship is utilized as a vehicle for recasting patients' concepts of themselves. The approaches of Harry Stack Sullivan (Mullahy, 1967, 1968), Frieda Fromm-Reichmann (Ballard, 1959), Otto Will (1967, 1970), and Harold Searles (1960, 1966) also make worthwhile reading.

In patients, therapy may consist of nothing more than sitting with them, without prodding them to express themselves. The very fact that the therapist refrains from probing their trends, avoids discussing the causes of their breakdown, and accepts them as they are may help these patients to regard the therapist as a less threatening force than other people. In many cases therapy may consist of working with the patient at occupational projects and playing games, such as cards, checkers or chess. Sometimes a more positive approach is made to the patient by giving him or her food, such as milk, candy, and cake. For a long time it may seem that these gratuities are the only reason that the patient desires to see the therapist. In querying the patient after recovery, however, one becomes convinced that the patient actually had a desire for closeness and was testing the therapist constantly.

Any relationship that the patient is able to establish with the therapist is at first bound to be extremely unstable. The schizophrenic individual feels very vulnerable and

helpless. His or her level of frustration tolerance is inordinately low. Schizophrenics are distrustful, suspicious, and inclined to misinterpret the motives of the therapist in accordance with their inner fears and prejudices. They feel incapable of coping with life and resent the intentions of the therapist to return them to reality, which holds unbounded terrors. Schizophrenics fear injury and frustration from people, and it may be months, sometimes years, before they are willing to accept the therapist as a friend. Even then they will sense rejection and neglect in the most casual attitude. Anxiety with a temporary return to regression will interrupt therapy repeatedly, and it must be handled by a consistently reassuring and friendly manner. Violent reactions may punctuate treatment from time to time, especially when the patients sense that liking the therapist will force them to leave the relative security of their reality retreat.

Fromm-Reichmann (1939) has commented on the unpredictable nature of the schizophrenic's relationship to the therapist. A sympathetic, understanding, and skillful handling by the therapist of the relationship is far more important than an intellectual comprehension of the operative dynamics. She ascribes difficulties in therapy to the fact that the therapist is unable to understand the primitive logic and magical reasoning that governs schizophrenic thinking.

Unless we analyze our own reactions repeatedly, our sense of frustration may arouse strong aggression that will interfere with treatment. It is manifestly impossible to treat any psychotic person if one does not genuinely like him or her. If we are able to regard the actions of the patient as essentially childlike, we shall best be able to understand the patient's outbursts. Cold logic fails miserably in explaining the reactions of the schizophrenic. Despite his or her age, the patient seeks an infantile relationship to the therapist and desires unlimited warmth, understanding, protection, and help. He or she seeks a mothering affiliation rather than a give-and-take encounter between two equals. At the same time, the patient distrusts the therapist and resents his or her own helplessness in seeking nurturing.

The therapist should try to be as sympathetic and reassuring as possible,

approaching the patient casually and informally and conveying an interest in him or her and in matters of immediate concern. Sometimes it is desirable to encourage the patient by touching a shoulder or arm as a gesture of friendship. I have found that I have been able to establish a relationship in a remarkably short time by offering to show the patient how to relax his or her tensions, utilizing a simple hypnotic relaxing technique (*q.v.*). Even frightened patients can be helped, but, obviously, they must be willing to cooperate. The therapist may say, "It's been rather tough on you, and you can't avoid being upset by all that has happened. If you'd like, I can show you how to relax yourself, which should make you feel a lot better." Patients who respond positively are asked to make themselves comfortable in their chair and to shut their eyes while relaxing suggestions are made.

It is important not to cross-examine the patient or subject the patient to questioning. An attitude of acceptance without reserve is best while conveying sincere interest in his or her needs and problems. Sicker patients will usually flood the therapist with their irrational ideas and delusions. One way of handling this situation is to focus as much as possible on matter-of-fact reality items. This is not as difficult as it sounds, although the therapist must avoid giving the impression of being bored with or disbelieving the patient's irrational concerns.

Probing for conflicts is taboo, as is the lying-down couch position. Only when the patient brings up topics for discussion is it desirable to discuss them, but this should be done in as a matter-of-fact way as possible. This does not mean that depth interpretations are always to be avoided; they may be made once the therapist-patient relationship is solidified and the patient brings up a conflictual topic and shows some awareness of its nature. It may be reassuring to the patient to have a dynamic explanation for some distressing problems. This may relieve the patient of the mystery of what is happening to him or her.

Therapy in schizophrenia must, in summary, be oriented around the immature ego of the patient. The patient's emotional reactions to people, like those of an infant, are unstable and ambivalent. Schizophrenics are easily frustrated and feel rejection without

ostensible cause. They are unreasonable and demanding. Their concept of reality is unreliable; they often confuse inner mental processes with outside reality. They may assume that the person on whom they depend is omniscient and will supply their every demand, expressed or unexpressed. They will react with hostility if they are not granted what they believe to be their due. Alone, their egos are so weak that they are unable to tolerate complete responsibility. They need help and support, and yet fear and resist assistance.

Federn (1943) has advised enlisting the aid of a relative or friend, preferably a motherly person who can look after the patient. He stressed that schizophrenics should not be allowed to depend on their own resources. They should at all times be surrounded by an atmosphere of love and warmth. Their stability and strength grow as a result of positive identifications with loved ones. If they are at all able to develop to self-sufficiency, their independence will grow best in the soil of this positive identification. The hope is to bring them to a point where they can function satisfactorily without the aid of a parental figure. In many cases the latter stage of self-sufficiency is never attained, and all one can do is adapt the individual to reasonable social functioning while attached to some kindly person.

The need to surround schizophrenic patients with a favorable atmosphere necessitates work with their families or with people with whom they live. This is essential to relieve the burden induced by demands and responsibilities that the patient imposes on the members. Often the inertia and apathy of the patient stir up resentment on those present, and when the patient is aware of their hostility, he or she may retreat further from reality. Considerable work with the patient's relatives may be required before they are sufficiently aware of the dynamics of the patient's reactions and before they are willing to aid the therapist in the treatment plan.

The chief emphasis in treatment in chronic schizophrenia must be on the creation of a human relationship with the patient that has pleasure values for him or her. Only by this means will the patient relinquish the safety and gratification of regression and, utilizing

the relationship with the therapist as a bridge, return to reality. The handling of treatment, however, requires considerable tact. No matter how detached the patient is, he or she is extremely sensitive to everything that the therapist says or does. An avoidance of situations that evoke anxiety in the patient is essential. This is often a very difficult task because the most casual remark may stir up powerful emotions.

The patient may choose to remain silent throughout the treatment hour and will appreciate it if the therapist refrains from challenging refusal to talk. It is expedient with such a mute patient to point out occasionally that perhaps there is abstinence from talking because of a belief that the therapist is interfering or because there is fear of what he or she might say. The patient may feel more at ease with such remarks and may finally break through the silence.

In most cases schizophrenic patients at first will feel alone, helpless, and misunderstood. They resent the intrusion of the therapist into their private lives and believe that the therapist, like everyone else, is unable to understand them. The initial task is to show them that their impulses and wishes are respected and that they are not required to comply with demands that are unreasonable. Usually in all of their previous interviews they have been bombarded with questions about their breakdown, and, even when they have responded to these questions in a more or less frank manner, they have sensed disapproval. The fact that the therapist accepts them as they are may eventually build up their self-respect and strengthen the desire to return to reality.

Constantly, during treatment, the patient may react with detachment or withdrawal or may subject the therapist to a testing period during which he or she is recalcitrant and hostile. The purpose may be to find out whether the therapist is the kind of person who can be trusted or whether the therapist, like all other people in his or her experience, makes unfair stipulations or react to expressed hostility with counterhostility. The patient may believe that what the therapist demands is that a person be "good." This "goodness" means to the patient that it is urgent to comply with standards that all other people impose. At first he or she will act as if the therapist actually expects unyielding submission

to these standards, threatening the patient with rejection or aggression if he or she resists. The testing period may be a trying one for the therapist, since it may continue for many months during which the patient constantly rejects the therapist's friendship. When the patient realizes that the therapist does not expect compliance with certain things, that the therapist sides with the patient against unreasonable demands made by the family, the patient may begin to regard the therapist in a new light.

The beginning of a feeling of closeness can precipitate panic; the patient may try to run away from therapy, or he or she will exhibit aggression toward the therapist. The ability to see the patient through this stage may finally succeed in breaking down the patient's reserve and in establishing for the first time an identification with a person based upon love. There exists within schizophrenics a psychic tug of war between the spontaneous forces of mental health that drive them to seek gratifying relationships with people and the security of their regressed state that harbors them from the imagined dangers of a hostile world. The therapist's attitudes will determine which of these impulses will triumph.

The method of handling the treatment hour is of signal importance. It is best not to cross-examine these patients because they may interpret this as censure. They must be convinced that the therapist does not want to invade and remove them from their private world, but rather seeks to participate in it with them. This does not mean assuming a cloying sweetness during sessions, because the patient will be able to see through this. It must be expected that the patient's attitudes will be ambivalent. He or she may profess little interest in the interview, yet resent its termination at the designated time. There may be attempts to defy or to provoke the therapist or refuse to cooperate. If the therapist becomes ill and cannot keep an appointment, the patient may react with rage and refuse to continue treatments. If the therapist is unavoidably late for an appointment, peevishness can occur. The patient may resent the therapist's taking any vacation or assigning another person as an assistant. Where customary routines have to be interrupted, it is best to prepare the patient far in advance and, if necessary, to enlist the help of family members with whom the patient has an attachment. If the patient becomes

hostile toward the therapist, every attempt must be made to explore why there is suspicion the therapist has failed. Should the patient persist with hostility and insist on seeing another psychotherapist, these wishes should be respected, for it is futile to do any work with a patient while being governed by feelings of resentment.

Once a positive relationship has been established, it is necessary to cherish it carefully. Nothing must jeopardize the relationship. For example, the patient must never be led to feel that cherished delusions are ridiculous. Any fanciful feelings and attitudes must be respected at all times. It is unnecessary to reinforce these attitudes by agreeing with them; but they should be accepted as something that the patient believes in sincerely. It may be impressed on the patient, however, that there might possibly be another explanation for a certain experience than the one that he or she supports. All probing for dynamic material must assiduously be avoided at this point. This is one of the most frequent errors in the handling of psychotic patients. It is also an error to interrogate the patient regarding previous mental upsets.

Because the aim in the psychotic patient at first, at least, is to increase repression, since the ego is already too weak and permits the filtering through of disturbing unconscious material, such techniques as free association are to be discouraged. Rather, the patient should be enjoined to talk about everyday reality happenings. In general, the past had best be avoided, and the patient may be aided in any expressed desire to regard it as a "bad dream" or something that should be forgotten. Under no circumstances should a positive relationship with the therapist be analyzed. If the patient exhibits inhibitions or phobias, these too should be respected, since they probably have protective values. All resistances the patient uses to repress psychotic material must be reinforced, although the symbolisms employed may sometimes be interpreted to the patient. Unlike the treatment of neurosis, analysis of resistances should be avoided to prevent the release of the unconscious content that will upset the patient more. When the patient brings up delusional material or symptoms and spontaneously talks about the connection with traumatizing circumstances in his or her past, an effort may then be made to explain in uncomplicated terms how these manifestations originated. The rule never to dissolve

resistance does not apply to resistances to getting well or to integrating more closely with the therapist and with reality. These impediments should be analyzed and removed if possible. Guilt feelings may be met by reassurance and hostilities dealt with in a manner that does not put responsibility or blame on the patient.

One of the ways in which a positive relationship with the therapist may be used is to try to show the patient that his or her thoughts and ideas often appear to be realistic but that it is necessary always to differentiate between what seems to be real and what actually is real. In the patient's case, too these may have been confused, even though there is no question of doubt in his or her mind that the two states are identical. An excellent sign of restoration of ego strength is the ability of schizophrenic patients to recognize the irrational nature of their ideas while they were in an upset condition.

While some patients achieve a fairly good grasp of reality and tend to return to their prepsychotic habitude, and even to tolerate relationships with other people along the lines of the close attachment they establish with the therapist, it may be necessary to continue the treatment process to prevent a relapse. The problems of some patients are kept alive because they harbor bloated ambitions of what they should accomplish in life. Their grandiose expectations inevitably lead to constant frustration. Under such circumstances it is essential to help the patient modify exorbitant goals through the careful use of the therapeutic relationship. It may be possible, for instance, to convince the patient that it is better to devote his or her life to the attainment of happiness in the immediate present than to strive for things in the unknown future. Character disturbances may exist that make relationships with people fraught with anxiety. An active manipulation of the patient's environment through consultation with interested family may enable the patient to function more comfortably. Attempts should also be made to motivate the patient gradually toward making contacts with other people.

In spite of such corrective measures, hostility, tension, and anxiety may constantly be created by inner cognitive, affective, and autonomic derangements. The intensity of untoward emotions may again tend to shatter the patient's ego. The danger of another

schizophrenic collapse may, therefore, be imminent. *It is best here, as mentioned before, not to attempt probing for conflicts until the patient evinces an interest in understanding his or her own problems.* Schizophrenic persons are remarkably intuitive and can grasp the dynamics of their disorder better than most neurotics. This is probably because they live closer to their unconscious and because ego barriers to deep impulses and fears are not so strong. It is for this reason that one must proceed very carefully in analyzing the patient's deepest impulses (Bychowski, 1952; Eisenstein VW, 1952; Fromm-Reichmann, 1952; Bruch, 1964). Haley (1961) has outlined some excellent suggestions for the practical handling of schizophrenics. Other suggestions, namely the use of projective techniques, may be found in the section on the treatment of the borderline patient (p. 1183).

Although the therapist assumes a directive role, it is the patient who is expected to uncover the meaning of ongoing communications (Bruch, 1964). This fact has been stressed by many therapists working with schizophrenics, particularly Sullivan (1962), Fromm-Reichmann (1954), and Lidz and Lidz (1952). In this way the therapist avoids bombarding the patient with useless interpretations or confronting the patient with a road map of his or her unconscious that will lead the patient nowhere. Inevitably, the relationship between therapist and patient will begin to stir up feelings and impulses that the patient will have to clarify with the help of the therapist. For example, if the patient identifies the therapist with his or her mother, interpreting this may mean little. Exploring in what way the therapist *acts* like a mother may, on the other hand, become meaningful.

The realization of unconscious guilt, hostility, and erotism has a dual effect on the psychic apparatus. On the one hand, it floods the ego with destructive emotion; on the other, by forcing a more realistic cognition, it attempts to liberate the psyche from incessant conflict. In this way the dynamic probing is like a two-edged sword; the ego has to be traumatized by the liberated emotions before it is able to mobilize defenses less destructive to the person than regression. In neurosis and character disorders this may prove helpful. In schizophrenia however defenses are so fragile and ego so weak that it collapses under the impact of emotion before it can adapt itself in a more adequate manner. This is always a danger in psychotic and prepsychotic conditions. All

interpretations must, therefore, be very cautiously applied. Reconstructive techniques should be abandoned if any excitement or great hostility develops, for only when the patient is positively attached to the therapist will it be possible to bear the suffering brought out by a realization of the deeper stirrings within.

Summary of general psychotherapeutic rules in schizophrenia:

a. *Establishing a relationship.*

1. The initial task is to establish a relationship and not to collect information. Asking the patient if he or she hears voices or believes someone is against him or her is a poor tactic. Nor should the patient be grilled about previous attacks or hospitalizations. The therapist should act attentive and reassuring. Sitting behind a desk is not as good as facing the patient directly. Walking with the patient, having coffee together, and touching the patient occasionally are not contraindicated.

2. Do not argue, cajole, or try to reason with a delusional or hallucinating patient, no matter how absurd the ideas or fantasies may seem. Not only will the effort be useless, but it may also convince the patient that you are aligned with the forces of evil against him or her. Listen respectfully to what the patient has to say. If he or she complains about something and if you must make a comment, simply say reassuringly, "This must be upsetting you."

3. If the patient is perturbed or agitated, one may say: "I certainly understand how upset you must feel, If such a thing happened to other people they'd be upset too."

4. If the patient prefers to remain silent, accept this, and do not try to bully or shame the patient into talking.

5. If an upset patient asks you for help in allaying tension or anxiety, you may reassure the patient that you will do everything you can. If the patient is not taking medications, ask if he or she would like to have some medicine to quiet the restlessness. You also may suggest teaching the patient how to relax his or her tensions. If he or she responds positively, utilize relaxing exercises or relaxing hypnosis. This may rapidly expedite the relationship.

6. Give the patient regular sessions, and be sure you keep the appointment times. If you will be late for a session, notify the patient in advance if possible and tell him or her you will make up the lost time. Anticipate the patient's breaking appointments and being tardy. If this happens do not chide the patient—merely say you missed him or her.

7. Bizarre behavior or attitudes may strike the therapist as humorous. To succumb to ridicule or laughter may shatter the chances of a relationship.

b. *The treatment process*. I have found the following 20 suggestions useful in working with schizophrenics:

1. Any activity that can bolster the patient's self-esteem should be supported. This includes the patient's grooming and clothing habits and positive achievements of any kind. These should be talked about and encouraged; the patient should be praised for even slight accomplishments in work, hobbies, and creative activities.

2. The best way to handle delusional or hallucinatory material is to listen respectfully and never ridicule or make light of them. One may even act as if uninterested in the hope of discouraging the frequency of these pathological responses. On the other hand, reasonable talk should command alert attention and active responses in an effort to reinforce rationality. If the patient is disturbed by what he or she brings up, the therapist may agree that if matters were as the patient reported, anybody would be disturbed. Then the therapist may gently offer an alternative explanation as a possibility, not pressing the point if the patient does not agree.

3. No matter how truculent, neglectful, disrespectful, or hostile the patient acts toward the therapist (even if the patient throws a tantrum), punitive, scolding, or rejecting responses should never be indulged. The patient may be merely testing the therapist. Nor should the therapist encourage any regressive behavior or talk to or treat the patient as if he or she were a child. In other words, irrespective of how "crazy" the patient acts, he or she should be treated with dignity and respect as an adult. After their recovery, many patients talk about how they appreciated the therapist's manner.

4. For a long time direct interpretation may have to be delayed and projective techniques used instead. The therapist may by illustration make comments such as: (to a patient in despair at being rejected) *"Most* people feel hurt if people neglect them"; (to a patient with fantasies of death and killing) "It often happens that when a person feels angry he may imagine that the person he is angry at will hurt him, or will die"; (to a woman who felt her looks repelled men) "I knew a woman once who felt she was so ugly, no man would want her and she would get furious if a man wanted to date her because she believed he was teasing her." These comments illustrate how one does not directly confront the patient with his or her actions, but uses other individuals as examples. The patient may or may not then pick up the implications. If the patient applies what is being said, the interpretations can be made more directly.

5. With paranoidal patients who have fixed delusions, disagreeing with these delusions will put the therapist in the class of all other persons who have tried to argue the patient out of what he or she believes to be true. Thus, a therapeutic relationship may never get started. Yet, to support the patient's delusion completely may not be wise. Here the therapist may give credence to the patient's right to believe what he or she knows to be true and express an interest in all the facts that have led to the patient's conclusions. One should not directly support the patient's conclusions but merely state: "I can understand how facts like these lead you to feel the way you do." For example, a patient felt he was being pursued by the Mafia, who wanted to steal his business away from him. As evidence, he cited seeing an automobile with New Jersey license plates in the area of his apartment. He was sure he was being watched and followed by New Jersey gangsters who were out to kill him. His complaints to the police and district attorney were greeted with amused disdain. Instead of challenging the patient, I asked him to be sure to keep a diary of all of his daily observations that pointed to his persecutions. At every visit he would bring many sheets of written matter containing detailed rambling "observations," which I would greet as interesting and important and which I promised I would later read in studied detail after our visit. I would then put the material aside and we would talk about his other interests and daily activities, avoiding the psychotic area as much as possible. The volume of the reports gradually dwindled to a single sheet and then stopped altogether, the patient apologizing for his neglect in bringing in this material. With

the cessation of his reports he began to concern himself with immediate problems in his daily life and work and soon lost interest in the Mafia delusion.

6. The management of transference reactions will call for fortitude on the part of the therapist. The range of how the patient regards the therapist is great: God, mother, father, sibling, the devil, seducer, lover, persecutor, friend. Dependency reactions must be expected and these release other impulses and defenses such as sexuality, hostility, masochism, devalued self-esteem, and detachment. Different phases of these reactions express themselves at varying times and the patient will try to involve the therapist in his or her schemes. The therapist must resist acting out with the patient and becoming countertransferentially rejecting, seductive, overprotective, or punitive. Yielding to the patient's importunate transferential demands will breed more irrationality. Yet, an honest careful explanation of why it is impossible to fulfill the patient's demands must be given so that the patient does not feel rejected as a person.

7. Expressed hostility will be especially difficult to handle, since it can be like a never-ending spring issuing out of depths that have no bottom. So long as it remains on a verbal level, the therapist may be able to tolerate it, realizing that some of the rage is in the way of a test, some a means of warding off a threatened close relationship with the therapist, some a belated effort to resolve a needed breaking away from the maternal figure, some a rebellious desire to assert and be oneself. We may suspect that the patient retains a ray of hope that the therapist will handle the patient's anger and not respond in an expected retaliating way that would justify a continued withdrawal. If the therapist can stand this test, feelings of unthreatened love and closeness may bubble through. On the other hand, should rage take the form of expressed violence that does not cease when met by a calm and self-assured manner on the part of the therapist, and by statements that the patient should try not to lose control, it will require firm but kindly and considerate action or physical restraint to protect the patient, the therapist, and others. The patient should later be given an explanation for the preventive action. The therapist here must act in a composed but determined way without giving the impression of retaliating for the patient's behavior. One way of diluting transference reactions is by involving the patient in some

group activity—a hobby, social group, or therapeutic group.

8. If there is no desire to work intensively with the patient (which will happen in a majority of psychotic patients), visits are gradually lessened in 12. frequency once improvement is stabilized but never discontinued completely. Rather, the patient is given the option of seeing the therapist once in two weeks, then once a month, and then at longer intervals.

9. False promises should never be made to a patient because they will inevitably be broken and with this the therapeutic relationship may terminate. Nor should deception be utilized as a way of escaping a difficult situation because here too the patient somehow will divine the deceit. Sometimes it is necessary to withhold the true facts temporarily from the patient since the patient may not be prepared to deal with them but may be able to handle them later when his or her ego gets stronger. Whatever explanations or interpretations are given the patient, these should be coached in frank but reassuringly optimistic terms.

10. Whether to engage in deeper insight therapy is a decision one must reach after working with the patient for a long period, seeing how he or she handles interpretations and observing the buildup of ego strengths. Schizophrenics live close to their unconscious and are often first in arriving at insights themselves. Whether such insights can help the patient is another matter. When stress becomes too 17. strong, the patient will collapse, insight or no insight.

11. The greatest use of therapy is to increase the patient's stress tolerance, and this means doing a careful assay of current and future stressors, preparing and helping the patient to cope with them. Behavior therapy can be of great value when properly employed (Agras, 1967).

12. Avoid language the patient cannot understand. If possible, use the dialect of the patient.

13. Point out in a non-accusatory and non-judgmental way patterns the patient exploits that can prove harmful and that tend to make others withdraw. The message should be given in as reassuring a manner as possible, reflecting the therapist's confidence in the patient's ability

to change.

14. Avoid interpreting the dynamics of the patient's symptoms. Without a firm working relationship with the patient and evidences of his or her trust, this will be counterproductive. Do not belittle or ridicule the patient's delusions, no matter how foolish they may seem.

15. Do not take notes while with the patient. This will enhance suspiciousness, especially if there is some paranoidal tendency. Notes can be made after the patient leaves.

16. Credit the patient's disturbed behavior, if he or she shows it, to the fact that he or she is being frightened and upset and not to the fact that the patient is a difficult violent person. The patient may be responding to the environment as dangerous and will need reassurance and support, not condemnation.

17. Before prescribing medications, explain why drugs are useful in quieting a person down, helping one sleep, and so on.

18. As soon as the patient's symptoms subside, reduce medications to as low a level as will control symptoms. When the relationship becomes firm, the medications may even be discontinued. If symptoms reappear, drug dosage may be increased.

19. Start family therapy as soon as the patient quiets down, building a relationship with the family and counseling them as to steps each member can take to improve communication. Establish a contact with the most stable family member, who will act as a liaison. Instruct this member when to increase medications. Invite this member to telephone you if problems occur.

20. There is no reason why patients cannot be taught to medicate themselves when they feel their equilibrium threatened. Having the proper medications on hand and utilizing such medications to quiet and stabilize oneself can often nip a psychotic break in the bud.

21. Flexibility in approach is the keynote of good therapy with schizophrenics.

General rules such as I have cited here are useful but they will have to be adapted to

each patient and modified according to individual reactions. Similarly, the use of aftercare services will depend on what special needs each patient has and the availability of services in the community in which the patient lives.

Somatic Therapy

The introduction of neuroleptics has introduced a new and more hopeful outlook in the therapy of many schizophrenics. Phenothiazines (e.g., Thorazine, Mellaril, Prolixin), butyrophenones (e.g., Haldol), thioxanthenes (e.g., Navane), and dihydroindolones (e.g., Moban) in proper dosage may, when indicated, rapidly resolve psychotic states and render the individual more accessible to social demands. (The choice and dosage of neuroleptics have been outlined extensively in the section on Pharmacotherapy in Chapter 56).

Useful as they have proven to be, neuroleptics unfortunately have their drawbacks since, apart from the side effects and serious sequelae (e.g., tardive dyskinesia) with prolonged employment, they tend to discourage the application of psychologically based therapies. Too frequently, young people suffering an initial psychotic break are saturated with massive amounts of drugs, which, while restoring homeostasis, prevent them from integrating the significance of the psychotic experience, which may, with the help of an empathic therapist, have a beneficial impact on their future development. This in no way minimizes the value of the neuroleptics, but it does necessitate some restraint in their use. With rare exceptions in the initial stages of therapy, patients with acute schizophrenia manifesting thought disorders will need neuroleptics. Once the patient's symptoms are brought under control and environmental stress factors regulated, the patient should be slowly taken off drugs but rehabilitative and psychosocial therapies continued. Should the patient decompensate again, medications may be resumed, although a considerable number of patients can be managed solely with counseling, milieu therapy, group therapy, family therapy, and other psychosocial treatments. Only if stress factors in the environment cannot be controlled satisfactorily or the stress from internal sources is unmanageable will the patient require prophylactic drug therapy. If neuroleptics are

resorted to after the acute phase is over, interruptions of drug intake with drug holidays are in order. While the utilization of insulin coma therapy has practically disappeared, some authorities still believe it has a utility in younger patients who have been ill for less than 6 months. Electroconvulsive therapy is also considered to be helpful under certain conditions, such as when a severe depression develops during a schizophrenic episode.

Aftercare

The aftercare of hospitalized schizophrenic patients constitutes a serious problem because of the large numbers of such persons in the community as a consequence of deinstitutionalization and the high rate of relapse. Good facilities for aftercare rehabilitative services are lacking in most communities. Those that are available provide the patient with an important means of retarding relapse because of the many modalities offered and the opportunities for patients to establish relationships with a case manager and rehabilitation counselor. If organized services are not available, some patients are able to take advantage of self-help groups such as Recovery, Inc., and Schizophrenics Anonymous. Different therapies are required at different stages of a schizophrenic illness. The proper choice of interventions can best be assured in an organized outpatient setting. Long-term social, behavioral, and problem-solving groups are of special importance, Additionally, social skills training, psychoeducation, supervision of maintenance drugs, resocialization techniques, work adjustment counseling, family therapy, and a variety of other activities geared to the special needs of patients can help many attain stability and lead more rewarding lives. We have seen this happen repeatedly in the Social Rehabilitation Clinic of the Postgraduate Center for Mental Health. What is outstandingly absent are residential facilities where patients without families and those whose homes are too riddled with stressors can be securely housed. But what is even more confounding is that those patients who most need rehabilitation services do not seek them for many personal reasons, including fear of new strange surroundings and of being sent back to a mental institution.

Chronically ill patients, especially when they are hospitalized for a long period and

then deinstitutionalized, lose their independent living and practical problem-solving skills, so essential for adaptation. Rehabilitative procedures designed to equip the individual to live independently and cooperatively in the community are important and pitifully lacking in programs of deinstitutionalization.

Examples of how chronic mentally disabled patients may be trained in community living skills have been described in the literature (Hersen & Bellack, 1976; Trower et al, 1978; Wallace et al, 1980). More recently, Wallace et al. (1985) have detailed a program organized into 10 modules designed to teach conversational skills, vocational rehabilitation, medication management, self-care and grooming, personal recordkeeping, how to find and maintain housing, leisure/recreational skills, food preparation, use of public transportation, and money management. How to obtain the necessary resources to implement the skills taught in each module is also included in the training, as well as how to adapt oneself to unexpected or unsatisfactory outcomes for the performance of the different community survival skills and problem solving under various contingencies. Such a program calls for staff who are empathic, resourceful, and capable of tolerating small increments of progress with difficult clients who are confronted with unique personal, environmental, motivational, and other deficits. The use of role playing, modeling, rehearsal, feedback, reinforcement, and homework assignments must regularly be employed as part of the training in social and independent living skills.

Some therapists believe that work rehabilitation is "more powerful than drugs, psychotherapy, social therapy or any other kind of intervention" (Greenblatt, 1983). The vital role of sheltered workshop programs in the rehabilitation of the mentally ill has been amply demonstrated (Black & Kase, 1986). Though a sheltered workshop is a valuable modality, we must realize that some patients will probably never be able to return to a normal competitive work role. Short-term hospitalization should be available should this be necessary. The psychiatric unit in a general hospital is adequate for this purpose. Psychotherapy on some level, ranging from supportive to behavioral, will be most effective if the above priorities are adequately fulfilled.

The use of maintenance medications as a routine procedure in aftercare has undergone challenge in recent years (Marder & May, 1986). Neuroleptics, once regarded as the greatest advance in the treatment of schizophrenia, have now become more conservatively evaluated in aftercare programs. They have not altered the long-term outlook of the disease; some patients do refuse to take the medications; some fail to respond to them; and there are side effects, some of which may be permanently disabling (e.g., tardive dyskinesia). All in all, neuroleptics are more carefully and selectively employed; acute active symptomatology such as excitement, for example, (hallucinations and delusions) responds best to drugs. On the other hand, their influence on symptoms such as withdrawal, apathy, and anhedonia is minimal. Prescribed prudently, drugs are an important asset, especially in patients with a poor prognosis whose ability to adapt to a stressful environment is enhanced through a regulated drug maintenance program. Contrarily, for patients with a good prognosis, neuroleptics may be detrimental. One of the problems produced by long-term maintenance neuroleptic therapy in aftercare is that the sensitivity of the dopamine receptors is so increased that any withdrawal of the drug causes a rebound of symptoms. On the whole, good psychosocial treatment is still the preferred approach in the average case of chronic schizophrenia. Psychosocial treatments operate under a handicap if the environment is irreparably stressful, and in this case one may be forced to employ supplementary drug maintenance to avoid a critical psychotic break.

A compromise solution for the maintenance drug dilemma considers that patients who have recovered from an attack of schizophrenia be withdrawn from medications and then watched carefully for symptoms of relapse, which may be detected at least for a week before the break occurs. These consist of tension, loss of appetite, problems in concentrating and sleeping, withdrawal tendencies, and depression. If these symptoms appear, appropriate pharmacotherapy is immediately instituted along with psychosocial treatment and family therapy, the intensity of such interventions being titrated to the seriousness of the patient's condition. In many cases the relapse may be aborted by these measures (Herz et al, 1982; *JAMA,* 1984).

In some patients continuing external or internal stress will put the individual on the brink of a relapse. In these cases, maintenance drug therapy will be needed. Some patients spontaneously take medications or increase the dose when their tensions increase or when they feel reality slipping away. But most patients will go off drugs if they are not closely supervised. Cooperation of the family is necessary to ensure that the patient takes the medications. Periodic visits to an outpatient clinic may help the patient maintain the proper drug balances and arrange for drug holidays.

One of the great problems in aftercare is that the schizophrenic is so often used as a foil to hold his or her parents or the rest of the family together. Even when a patient has been removed from a home where there is highly expressed emotion or continuing criticism, the family will not let go. As long as a vehicle for projection exists in the form of a sick child or young adult, hostility and other disturbed feelings are focused on the assigned target and disguised by overconcern. The patient's illness becomes a valuable investment, and signs of recovery threaten the tenuous family balance. A sabotage of treatment may then be expected. Under such circumstances it is vital to get the parents or the entire family into couples, family, or individual treatment to safeguard the patient's treatment. The combination of family treatment and medication has been shown to lower the relapse rate greatly (Hogarty et al, 1986).

Rehospitalization

Rehospitalization for severe psychotic disorganization may be mandatory not only to provide the patient with an atmosphere of protection and to dispense therapeutic measures, but to get the patient away from the family and other environmental stressors that may have initiated the relapse and tend to sustain it.

More and more patients are being admitted for treatment of acute attacks to selected wards of a general hospital rather than to mental institutions. To an extent this is due to the regulations governing compensation by insurance companies and other third-party payment resources. It is due also to the growing deemphasis on institutionalization in mental hospitals. One disadvantage is that payments for hospitalization may be restricted

to a limited number of days. This encourages massive tranquilization to bring the patient speedily out of the psychotic state, resulting in discharge before the patient has had an opportunity to establish a relationship with a therapist who may carry on treatment in the posthospital period. What is sorely needed are units strong on psychosocial treatment in which the patient can live for 5 or 6 weeks. This provides the patient with sufficient time to work through his or her experience, in part at least, and to consolidate a continuing therapeutic plan.

To prevent another relapse as much as possible, the home to which the patient returns must be relatively free from stress. If members of the patient's family continue to be hostile, unconcerned, or disturbed, the chances of a further relapse are great. Under such conditions, the patient, if possible, should be housed elsewhere. If this is not feasible, provision should be made to get the patient out of the house, to a day hospital or rehabilitation unit, for instance, for a good part of the day. Maintenance drug therapy is more essential for these patients than for those whose families are loving and understanding. In either instance, psychosocial treatment is important.

Continued hospitalization over a long-term period may be required for certain patients and is preferable to depositing those lacking in social skills in a furnished room where they will languish in psychotic isolation, refusing to participate in social rehabilitation programs on an outpatient basis and, if they are on maintenance drugs, eventually giving them up.

Prognosis for Schizophrenia

Among patients discharged to families with high degrees of emotion, we can expect a rate of relapse of about 68 percent within the first year of discharge. Maintenance drug therapy will cut this high relapse rate to about 41 percent. A controlled study by Hogarty et al. (1986) has shown that adding psychoeducation and other family-oriented treatments for families, as well as social skills training for patients, lowers this figure to 20 percent. In households where the high degree of emotion has been reduced, the relapse rate has been brought down to negligible percentages. Beyond the first year, the relapse

rate rises even among treated patients and families, probably because many schizophrenic patients have psychobiological deficits in dealing with what would be ordinary life experiences for those not affected by the disorder. Internal stress factors include faulty information processing and inherent affective and autonomic dysregulations that over a period of time can override maintenance drug and psychosocial therapies, although the latter interventions may, as indicated above, reduce the relapse rate.

The outlook for chronic schizophrenics is not nearly as gloomy as it was once believed to be. In Third World countries, where schizophrenics are more socially accepted in the community and family and where they do not suffer rejection, discrimination, and degradation for manifesting their symptoms, the illness runs a relatively benign course. In Western industrial countries, however, patients do not have opportunities for appropriate work, social acceptance, or means of improving their status or integrating into community life. These deficiencies tend to interfere with emergence from the psychotic illness and to promote retreat from relationships so characteristic of this group of patients (Warner, 1985). But even in the United States, long-term studies have shown that many patients released from institutions somehow, after years have gone by, adjust to the outside world and even do productive work, marry, and have children. A 30-year longitudinal study by a group of researchers from Yale University and the University of Vermont have shown that "one-half to two-thirds of 82 subjects released from a State mental hospital and rehabilitation program in the mid-1950's now live in the community, care for themselves, act as productive citizens involved with their families and friends, and show few or no signs of schizophrenia" *(Psychiatric News,* 1985). Other long-term studies of 1400 schizophrenics observed over two decades have revealed that more than half are significantly improved or recovered. This argues for a change in our traditional pessimistic attitude about chronic schizophrenia toward a more favorable outlook.

Psychosurgery

Psychosurgery has been prescribed with variable results for seriously ill schizophrenic patients who have failed to show improvement after 2 or 3 years on

psychotropic drugs and psychotherapy. This form of treatment is said to yield the best results where the prepsychotic personality was fairly well integrated, there is no emotional deterioration, and the patient's current symptoms include tension, restlessness, motor activity, combativeness, and destructiveness. Catatonic and paranoid reactions respond best; hebephrenic reactions poorly. After schizophrenia has existed for 10 years or more, psychosurgery is rarely of value.

MISCELLANEOUS PSYCHOTIC REACTIONS

A number of other categories of psychotic disorder are included in DSM-III-R Codes: *schizophreniform disorder (295.40), brief reactive psychosis (298.90), atypical psychosis (298.90), schizoaffective disorder (295.70),* and *induced psychotic disorder (297.30).* There are also a number of organic mental disorders in the form of dementias arising in the senium and presenium, as well as a host of psychoactive substance-induced organic mental disorders, and those associated with physical disorders or conditions.

In *schizophreniform disorder* the duration of the illness is less than 6 months; there is a rapid onset and a high degree of confusion and emotional turmoil, but there is also a good likelihood of recovery to pre-morbid functioning. A *brief reactive psychosis* must be differentiated from schizophrenia. Here the psychosis follows a strong stressful environmental stimulus and there is recovery within 2 weeks. If no such psychological stress has occurred and there is still a psychosis (disturbed behavior, hallucinations, delusions, associational disorganization, etc.) that disappears in less than 2 weeks, the diagnosis of *atypical psychosis* is often given. The diagnosis of *schizoaffective disorder* is more difficult to make since it is a wastebasket for combinations of affective and schizophrenic symptomatology in the form of mood-incongruent psychotic features that do not fit into any of the other categories.

Induced psychotic disorder occurs when a dominant psychotic person, the primary patient, influences others in the family to display the same delusional beliefs. One form of this disorder is *folie a deux* involving two persons. The intensity of the psychotic symptoms in these conditions may necessitate hospitalization during which antipsychotic

drugs are administered. In schizoaffective disorder antidepressants and lithium may additionally be needed and, if medications are ineffective, occasionally ECT.

Symptoms of psychosis may occur with various organic brain diseases of neurological origin or as a toxic effect of drugs (alcohol, hallucinogens, etc.). Among the most common of these neurologically based disorders is primary degenerative dementia, especially Alzheimer's and Pick's diseases, which are characterized by progressive deterioration of intellectual, social, and occupational functioning. Multi-infarct dementia presents similar symptoms, combined with focal neurological disease and cerebrovascular residues. Impulsiveness, poor judgment, memory loss, and personality problems create difficulties for the patient and those around the patient. A variety of other organic brain syndromes may be seen in which the symptoms are delirium and dementia, clouding of consciousness, disturbances in psychomotor activity, memory impairment, aphasia, and other disturbances of the higher cortical functions. Persistent delusions and hallucinations, appearing in a normal state of consciousness, may also develop as a consequence of organic illness and are diagnosed according to the symptoms (organic delusional syndrome, organic hallucinosis, organic personality syndrome). Management of these conditions depends on the symptoms. Restlessness and uncontrollable hostility may be helped by Thorazine or Mellaril (10-50 mg or more in divided doses). Sometimes a beta-adrenergic blocker like Inderal (60 mg daily) or an antidepressant like Desyrel (200-400 mg daily) may be found useful. Delirious overactivity, confusion, agitation, and paranoidal excitement call for antipsychotics (Haldol, 5 mg, or Navane, 4 mg, intramuscularly) repeated as needed. Cogentin (1-2 mg) intramuscularly to offset extrapyramidal complications is sometimes coordinately given as a precautionary measure. Intravenous benzodiazepines (Valium, 10 mg; or Librium, 50 mg; or Ativan, 2 mg) repeated every 2 hours until symptoms are under control are often preferred as an alternative. When the delirium has abated, oral medications may be employed. A search for causes of both delirium and dementia is imperative, and, when found, specific and nonspecific therapies should be instituted. Supportive and directive psychotherapy may be required, bolstered by antianxiety, antipsychotic, and antidepressive medications as needed. Needless to say, family counseling will usually be adjunctively required.

Supervision of the Psychotherapeutic Process

Supervision of the work of the beginning therapist is an essential requirement in the learning process (Greben, 1985). Without supervision it will be difficult or impossible for the therapist to translate theoretic knowledge into effective practice, to work through blocks in understanding, and to develop skills to a point where the therapist can help patients achieve the most extensive goals. Supervision, then, in psychotherapy is essentially a teaching procedure in which an experienced psychotherapist helps a less experienced individual acquire a body of knowledge aimed at a more dexterous handling of the therapeutic situation.

LEARNING PRINCIPLES IN SUPERVISION

Adequate learning necessitates, first, an appropriate presentation of data in terms meaningful to students, second, the incorporation of this data by the students, and third, the ability of the latter to organize experiences cognitively and to generalize from them to related aspects of their work.

The first requirement presupposes an ability on the part of the teacher to develop an empathic understanding with the students and to discern what aspects of the available material are pertinent to their immediate needs and to the teaching task. The second essential assumes the existence of motivation, an adequate intellectual capacity to integrate the information, and the relative absence of anxiety. The third requisite entails the presence of a synthesizing function of the ego that enables students to examine themselves critically, to give up old modes of conceptualizing, and to apply themselves to new creative tasks. Helpful is alertness and ability of the teacher to keep the relationships on a level where transference resistances' do not interfere with this process. Helpful also is detection of the students' specific learning problems and the evolvement of techniques designed especially to deal with these problems.

Unfortunately, there are many interferences with the expeditious learning of psychotherapy, not the least of which is the ambiguity of the concepts that constitute the marrow and lifeblood of the psychotherapeutic process. It is difficult to authenticate techniques that are universally applicable. A method that works in one case may not be effective in another; it may produce good results for one therapist and a string of failures for another with a different kind of personality; it may be highly productive at a certain phase of treatment and backfire in the same patient at another phase. What appears to be necessary is more research into the actual procedures of teaching psychotherapy. Christine McGuire (1964) has pointed out that much of the ongoing clinical teaching is conducted in a manner that runs counter to basic principles about learning long known to educators and psychologists. A professional coach who sends his or her players out to complete a number of practice games with instructions on what to do and who asks them to provide at intervals a verbal description of how they had played and what they intend to do next would probably last no more than one season. Yet this is the way much of the teaching in psychotherapy is done. What is lacking is a systematic critique of actual performances as observed by peers or supervisors. This is not to say that an account, highly screened as it may be, of what a therapist says he or she has done with a patient may not lend itself to a dynamic learning relationship. The account, however, is most valuable when it is compared to what the supervisor has actually observed in a live session between the student and patient through a one-way mirror or in viewing a videotape of the session.

A sensitive question relates to the validity of using data in teaching psychotherapy drawn from the teaching of related disciplines. Can the information, for example, derived from such areas as social work supervision, the psychology of learning, communication theory, and programmed instruction be applied to psychotherapy? On the surface the reply would be "yes." Yet there are special problems in the teaching of psychotherapy that force a qualification to this answer.

An individual who masters a complex skill proceeds through a number of learning phases, namely (1) the acquisition and retention of certain factual information, (2) the

development of ways of using this information in a practical way, and (3) the evolvement of a capacity of altering this information when new situations arise that call for different approaches. In psychotherapy modern methods of acquiring information embrace exposure to didactic materials through fact-finding learning (lectures, reading, and observation of therapy performed by expert therapists through a one-way mirror, videotapes, and sound movies) and problem-solving learning (programmed instruction and role playing with immediate feedback). Practical applications of what has been learned are inherent in observing the consequences of treatment techniques by actually *doing* psychotherapy under supervision, by listening to audiotapes and watching videotapes of one's own performances, by observing others performing in psychotherapy through a one-way mirror, or viewing videotapes of their actions, and by clinical conferences and case seminars. The creative employment of psychotherapy with the development of methods designed for the special problems of each patient are consequences of continued supervision and prolonged experience. Through such a program of scholarship, searching inquiry, observation, and experiment, a body of organized knowledge is eventually developed in the matrix of sophisticated theory.

Research into teaching method indicates that the effectiveness of teaching is increased "when the teacher accepts a teacher's responsibility for directing learning, providing every opportunity and inducement for the student to accept a larger responsibility for his own education, and holding out always his and their goal the maximum achievement of which they are both capable" (Hatch and Bennet, 1960). Fundamental is a spirit of inquiry that provides the motivational fuel for the powering of proper learning (Matarazzo, 1971). This is the most sustained when the content of teaching is related to the needs and educational level of the students.

Once teaching goals have been explicated in operational terms and the most effective methods have been designed to help the students achieve these goals, the effectiveness of learning experiences must be tested through the students' demonstrating how much they have mastered. Reliable methods of recording and measuring performance are needed here. This should be more than a matter of clinical impressions, for, as McGuire (1964) has

pointed out, these "are no more acceptable in a scientific study of the educational efficacy of a training program than they are in a scientific appraisal of the therapeutic efficacy of a new drug." The crucial obstruction is, of course, the current relatively undeveloped methods of evaluation. In psychotherapy, where the clinical data may be interpreted in endless ways and where criteria of competence are so vague, evaluation techniques are still more pedantic than precise. Yet it must be agreed that, however tenuous they may seem, measures of competence must be constructed to require students to demonstrate that they can perform in a desired way. Both the continuous case conference and supervision offer means of approaching the thorny problem of evaluation. Important leads may perhaps be taken from the study of the evaluation of the teaching of psychiatry at the undergraduate level in the film test series developed at the University of Rochester, the University of Nebraska, and the University of Pittsburgh. At the postgraduate level a number of interview films have been developed—for instance, those at Temple University Medical School, which may be used to test clinical judgment and problem-solving skills and which can be adapted to the evaluation of different training programs.

PSYCHOANALYTIC CONTRIBUTIONS

Some outstanding work on supervision has been done in the field of social work (Towle, 1954). But the area that has commanded greatest interest for many psychotherapists has been psychoanalytic supervision (Balint, 1948; Benedek 1954, 1972; Blitzstein & Fleming 1953; Brunner, 1957; Dewald, 1969; Ekstein, 1953; Gitelson, 1948; Kubie 1958(a); Sloane, 1957). The early publications of Ekstein and Waller-stein (1958), Fleming (1963), and Fleming and Benedek (1964) are still considered valuable. The latter authors, using electrically recorded sessions of students with patients and their supervisors, developed a project to investigate "the processes of interaction between communicating systems in the teaching-learning relationship" that involved the triadic dimensions of supervisor, student-analyst, and patient. Assessment of students brought into play a complicated network of motivations in the supervisor, for instance, the preconceived expectations of students, the supervisor's own investment in teaching, and the defensive reactions to students' resistances. "Our experience demonstrated again and

again the necessity for a supervisor to listen to and evaluate himself in interaction with his student; and it is our opinion that the more aware a supervisor is of the various aspects of his educational role, the more effective he will be as an object for identificatory learning and as a developer of students in general."

These and later data from studies of supervision of the psychoanalytic process (Chessick, 1985; Buckley et al. 1982; Gauthier, 1984; Glass, 1986) require a reconciliation with treatment situations of greater activity and more limited goals, as in the less intensive dynamic, reeducative, and supportive therapies (Sandell, 1985; Winokur, 1982).

It is almost inevitable that psychotherapists will be influenced by unconscious processes in their patients. Patients who have incorporated parental messages and repudiated their presence may through projective identification accuse the therapist of the very impulses that they deny within themselves. More insidiously the projections may not be direct, but the therapist will become aware of them through countertransference, perhaps reflected in dreams or fantasies (Langs, 1979). Failure to understand what is happening may provoke defensiveness and hostility. Moreover, the therapist may with some patients develop transference, which can lead to antitherapeutic acting out manifested by smothering overprotectiveness, aggressiveness, or sexual misbehavior. One of the supervisor's prime duties is to be alert to such transferential and projective identification interferences and, when they occur, help the supervisees recognize them. This is a tricky task because the supervisor will in so doing be playing the role that should be assumed by the supervisor's therapist, if there is one. What may result is that the supervisees will begin developing more irrational transferences toward the supervisor and, if the supervisor does not watch it, the supervisory teaching process may become converted into a prolonged therapeutic venture with the focus away from the learning of psychotherapy and the welfare of the supervisees' patients.

FUNCTIONS OF SUPERVISION

All participants in the supervisory process bring to it a separate agenda. The supervisees are interested in learning how to do good psychotherapy, and perhaps in

achieving certification or earning a degree. The supervisor seeks to demonstrate competence as a senior clinician while teaching the students a skill and contributing to their growth. The institution that sponsors the treatment desires that standards imposed by licensing and regulatory bodies be meticulously followed. The paying agencies insist that records and documentation be carefully maintained and available for auditing. The central members of the conglomerate, the patients, seek the most effective help to reduce their problems and want to be assured that their therapy is going well. Such aims may be contradictory, and the supervisor will deftly have to weave through the tangle of these self-oriented objectives and bureaucratic rules. There may be difficulty in deciding where loyalties should be placed. Good supervisors are able to fuse the disparate elements into a serviceable amalgam. Skills *can* be taught while considering the welfare of the patient, the needs of the student, and the rules of the institution. Coordinately the supervisor will have to deal with personal frustrations and countertransference, with the students' transferences and resistances to learning, with the intransigence and arbitrariness of the school or agency, and, by remote control, with the anxieties of the patient.

The traditional type of supervision, unfortunately, has become so contaminated with overseeing, directorial, and inspective functions that it has frequently been diverted from its teaching objective. This has particularly been the case in agency work, where the supervisor, as part of the administrative body, is responsible for the quality of service rendered to clients. Many difficulties arise here because the supervisor serves in a dual role—as an overseer and a teacher.

As overseer, the supervisor may be so concerned with maintaining the standards of the agency that he or she may not be able to exercise the kind of tolerance and patience required in a teacher. For instance, under press of responsibility, the supervisor is likely to "jump in" and interfere with the treatment plan set up by the supervisees, the execution of which, while perhaps less expert than a plan devised by the supervisor, would prove of greatest learning value to the supervisees. Because the students' status is dependent on evaluations by the supervisor, the process of supervision in agencies is apt to become extremely trying. A parallel situation develops when the supervisees are in training at a

psychotherapeutic or psychoanalytic school and their careers are dependent on the evaluation by the supervisor. Similarly, if the supervisees are staff members of a clinic, the supervisor as part of the administration may subordinate the teaching role to overconcern with the total case load. This shift in emphasis cannot help but influence adversely the quality of training received; this is inevitable whenever the training is oriented around circumscribed goals set up in relation to specific kinds of service for which the clinic is responsible. Much less complicated is the supervision of psychotherapists in private practice, who choose a supervisor principally to expand technical skills, not being dependent on the supervisor for an evaluation that may destroy their careers or eliminate their means of livelihood.

In schools or clinics, the supervisor will usually operate as a teacher, an evaluator, an administrator, and a policymaker.

Teaching

The first responsibility of the supervisor is observation of the total functioning of therapists to help in the supervisees' educational growth. Toward this end, it may be essential to bring the supervisees to an awareness of how they have failed to live up to therapeutic potentialities, either because of insufficient knowledge or because of neurotic character problems that inject themselves into the psychotherapeutic relationship. It is incumbent on the supervisor, among other things, to help the supervisees (1) to gain knowledge that is lacking, (2) to achieve an awareness of their own character problems that may interfere with the establishment and maintenance of a therapeutic relationship, and (3) to overcome resistances to learning.

Evaluating

A second responsibility of the supervisor is an evaluation of the capacities and progress of the supervisees for the purposes of determining professional development and current skills as a therapist. Evaluation involves a number of areas, including theoretic understanding, therapeutic aptitudes, and the kinds of relationships that are

established with patients and the supervisor.

Administration and Policy Making

The third responsibility of the supervisor lies in the helping of administration and policy making of the school or clinic under whose aegis the program is being conducted. The supervisor recommends modifications of the therapeutic and teaching programs that may influence adversely the training and the work of the therapists as well as the patients' responses to treatment.

To summarize, supervision in psychotherapy is fundamentally a teaching process in which a more experienced participant, the supervisor, observes the work of less experienced participants, the supervisees, with the aim of helping the supervisees acquire certain essential therapeutic skills through better understanding of the interventions involved in mental illness and through resolution of personality factors that block performance of effective psychotherapy. Supervision embraces a sharing of experiences; not only those gathered in the relations between therapist and patient, but also those occurring in the relationship between the supervisor and supervisees.

Qualifications of a good supervisor are the following:

1. Ability to function expertly as a psychotherapist.

2. Ability to function effectively as a teacher.

3. Ability to accept the supervisees unconditionally, without contempt, hostility, possessiveness, and other unwarranted attitudes and feelings.

Supervisory problems may roughly be divided into five categories of problems: orientation, recording, technical performance, learning and termination of supervision.

PROBLEMS IN ORIENTATION

Differences in Theoretic Orientation

Important and often irreconcilable differences occur in the theoretic background and orientation of the supervisor and the supervisees, a product usually of varying kinds of preclinical training. Illustrative of such differences are the following:

1. The relative weight to be placed on constitutional as compared with experiential factors in the genesis of neurosis.

2. The importance of biologic as contrasted with sociologic factors.

3. The respective emphasis on past childhood experiences and on current environmental hardships.

4. The degree of stress placed on unconscious conflict as the focus of neurotic and behavioral difficulties.

5. The extent of acceptance of the Oedipus complex, castration fears, and penis envy as universal phenomena.

6. The primacy of sexual over other drives and behavioral disorders.

7. The significance of character structure in creating and sustaining emotional disturbance.

8. The relative emphasis of conditioning theory in accounting for anxiety.

9. The value of short-term as compared to long-term approaches and of psychoanalytic versus behavioral and cognitive therapy.

The most effective supervisor is one who respects the right of therapists to their own ideas and opinions, yet who realizes that some of these may interfere with good psychotherapy.

Differences in Communication

Since communication is the basis of the supervisory relationship, it is important that verbalizations and concepts be understood by both supervisor and supervisees. Assuming that there are no important language differences, problems in communication are frequently related to differences in terminology.

A poignant objection to psychology by scientists in other fields is that it is partial to neologisms. Tendencies to use unconventional and complex terms have been one of the strongest barriers in a rapprochement with other sciences. Both supervisor and supervisees may be victimized by dedication to an esoteric terminology. Translation of complex terms into concepts with which supervisor and supervisees are conversant is vital to a mutual understanding and to the establishment of a common frame of reference.

Difference in Method

Another problem in supervision relates to differences in method—that practiced by the supervisor and that accepted or practiced by the supervisees. Such differences may involve various matters, such as the most desirable number of treatment sessions per week, whether or not to employ routine history taking and psychological workups, the use of free association, the emphasis on dream material and the manner of its employment, the use of the couch, the degree of activity in the interview, the extent to which a transference neurosis is permitted to develop, and the adjuncts to be used during therapy. Resolution of serious differences in method is to be expected in the course of good supervision.

Considerable flexibility will be required in methodologic approaches, particularly when the therapists are expected to handle, in the practice for which they are being trained, a wide assortment of clinical problems. Supportive of the principle of technical eclecticism is the fact that no single approach is applicable to all types of emotional difficulties. Some problems seem to respond better to certain kinds of therapeutic intervention than to others.

Differences in Goals

Problems may arise between supervisee and supervisor on the basis of varying concepts of what makes for success in psychotherapy. Is success in therapy the achievement of complete resolution of all blocks in personality maturation with effective functioning in all areas of living? Or is success to be graded in terms of optimal

development within the practical limitations imposed on individuals by their existing motivations, ego strength, and environmental pressures from which they cannot reasonably escape?

Reasonableness dictates that though a responsibility exists in bringing patients to the most extensive personality reconstruction possible, there are circumstances that block this. A modest treatment objective may be the only possible alternative. Supervisees trained in the tradition that therapeutic change falling short of complete reconstruction is spurious, however, may look askance at the supervisor who considers goals in terms of optimal functioning within realistic limitations. Or conversely, the supervisor may be unwilling to accept goal modification and may downgrade changes that fall short of absolute psychosocial maturity and then blame the supervisees for not being able to do the impossible.

PROBLEMS IN RECORDING AND REPORTING

Careful listening to the supervisees' accounts, to the manner of reporting, to evasions and points of emphasis, to slips of speech, and to casual off-the-record references to feelings about patients help the supervisor to evaluate the therapeutic work of the supervisees.

In making this appraisal, the supervisor must take into account that the role being played by the supervisees with the supervisor, and the attitudes harbored, are not a reliable index of what the supervisees actually do with patients. With patients, supervisees are operating in an entirely different setting than with the supervisor, with whom they are in a more subordinate status, more vulnerable, and more capable of being challenged or criticized. They may respond to the supervisor with fear, detachment, resentment, and other character patterns related to feelings about authority. Therefore, it may not be possible for supervisees to communicate to the supervisor their true capacities to be spontaneous, empathic, and responsive such as may occur with patients in the relatively secure atmosphere of one's office.

For instance, a therapist presented material to her supervisor in a cocky, superior manner, reflecting a somewhat contemptuous attitude toward the patient about whom she talked. It soon became obvious to the supervisor, however, in listening to tape recordings of actual treatment sessions, that hostile feelings were not manifest in the therapist's responses nor in her manner with the patient. Hostility, marshalled by transference feelings toward the supervisor, was seeping into the supervisory session and was influencing the nature of the reporting.

Neurotic feelings toward the supervisor may thus distort therapists' presentation of material. Pertinent data may be deleted, irrelevant items may be introduced, and secondary elaboration may destroy the value of the presentation. Fear of exposing deficiencies, of appearing ridiculous, and of incurring the displeasure and contempt of the supervisor are among the more common causes of poor reporting.

Anxiety to please the supervisor, to hold back differences of opinion, and to suppress transferential displays so as not to antagonize the supervisor may interfere with factual reporting. The supervisees may fear revealing what is happening in treatment so as not to appear incompetent.

Some of the difficulties in reporting may be obviated by insisting on process recording in which there is a verbatim account of both patients' and therapists' verbalizations. Process recording has the advantage of presenting a reasonably cogent picture of what is going on, since the tendency toward distortion or deletion will be minimized. There are certain objections to this method, however, in that the supervisees may be unable to record simultaneously while doing good therapy or because patients protest not being able to make good contact with someone immersed in writing. Furthermore, no matter how careful an attempt to record, the students will be unable to include everything that is said. There will then be a tendency to curtail the material, consciously or unconsciously eliminating elements that cause them to feel that they are revealing themselves unfavorably. In intensive supervision, in which one case is being presented over a long period of time, the supervisor may, nevertheless, have to insist on

process recording until convinced of the therapist's ability to report correctly in a more abbreviated way. (See [Appendix K](#) for a case outline.)

Perhaps the most effective type of recording is done with a video machine. These machines are now sufficiently improved and modest in price to become an almost indispensable item of equipment for supervision. This use is described and illustrated by Maguire et al. (1984) and Morgan (1984). Videotaping is valuable not only to the supervisor but also for playback to patients, who observe and listen to themselves communicating (Geocaris, 1960); Gutheil et al. 1981). Video recording is also helpful for playback to the supervisees, who may learn as much by self-observation as from the supervisor (Moore et al, 1965; Beiser, 1966). Moreover, the supervisor may profit from self-observance in supervisory operation. Audio recordings on tape are cheaper but less effective. For purposes of record keeping and for later transcription, however, audiotapes are sufficient. Few patients object to the use of machine recorders, and once the fears about revealing themselves have been overcome, the supervisees can function freely.

The value of video recording cannot be overestimated. It gives a most factual picture of what has actually gone on in the session, not only in content, but also in revealing bodily movements, intonations, and subvocal utterances that cannot be communicated in written types of recording. The method enables the supervisor to observe aspects of the interviewing process that are handled well or poorly. It helps to understand how the different kinds of content are dealt with, whether the supervisees exaggerate, minimize, or negate the importance of certain types of material. It permits observation of how the therapist responds to unreasonable demands of patients, to hostilities and other transference manifestations that are developing in the relationship. It enables the supervisor to study how techniques are being implemented. The difference between the written or verbal account and what actually went on, which is revealed in observing and listening to a playback, is often so astonishing as to leave little question about the value of this kind of recording (Gutheil et al., 1981; Maguire, 1984; Morgan, 1984).

For instance, one supervisee's verbal account made no mention of hostile feelings in

the patient, to which the therapist was responding by shifting the topic of discussion and by complacent, reassuring utterances whenever the patient introduced a slightly antagonistic remark. The supervisee was totally unaware of his diversionary responses, but in the playback he could not escape what had happened. Another supervisee reported a progressively deepening depression in a borderline patient. The process recording related that the patient talked incessantly about how she had been neglected, particularly by a mother preoccupied with outside activities, and a detached father. The supervisee, in her recorded responses, appeared to be saying the right things. A session of the supervisee working with the patient, which was recorded on videotape, however, demonstrated that the therapist had placed her chair so that she was not facing the patient; she was in effect detaching herself from her and repeating the patient's childish trauma. Correction of this position, with the closer interaction that the face-to-face placement encouraged, rapidly brought the patient out of the depression and accelerated progress.

The advantage of watching students performing with patients behind a one-way mirror and of recording the session on videotape so that it may be played back for the students is incalculable, since immediate feedback is possible. Parenthetically, a session in which the supervisor treats a patient, observed by students through a one-way mirror or by watching a video recording, is helpful in pointing out techniques that are difficult to describe verbally. Understandably, it will be impossible to use recordings at every supervisory session due to lack of time. Several recorded sessions presented during each six months of supervision will usually suffice to measure the therapist's progress, and in themselves will justify the use of the video machine. A unique device described by Boylston and Tuma (1972) is "bug in the ear," a receiver placed in the therapist's ear through which a supervisor gives instructions via a transmitter from behind a one-way mirror.

From the standpoint of research, recordings, videotapes, or sound film recordings of interviews permit the researcher to approach the problems of both process and outcome evaluation with greater objectivity (Davidman, 1964; Kubie, 1950b; Strupp, 1960).

Although the students' written notes and observations about therapeutic work are valuable (Beckett, 1969; Bush, 1969; Moulton, 1969), they are rendered more significant by studying the inclusions, omissions, and exaggerations in video recordings of the same sessions. As Schlessinger (1966) points out, different kinds of data are dealt with in both types of recording, each of which has a different potential for teaching but which is by no means mutually exclusive.

Recently, computer programs have been made available that have been found useful by some therapists, for example, Harless's Computer-assisted Simulation of the Clinical Encounter (Harless, 1971, 1972), which deals with diagnostic problem solving. Elaborations of this computer-assisted instruction involving typical psychotherapeutic situations will probably have a significant impact on some students since, as Hubbard and Templeton (1973) have pointed out, they can expose students to a wide variety of clinical problems, provide modes of practice and diagnostic skills in a simulated therapy setting, and permit early feedback by a consensus of experts in the field. The authors predict, because of such technological instruction, that a different role for teachers is possible. Heifer and Hess (1970) and Lomax (1972) have published interesting material on related new trends in teaching.

PROBLEMS IN TECHNICAL PERFORMANCE

The supervisees will experience trouble in various areas in the process of psychotherapy. These difficulties are the consequence either of lack of understanding, experience and skill, or of negative countertransference. They will have to be handled by the supervisor in relation to their origin and function. Most common are the following problems:

1. Difficulties in the conduct of the initial interview.

2. Inability to deal with poor motivation.

3. Inability to clarify for the patients misconceptions about psychotherapy.

4. Inability to extend warmth and support to the patients or to establish a good

initial contact with them.

5. Inability to define for the patients goals in therapy.

6. Inability to structure the therapeutic situation adequately for the patients.

7. Inability to recognize and to handle manifestations of transference in the therapeutic relationship—specifically, dependence, sexual feelings, detachment, hostility, and aggression.

8. Lack of knowledge about how to explore and to bring to awareness conflicts that mobilize anxiety in the patients (in insight therapy).

9. Lack of sensitivity and perceptiveness to what is going on in therapy.

10. Lack of technical skill in the implementation of free association, dream interpretation, and analysis of the transference (in insight therapy).

11. Inability to deal with resistances in the patients toward verbal exploration of their problems.

12. Tendencies to avoid problems of the patients that inspire anxiety in the therapist.

13. Tendency to probe too deeply and too rapidly at the start.

14. Impatience with resistances toward the acquisition of insight (in insight therapy).

15. Faulty techniques of presenting interpretations.

16. Frustration and discouragement at the patients' refusal to use insight in the direction of change.

17. Tendency to push the patients too hard or too rapidly toward normal objectives.

18. Fear of being too directive, with resultant excessive passivity.

19. Lack of understanding of how to create incentives for change.

20. Lack of understanding in dealing with forces that block action.

21. Lack of understanding about how to help the patients master anxieties surrounding normal life goals.

22. Inability to scale down therapeutic goals when modification of objectives is mandatory.

23. Lack of understanding about how to implement the translation of insight and understanding into action.

24. Inability to deal with resistance toward abandoning primary and secondary neurotic aims.

25. Inability to deal with resistance toward normality.

26. Inability to deal with resistance in the patients toward activity through their own resources.

27. Tendencies to overprotect or to domineer the patient.

28. Inability to assume a nondirective therapeutic role.

29. Lack of understanding about how to deal with the refusal on the part of the patients to yield their dependency.

30. Lack of understanding of how to handle the patients' fear of assertiveness.

31. Lack of understanding about how to analyze dependency elements in the therapist-patient relationship.

32. Lack of understanding about how to terminate therapy.

Good supervisors exercise tolerance for the specific style of activity of the supervisees. They realize that irrespective of intensive training and exposure to specific schools of psychological thought, basic personality patterns of the supervisees will infiltrate the treatment situation. These cannot help but influence the techniques that have been learned. Some modification of learned techniques will always occur, particularly those that are not compatible with the therapists' style or personality structure. The supervisees will probably never be able to duplicate the exact style of the supervisor, nor vice versa, since they are individuals and relate to patients in their own unique ways. Yet

certain basic principles in psychotherapy must not be violated, no matter what kinds of relationships are established and what types of techniques are employed. By defining the broad bounds of psychotherapy, and by elucidating on the fundamental principles to which every therapist must adhere, the supervisor may help the supervisees perfect skills yet maintain spontaneity, which is a most cherished characteristic in the psychotherapist.

PROBLEMS IN LEARNING

A number of propositions are involved in the learning of psychotherapy that may be expressed as follows:

1. All learning necessitates a substitution of new patterns for old. This requires a working through of blocks that constantly impede the acquisition of new patterns. Sometimes the struggle is minimal; sometimes it is intense.

2. The manner in which learning proceeds is unique for individuals both in relationship to the rate of learning and the methods by which material is absorbed and integrated. Some people learn by leaps and bounds, others by cautious, precarious crawling. Many variants expedite or interfere with learning in different people. What is taught to individuals has to be accepted by them in their own terms.

3. Learning involves both an understanding of theory as well as its integration and translation into effective action. The instruction leading toward an understanding of theory is vested in the instructors and teachers with whom the supervisees have had preliminary training. The instruction for execution of theory into practice is vested in the clinical supervisors.

4. Little learning is possible without a motivation to learn. This motivation must be sufficiently intense to overcome the difficulties that are inherent in all learning. It is assumed that the supervisees have sufficient motivation— in terms of desire to be psychotherapists—to expose themselves to the ordeals of the learning process.

5. Anxiety is present in all learning. Its sources are related to fear of change and the desire to cling to familiar patterns as well as to resistance in altering basic accepted attitudes and behavior tendencies.

6. Some resistances to learning are present in all people in response to anxiety.

The kind and the degree of resistance will vary with each individual. Most common are lack of attention, lack of retention, amnesia, and simulated stupidity. In addition, resistance may take the form of dependency, submissiveness, self-depreciation, ingratiation, arrogance, grandiosity, resentment, aggression, and detachment. These are products of specific neurotic character problems but there also may be a universality of expression of such trends in certain cultures, reflecting accepted attitudes toward education and toward the authorities that are responsible for education.

7. Resistances to learning must be overcome before learning can proceed. The attitudes of the supervisor are crucial here. The supervisor's tolerance, flexibility, and capacity to extend warmth, support, and acceptance toward the supervisees, irrespective of the errors that the latter make, promotes the most effective medium for the handling of resistance.

8. Learning is thus facilitated by a warm working relationship between supervisor and supervisees. It is impeded by hostility that develops in this relationship. A primary focus, then, in the supervisory process is the existing relationship between students and teacher, with thorough ventilation of negative feelings before these exert a corrosive influence on the learning process. The supervisees must be encouraged to express disagreements, criticisms, or feelings in relation to the supervisor. The supervisees must also be able to accept criticism, and this will be possible where there is a good rapport with the supervisor.

9. As a general rule, learning blocks are resolved during the first few months of supervision. An inability to master such blocks after several months indicates a severe problem that necessitates incisive investigation.

10. In learning, the supervisees have a backlog of past experiences on which to build. They cannot be expected to progress any faster than would be warranted by the degree of this experience, no matter how hard the supervisor may push; severe demands will be a hindrance.

11. As a rule, in the early stages of learning, the supervisees will feel resentful, unsure, and certain of failure. They will want to be told how to function— indeed, will demand that the supervisor demonstrate exactly what to do. The supervisor must accept the presence of dependency and yet treat the supervisees as equals. The setting of supervision is best permissive, the supervisees being given the feeling that they are free to act, experiment,

and make mistakes. Mistakes are to be expected since even expert therapists make them.

12. Learning how to become a therapist is a tedious process enhanced by the active participation in the learner's growth. It is facilitated by selected case studies that serve a specific purpose in filling in gaps in experience, as well as by assigned readings and recommended courses. At all times, critical thinking is to be encouraged.

13. Learning is more an educational than a therapeutic process, and the focus in good supervision is on supervisees' work rather than their personal problems. It is essential that supervisees be treated as adults and not as problem children.

14. Learning is expedited by successes, and it is impaired by failures. Provision should be made for some successes that will reinforce learning. If supervisees encounter repeated failures, damage will be done to their learning capacity. The supervisor should therefore be encouraging and commendatory of any successes that are scored.

PROBLEMS IN TERMINATION OF SUPERVISION

The relationship that supervisees establish with the supervisor will, in general, proceed through various phases, including the establishing of rapport, the understanding of problems that occur in relationship to the supervisor, the translation of this understanding into corrective action, and, finally, the ending phase in which supervisees develop the capacity to carry on, on their own, with working through of the dependence on the supervisor.

If the supervisor has an authoritarian personality structure, it may be difficult to operate on equal terms with the supervisees. The supervisor will want to continue to make decisions, to utter judgments, and to offer interpretations, consciously or unconsciously resenting the supervisees' right to self-determination. Under these circumstances the ending of supervision may impose great hardships on both supervisor and students.

On the other hand, the greater the dependency needs in the supervisees, the more

difficult it will be to countenance termination. An inability to resolve dependence on the supervisor indicates severe characterologic problems for which the supervisees may require further therapeutic help.

During the terminal phases of supervision the supervisor, in anticipation of the trauma of separation, may assume a nondirective role, insisting that the supervisees be more active and figure things out entirely alone. One may expect that the supervisees will respond to such nondirectiveness with anxiety and hostility and that there will be an attempt to force the supervisor to abandon this passive role. If the supervisor is persistent, however, justifying the passivity displayed on the basis of a respect for the supervisees' growth process, the latter will eventually be convinced of the rationale of the supervisor's behavior.

TECHNICAL DETAILS OF SUPERVISION

Preclinical Training of the Therapist

Before supervision begins, the supervisor will desire information about the preclinical training of the prospective supervisees. Questions that may arise include these: Is the theoretic background of the supervisees adequate for functioning in psychotherapeutic practice? Have the required courses been taken and the essential reading done? Has this theoretic material been integrated satisfactorily? Do the supervisees have the personality qualities that will make for a good therapist? How profound an understanding do the supervisees have of their own emotional and interpersonal processes? Will the supervisees be able to resolve or to control the expression of hostility, detachment, sexual interest, overprotection, rejection, and other strivings on the part of the patient that will be inimical to the psychotherapeutic relationship? Can it be reasonably assumed that the supervisees are sufficiently adjusted to life now, so that they will not use the therapeutic situation and the experiences of the patient to live through vicariously certain frustrated ambitions. dependencies, and hostilities? Do the supervisees have a capacity to empathize with people, to feel warmth

toward them and to communicate it? Is there the capacity to be resolute and firm on occasion, capable of insisting on certain essential actions during the therapeutic process? How much experience have the supervisees had in psychotherapy? What kinds of cases have been treated and with what results? Has there been previous supervision, and if so, with whom and for how long? Do the supervisees believe such supervision has been beneficial?

There is general agreement that the prospective psychotherapist requires an extensive amount of preclinical training. A review of training that is being given in most of the recognized schools reveals a close similarity in prescribed courses and requirements. These include the following:

1. Courses in basic neuropsychiatry, normal psychosocial development, psychopathology, psychodynamics, techniques of interviewing, techniques of psychotherapy, dream interpretation, child psychiatry, group psychotherapy, and behavior modification.

2. Clinical conferences and continuous case seminars that have been attended regularly.

3. Readings in psychiatric literature of sufficient scope to provide the students with a good background in history, theory, and practice.

4. Ideally, enough personal psychotherapy or psychoanalysis to provide the students, first, with an opportunity to achieve self-understanding through self-observation, studying their own emotional conflicts, the genesis and projection of such conflicts into present functioning; and, second, to liberate themselves sufficiently from personal problems and character disturbances that interfere with the establishment and maintenance of a therapeutic interpersonal relationship.

Should the supervisees be lacking in any of these basic requirements, the supervisor must help find ways of making up these deficiencies. (See Appendix L, for a form that supplies the supervisor with essential information.)

The Beginning Stages of Supervision

The first contact of the supervisor with the supervisees is in the nature of an exploratory talk. At this time there may be a discussion of the supervisees' preclinical training, and arrangements may be made as to the hours, frequency of visits, and the method of recording and presentation. The supervisees may be given preliminary orientation as to what will be involved in supervision and how supervisory sessions may best be used. Arrangements may be made for the handling with the supervisor of any emergency situations that may occur during the course of supervision.

In the early months of supervision, a period of disillusionment is to be anticipated. Supervisees will be brought face to face with practical problems in implementing therapy that may be at variance with what has been learned from books. Student therapists often are upset by the fact that the specific kinds of problems that provoke their patients may be precisely those that are disturbing to themselves. They may be exposed to certain situations that develop in treatment that have a violent impact on them and tax their own capacities for adjustment. It is incumbent upon the supervisor to extend to the supervisees during this period a good deal of warmth and understanding. The primary focus in early supervision is the relationship between supervisor and supervisees, since little progress will be possible until good rapport exists.

Later Phases of Supervision

In supervision the supervisor seeks to ascertain whether or not the supervisees are living up to their potential. If not, the sources of this lack must be diagnosed. For instance, the problem may relate to deficiencies in the kind of preclinical training received, or in the assimilation of educational materials presented in training. It may be due to an absence of perceptiveness or to insensitivity about what is going on in the therapeutic situation. It may be the product of personality problems that prevent the supervisees from establishing a meaningful contact with patients.

The areas in which supervisees need help will soon become apparent. In the main, technical problems break down into difficulties in diagnosis, conduct of the initial interview, use of interviewing techniques, understanding of the operative dynamics,

detection and handling of transference, awareness and mastery of countertransference, dealing with resistance, use of interpretations, and termination of therapy.

The task of the supervisor here is not to tell supervisees what to do but rather to teach them how to think through solutions for themselves. Toward this end, it will be essential to ask questions and to structure problems so that the supervisees can come to their own conclusions. Learning problems are to be diagnosed and handled along lines indicated previously. Modes of improving sensitivity are described by Fielding and Mogul (1970).

In the course of supervision, supervisees are bound to show transference manifestations. The supervisor will also have emotional attitudes toward the supervisees. Both positive and negative feelings will have to be subjected to close scrutiny to permit development of empathic yet objective attitudes. Furthermore, the supervisor will have to maintain a certain amount of tension in the supervisory sessions to expedite activity.

The beginning supervisor, particularly, may respond to supervision with untoward feelings. There may be a tendency to be pompous and overbearing and to overwhelm supervisees with material. The supervisor is apt to feel irritable when supervisees do not learn rapidly or defy suggestions and criticisms, even though these are offered in a constructive way. The supervisor may be provoked when there is persistence in errors that are so obvious that they scarcely need identification. Such attitudes on the part of the supervisor will, of course, interfere with learning. An honest self-questioning by the supervisor will often reveal tendencies that stifle the development of supervisees. It must be emphasized again that some countertransference is always present and that it need not be destructive to the teaching objective, provided that the supervisor is capable of understanding his or her feelings and of modifying and correcting them before they get out of control.

Disagreements between the supervisor and supervisees are inevitable, even desirable. All learning inspires resistance. Supervisees will voice protests in changing habitual patterns. They are bound to be critical. Actually, they cannot change unless they

are given an opportunity to voice and to work through their criticisms. The supervisor may be offended by such challenging reactions, but will best be able to respect the supervisees' right to their own opinions, realizing the unavoidable learning struggle that is involved.

Essential for learning is an open mind to new ideas. Some students have already settled their opinions about psychological theory and process and seal themselves off from fresh points of view. What they seek from the supervisor is a confirmation of their frozen ideologies. Similarly, there are supervisors so rigidly wedded to their credos that they insist on their students becoming a mirror image of themselves. Vital for learning in the supervisory process, then, are participants who are willing to collaborate, share experiences, and, if necessary, change. Students must be able to countenance exposure of deficiencies in psychotherapeutic performance. The supervisor must be able constructively to bring students to an awareness of these deficiencies and to provide students with an appropriate means of rectifying them.

Illustrative of some of the problems are the following comments of a supervisor:

> I have a supervisee who is a chatterbox and who is highly defensive about any comment I make—even a casual comment on the dynamics is interpreted as a criticism of her. Her defense is to interrupt, challenge me, justify herself, etc., without permitting me to finish what I have to say. Often, by the end of the session, I find that I have been able to tell her very little. I have been debating with myself whether to take up the problem with her directly, which might merely provoke additional defensiveness, to pull back and tell her virtually nothing until she complains about it to me, or to go on as I have but being very supportive until she feels less threatened.

These are the remarks of a student:

> The trouble with my supervisor is that he is constantly trying to force his point of view on me. I would think that he would know I can't do things exactly how he does them. I would like to have him help me work better with my good points and to help me eliminate my bad points. When I show him what I believe is a gain in my patient, he usually criticizes it as merely defensive, a new resistance.

In both of these illustrations effective learning is being blocked by problems that are influencing the relationship between student and supervisor. The supervisory encounter is far more complex than that of a simple teaching contingency. It embraces unconscious

processes that may require mutual exploration. In any of the social sciences where professionals function as investigative or therapeutic tools, there are bound to be differences in theoretical assumptions and methodological approaches. These differences may interfere with the manner in which individuals communicate themselves to other professionals. Even within the same school, problems in communication may be vast. They are particularly annoying in the psychotherapeutic learning and teaching situation.

The supervisor is constantly involved in a process of self-analysis while relating to supervisees and examining personal reactions, both transferential and reality determined. There is recognition that students will be carrying out therapy with their own personalities and not with the personality of the supervisor. Students may not be able to perform exactly the way the supervisor performs, nor will students be able to deduce from interactions with patients all of the nuances that are apparent to the supervisor. A tremendous amount of tolerance and acceptance will be required from the supervisor that may tax the latter's patience and bring countertransference into play. Although the supervisor serves as a model for the student, it must be a flexible model and not one that demands a clone. These conditions should readily be acceptable to anyone who possesses the sophistication that is a prerequisite for becoming a supervisor, understanding from experience that there is no single accurate way of providing therapy. There are many ways. What can be taught is a broad framework of psychotherapy with a buttressing up of those elements of the students' functioning that permit good therapeutic process, while expurgating interfering elements.

'Intensive' versus 'Technical' Supervision

In practice, two general types of psychotherapeutic supervision may be defined. The first type, "intensive" supervision, consists of the "continuous-case" type of reporting with a single patient, preferably from the initial interview to termination, using video recordings if possible. This enables the supervisor to help supervisees in all phases of treatment by observing operations with one patient over a long-term period. "Intensive" supervision is the most effective kind of teaching for beginning therapists.

The second type of supervision, arbitrarily called "technical" supervision, may be further divided into two subtypes. The first, or "case-load" supervision, which is usually prescribed especially for beginning therapists in a clinic, covers the general progress and specific difficulties being encountered in the entire case load of the supervisees. This might be considered a kind of administrative supervision. The second subtype, which we may, for want of a better name, call "special-problem" supervision, is handled in a manner similar to a clinical conference. Any pressing problem in diagnosis, psychodynamics, or technical management may be presented, and the discussion is centered around the specific difficulty encountered by the supervisees.

The latter kind of supervision is more highly advanced than other types and presupposes more experience on the part of the supervisees. It may also be effectively practiced in a group of no more than three or four therapists, who participate in the discussion with the supervisor. Each therapist may be given the privilege of presenting material on successive sessions. In practice, this proves to be a highly provocative teaching device, provided all the supervisees are on approximately the same level.

The Evaluation of the Supervisee

Evaluation is a means of helping supervisees develop skills through a continuous assay of strengths and weaknesses. As such, it becomes part of the teaching method, pointing to areas in which more development is needed and helping in a positive way to promote such development. Criteria of evaluation may be along the following lines:

1. Method of presentation, and recording ability.

2. Theoretic understanding.

3. Diagnostic ability.

4. Integration of theory into practice.

5. General therapeutic aptitudes, sensitivity, empathy, and capacity for critical thinking.

6. Kinds of relationships that the supervisees establish with patients and the skill in handling these relationships.

7. Type of relationship that the supervisees have with the supervisor and the use made of the sessions.

8. Types of relationships that the supervisees establish with colleagues and personnel of the clinic, if any, with which they are affiliated.

9. Supervisees' good points and special skills.

10. Supervisees' deficiencies.

11. General learning ability and the progress that has been made in learning.

12. Positive recommendations for increasing learning, including recommended readings, prescribed courses, and preferred kinds of cases to be assigned.

Yardsticks of expected progress have never been set. Arbitrarily, a rough gauge such as the following may be useful to indicate minimal levels of achievement:

End of first six months of supervision: Ability to make diagnoses, ability to keep patients in therapy.

End of first year: Ability to understand what promotes, aggravates, and helps emotional illness; capacity to establish good rapport with patients.

End of one and one-half years: Recognition of personal problems in therapeutic functioning.

End of second year: Ability to overcome most personal problems in therapeutic functioning.

End of two and one-half years: Ability to function without serious mistakes. *End of three years:* Ability to do good psychotherapy.

Evaluation imposes burdens on both supervisor and supervisees. The supervisor may not want to criticize out of fear of hurting or offending the supervisees. The latter, in turn, may feel humiliated at having weak points exposed. The manner in which evaluation is presented, and the purpose for which it is used, will largely determine the reactions of

the supervisees. If understanding is clear that there will be periodic evaluations, say every six months, to point out the areas in which the greatest or least development has been made, the experience can prove to be an aid to learning.

The evaluation conference may be set up in advance, and supervisees and supervisor may prepare their observations for mutual discussion and consideration. At the conference a common understanding must be reached. If a written evaluation must be sent to the head of a clinic or school, agreement on as many points as possible is best achieved in advance of sending the report.

The point at which the supervisor certifies the student therapists as competent to do psychotherapy will vary with the kind of therapy for which the students are being prepared. Table 61-1 shows an outline for evaluation for certification that has been used at the Postgraduate Center for Mental Health.

Administrative Responsibilities

If the supervisor and supervisees are associated with the same clinic, the supervisor will have further responsibilities. For instance, the supervisor may participate in an analysis of administrative or intake policies, making recommendations toward alteration of old, or the devising of new, policies. The object here is the elimination of influences that are destructive to the patients' therapy or to the therapists' functioning. If supervision is part of a school training program, the supervisor will also probably be engaged in an analysis of administrative and pedagogic procedures in the program. This will include methods of choice of students, modification of curricula, introduction of new courses, and proposed changes in instructors or instructional methods. Routine meetings among the supervisors, or between supervisors and the supervisory head, will cover discussion of such problems in detail, with the introduction of whatever current difficulties the supervisor is having with supervision and routine evaluations of the progress shown by the different supervisees.

SUPERVISION AS AN INTERPERSONAL RELATIONSHIP

The supervisory relationship is one to which supervisees react with mingled attitudes of admiration, jealousy, fear, and hostility. Admiration and jealousy are usually inspired by the supervisor's superior knowledge, training, and status. Fear of the supervisor is often the product of the therapists' helplessness in the face of an authority, who, they feel, may judge them unfairly and destroy their careers and livelihood in the event they fail to live up to expectations. Hostility issues from many sources. On the one hand, it is the product of dependency on the supervisor, which is especially inevitable at the beginning of supervision. Dependency yearnings that are mobilized are usually accompanied by expectations that these yearnings will be frustrated. Feelings of being victimized by these dependency needs, and the threats imposed by these needs on independence and assertiveness, inspire further resentment. The very acceptance of supervision implies to some supervisees a kind of subordination that imposes burdens on adjustment, particularly when independence has become the keynote in the students' life struggles. The supervisees, in addition, resent demands that they believe the supervisor makes on them. The restrictions imposed on the students, the criticisms directed at their functioning, deliver blows to their narcissism and contribute to further fears of loss of self.

Supervision will thus produce feelings in the supervisees that are related to neurotic attitudes toward authority. Difficulties may come out openly in the form of verbalizations or behavioral acting-out. They may also be concealed behind a barrage of defenses that reflect supervisees' habitual covert patterns in their dealings with authority.

The supervisor, in turn, will respond in supervision with untoward feelings toward the supervisees, many of which are the product of neurotic attitudes toward subordinates. In a flush of omnipotence, a patronizing attitude may be displayed toward the supervisees, with presentation of ideas as if they were irrevocable pronouncements. Contempt may be expressed for the relatively inferior knowledge, skill, or status of the supervisees. Hostility may appear when supervisees challenge the supervisor's opinions or theories. The growth or advance of the supervisees may be resented from a desire to keep them on a subordinate level, in an effort to preserve superiority. Accordingly, successes of the supervisees may be threatened with chariness of praise, so important in learning. Such

attitudes are rarely expressed directly. They may be cloaked in solicitous, ingratiating behavior with overkindliness and overattentiveness. Or they may show up as disinterest, offering the supervisees little help or reassurance. Searles (1955) and Benedek (1972) have written on the use of the supervisor's feelings and "intuition" as a way of gaining understanding into the problems of supervisees.

The supervisory process will thus arouse varied feelings and attitudes in both supervisor and supervisees that are inimical to learning. Sufficient resolution of such deterrents must occur before progress is possible. As a general rule, assuming that the participants are mature people capable of facing their feelings and communicating with one another, differences should be satisfactorily resolved. Problems may persist in some cases, however.

The supervisor may be tentative, indecisive, irritable with the students, overprotective, and patronizing, all of which put a damper on the students' need to express criticism and verbalize doubts. Lack of interest in the students and their growth acts as a damper to learning.

In supervisees, character problems show up in the form of many resistances, some of which persist with an amazing tenacity. Among these are attitudes of conformity and a seeming absorption of every gesture and utterance of the supervisor. This spurious kind of admiration is accompanied by a constant repetition of mistakes, as if all knowledge is shed immediately after leaving the supervisor's office. There may be a continuing fear of losing one's independence by yielding to the supervisor's dictates and demands. Resisting learning then becomes for the supervisees a means of retaining identity.

Another kind of resistance is the need to dominate and to take control by out-supervising the supervisor. In such cases, the supervisees overwhelm the supervisor with material, edit reports—even falsifying material—to impress the supervisor. Belittling and derisive attitudes and feelings may exist toward the supervisor that are only indirectly expressed and that serve to protect the supervisees from fancied exploitation and injury.

On the other hand, those supervisees with many personal problems may become so terrified about what is happening in the relationship with the supervisor as to seek reassurance, affection, and support in sundry ways. One way is to become helpless and hopeless, assume a defenseless attitude, and seek from the supervisor various panaceas for difficulties. In making such demands, the student-therapist may express lack of confidence in resolving developing problems in an attempt to force the supervisor to shoulder all obligation for decisions. Self-devaluation may follow in the wake of this attitude, much of which is an effort to avoid criticism and to forestall responsibility.

Resistance to learning may also be expressed in the form of hostility. The patterns that hostility takes are legion, depending upon the individuals' habitual modes of dealing with this emotion. When supervisees find it hard to express rage, their response may be depression and discouragement. One individual may seek to terminate supervision on the basis that he is completely incapable of learning. Another may mask her hostility with dependence, with feigned amiability, and with strong gestures to force the relationship with the supervisor into social channels. In instances where the student-therapist is capable of expressing her hostility openly, she may become defiant, challenging, and overcritical. She may develop feelings of being exploited, misunderstood, and humiliated, and she may attempt to find evidence for these feelings by misinterpreting what goes on between herself and the supervisor. She may become suspicious about the supervisor's abilities, training, and personal adjustment. She may enter into active competition with the supervisor, bringing in materials, quotations, and references from authoritative works to challenge the supervisor or to nullify suggestions the latter has made. In some instances, the supervisee may actually become uncooperative, negativistic, and even defiant. In other instances, hostility is masked by apathy and detachment. Here one will get the impression that the supervisee, while presenting material and listening to the comments of the supervisor, is mentally "off in the clouds."

Supervisees may also try to ward off the supervisor by discursive talk about superficial topics or by self-interpretations that are expressed with great vehemence. This attempt to disarm the supervisor by spurts of productivity has little corrective value for

the supervisees, since it is motivated by an effort to belittle the supervisor rather than to learn.

Other resistances take the form of an inability to think clearly and an incapacity to express one's ideas. There may be an insistence by the supervisees that there is great development that is not supported by facts, and though self-confidence and assertiveness may be expressed, these will be found to be without substance. Another defense is an attempt to seduce the supervisor with gifts, lavish praise, and compliments. The overvaluation of the abilities of the supervisor may be boundless, and an unwary supervisor is apt to respond to these devices with omnipotent feelings.

Assuming that the supervisor is capable of controlling or of resolving countertransference, can help be rendered the supervisees to overcome such varied resistances to the supervisory relationship?

One must remember that supervision is a student-teacher, rather than a patient-therapist, relationship. Emotional problems stirred up in supervisees during work with patients cannot entirely be handled by the supervisor in the setting of supervision. Although the outcome of supervision may be therapeutic for supervisees, the goal is toward more adequate functioning in psychotherapy rather than the helping of personal neurotic difficulties. Naturally, the supervisor does point out neurotic problems that express themselves in resistance to learning and in countertransference in the hope of dispelling blocks in functioning. Since some of the problems that supervisees experience with the supervisor may be similar to those being experienced with their patients, working them out with the supervisor is bound to have some salubrious effect on overall therapeutic functioning. It is assumed that most supervisees have had sufficient personal psychotherapy, or are sufficiently integrated emotionally, to be able to resolve blocks through their own resources in the supervisory setting. The supervisor will have to handle those aspects of feeling and attitude that impede the acquisition of therapeutic skills. This experience, as has been mentioned, may prove itself to be therapeutic for supervisees, but, if this occurs, it is a byproduct of the chief objective—the learning of psychotherapy.

Should the supervisor's effort to help supervisees resolve difficulties fail, referral for personal psychotherapy may be advisable, which the supervisor may also benefit from receiving if personal problems in the existing relationship with particular supervisees cannot be worked through. In the event mutual trust and respect do not develop between supervisor and certain supervisees and no progress in learning has occurred after these avenues have been tried, transfer to another supervisor may be necessary.

These difficulties are not uncommon in a school or clinic. They are attenuated, though not entirely obliterated, when a therapist in private practice chooses and pays for a supervisor who does not need to render reports to the school or clinic.

Among the recommended readings on supervision are Alonson (1935), Arlow (1963), Blumenfield (1982), Caligor (1983), Collins (1962), DeBell (1963), Ekstein and Wallerstein (1958), Fleming (1961, 1963, 1967), Fleming and Benedek (1966), Grinberg (1970), Grotjahn (1955), Hess (1980), Kris (1956), Langer et al. (1964), Langs (1979), Schuster (1972), Solnit (1970), Steinhelber (1984), Szasz (1958), Towle (1954), and Windholz (1970).

Sundry questions plague the individual doing psychotherapy. Answers to these questions are not easily provided, since there are many ways of accomplishing the same task in psychotherapy, some of which are suitable for one therapist and wholly inappropriate for another. In this chapter a number of common questions, posed by therapists participating in case seminars conducted by the writer, and not answered completely in the text of this book, are considered. The answers given to these questions are, of course, not absolute and will require modification in terms of the individual's unique experience and specific style of working.

Q. If a patient attacks you verbally at the initial interview, how would you handle the situation?

A. An aggressive outburst in the first interview is clearly an indication of great insecurity or fear in the patient. Patients will generally rationalize the hostility on one basis or another. A way of handling the situation is to accept the patients' hostility and to inform the patients that under the circumstances, you do not blame them for being angry. As a matter of fact, it would be difficult for them to feel any other way. If possible, an effort should be made to bring the meaning of the aggressive outburst to the patients' awareness. If this can be done, it may alleviate their tension and initiate more positive feelings toward the therapist.

Q. How do you handle patients who come to see you while they are being treated by another therapist?

A. This situation occasionally happens and will have to be managed diplomatically. There are a number of reasons why patients find it necessary to consult a second therapist. They may be in a state of resistance, and their visit constitutes an attempt at escape from, or a gesture of hostility toward, their therapists. Or the patients may sense that they are unable to relate to their therapists, or that their therapists are unable to relate to them, and they are reaching out for a new, better therapeutic relationship. In either instance, one must respectfully listen to the patients and focus particularly on the specific meaning of their consultation with you. Under no circumstances should one participate in criticism of the other therapists, no matter what outlandish activities are ascribed to them by the patient. On the contrary, one should be alerted to transference manifestations and attempt to clarify any misconceptions or irrational attitudes about the patients' therapists that present themselves. The ultimate result of the interview may be emotionally cathartic for patients, and they may return to their therapists with insight into their resistance. Should there be reason for your considering treating the patients, and if they had not informed their therapists about the prospective consultation with you, it will be important to emphasize the need to discuss the situation with their therapists. The patients may be told that for

ethical reasons it will be impossible to start treatments with them unless both they and their therapists agree that a transfer is indicated. In the event the patients have, when they consult you, discontinued treatment with their therapists, the visit may, of course, be conducted as an initial interview.

Q. Is it permissible to treat one's friends or relatives?

A. It is extremely difficult to be therapeutically objective with friends and relatives. Nor will they be able to establish the proper kind of relationship with you. For these reasons, if they need treatment they are best referred to another therapist.

Q. How far can the therapist go in making interpretations at the beginning of therapy?

A. An experienced therapist may discern important dynamics in the first interview or shortly thereafter. To interpret these to patients may be harmful. A strategic moment must be waited for—which may come many months later—before revealing to patients what the therapist already knows. New therapists, in their enthusiasm, frequently violate this rule, as do experienced therapists with strong narcissistic leanings who attempt to demonstrate to patients how much they know about them.

Q. What causes violent feelings that are stirred up in patients after the first interview?

A. These may be caused by transference or by something the therapist has done in error.

Q. Are mistakes that a therapist makes in psychotherapy irretrievably destructive?

A. Even the most experienced psychotherapist makes mistakes in the conduct of therapy. There are many reasons for this, including the fact that the therapeutic relationship is so complex that the therapist cannot see all of its facets. Such mistakes are not too important if the working relationship with patients is a good one.

Q. Are the various psychotherapeutic approaches ever used together?

A. Practically all forms of psychotherapy purposefully or inadvertently employ a combination of approaches. Even in formal psychoanalysis one may, at times, be unable to avoid suggestion and reassurance. Persuasive and other supportive influences may by design enter into insight therapy from time to time, and disturbing environmental factors may deliberately have to be handled in order to promote maximal progress. Wittingly or unwittingly, then, no approach is used in isolation. Rather, it is blended with other approaches, made necessary on occasion by the exigencies of the therapeutic situation.

Q. Does one ever start off using one approach and then, in the course of treatment, switch over to another approach?

A. This is very frequently the case. One may start off with an approach aimed at a supportive or palliative goal. In the course of treatment it may become apparent that no real improvement will be possible unless one deals with underlying causative factors. One will consequently have to motivate the patient toward accepting therapy aimed at more extensive goals. On the other hand, one may begin reconstructive treatment and, in the course of administering this, discover that circumstances make less extensive goals desirable. A supportive

approach may therefore become advisable.

Q. Should patients be required to pay for their own treatment?

A. Some patients will get more out of therapy if they feel in some way responsible for its payment. This does not mean that they will not benefit from treatment financed for them if they cannot afford it. With the increasing incidence of third-party payments (insurance, Medicare, Medicaid), a considerable body of experience shows that good psychotherapy is possible even though patients do not pay for it themselves. In child and adolescent therapy, parents or guardians assume responsibility for fees, and this fact does not denigrate the therapeutic effort. When therapy is given free, and no payment is made for it by any party, some patients are handicapped in expressing any feelings toward the therapist that they believe will cause offense. A perceptive therapist can detect this reluctance and deal with it to promote freedom of expression.

Q. How is the matter of fees best handled?

A. The matter of setting a fee satisfactory to both therapist and patient, and of agreeing on the manner in which payments are to be made, is part of the reality that therapy imposes on patients. Many therapists gauge their fees according to patients' ability to pay. In setting a fee, it is important that the therapist consider the patient's capacity to carry the financial responsibility over the estimated treatment period. Unless this is done, both therapist and patients will find themselves in a difficult situation later on. Though grading the patients' fees according to the patients' ability to pay over the estimated time period of treatment, the therapist must be assured that the fee is adequate. Should the therapist accept a fee too low to meet personal obligations, the therapist will feel insecure. Resentment or anxiety may occur that will impose a destructive influence on the therapeutic relationship. Once a fee is set, it is difficult and unfair to raise it unless patients' financial situation has improved. Often a neurotic problem interferes with the work capacity and productivity of patients. At the start of therapy, patients' earning ability will therefore be minimal. Once therapy gets under way, patients may be able to earn a great deal more money. Under such circumstances, discussing with them the raising of a fee is justifiable, and an adjustment of fees upward usually will be acceptable. On the other hand, financial reverses may occur during the course of therapy. In such instances a reduction of fee may be required.

Q. What do you do when patients neglect payment of fees?

A. Lack of punctuality in the payment of fees may be a manifestation of temporary financial shortage, a problem related to money or to giving, or an indication of resentment toward, and desire to frustrate the therapist. Should patients disregard the payment of bills for a considerable period, the matter may merit inquiry and therapeutic handling. If the therapist has neurotic problems in relation to money, he or she may evidence marked anxiety when payments are not being made on time. The therapist may consequently tend to overemphasize the importance of punctuality in payments and may introduce the matter of finances completely out of context with the material that concerns the patients. On the other hand, the therapist may be negligent on the matter of payments and may fail to bring to the patients' awareness possible avoidance of a responsibility that is part of reality. Unless justified by financial reverses, the accumulation of a debt creates hardships for patients that may be harmful to their relationships with the therapist.

Q. If you discover that patients' finances are greater than those reported at the beginning of therapy, would you boost the fee?

A. Financial arrangements with patients may have been made on the basis of a reported low income. If patients have purposefully concealed their finances from the therapist, this deception will, in all probability, later create guilt and tension. The therapist may assure patients that there must have been reasons for falsification of income. Understandably, careful handling is necessary to avoid mobilizing further guilt. In the event the set fees require adjustment because of patients' larger income, this matter must be discussed thoroughly with the patients, no change of fees being made except on mutual agreement. If the patients' fees are arbitrarily raised without their complete cooperation, grave difficulties may be anticipated in the therapeutic relationship.

Q. Should the therapist ever visit patients in their home?

A. Only in the event of a crisis or serious incapacitating illness or accident when it is impossible for the patients to come to the therapist's office and when it is urgent to administer psychotherapy.

Q. What do you do when patients talk too much and don't allow the therapist to speak?

A. If patients are focused on an important area and doing good therapeutic work, one does not interrupt. If they are talking about irrelevant things or their rambling seems to be resistance, one interrupts and focuses on pertinent topics. If this does not help, one may question the reason for rambling, or perhaps attempt its interpretation.

Q. Is there not a similarity between friendship and a working relationship?

A. Only peripherally. The therapeutic relationship is a professional one. Implicit in it is the absolute promise of confidentiality, the recognition that the time span is a limited one, and that termination of the relationship will eventually come about.

Q. What do you do if patients have been in negative transference for a long time and this continues no matter what the therapist does?

A. First the therapist might undertake self-examination to see if he or she is provoking these feelings. If the therapist is sure there is nothing in the therapeutic situation that is stirring up the patient, analysis of possible projections by the patients into the present relationship of negative attitudes toward important past personages may be undertaken. If this does not help, the therapist may go back to the first phase of therapy and actively try again to establish a working relationship with the patients.

Q. What is the relative merit of focusing on past, as compared with present life difficulties in reconstructive therapy?

A. In reconstructive psychotherapy, some controversy exists as to the relative importance of material that deals with the past and material relating to the present. Extremists of both points of view argue the merits of their particular emphasis. On the one hand, there are those who regard the present problems of individuals as a peripheral product of personality disturbances arising out of insecurities in childhood. These insecurities have undermined

self-esteem and blanketed sexual and aggressive drives with a mantle of anxiety. Environmental difficulties and current situational distortions stir up hardships for individuals by agitating past problems. Dealing with provocative current situations may restore the individuals' equilibrium. This stability is, however, precarious due to the continued operation of immature strivings. Although harmony may be reconstituted, the recurrence of environmental stress will promote a new breakdown in adaptation. It is fruitless, therefore, always to concentrate on the present since the roots of the difficulty, imbedded in the past history, will remain firmly entrenched. On the other hand, there are therapists who are opposed to an emphasis on the past. It is claimed that individuals repeat in present-day patterns their important childhood disturbances. A concern with the present must of necessity involve a consideration of the past. To discuss the past in detail results in a mere raking over of dead historical ashes; though interesting material may be exposed, it may bear little relationship to current happenings. A dichotomy may then be set up between the past and the present, without unifying the two. As irreconcilable as these two viewpoints appear, they are not so disparate as the proposed arguments would seem to indicate. In psychotherapeutic practice one constantly uses current life experiences as vehicles for discussion, for it is in the present that individuals live and feel. Yet, a consideration of the past is mandatory in understanding what is happening in the present. Current life experiences may be regarded as reflecting the past through the use of present-day symbols. It is therefore necessary to blend the past and the present and to focus on whichever element is of immediate importance.

Q. Is it ever permissible to assign "homework" to patients?

A. This can be very rewarding, particularly if patients are not too productive and do not work industriously at therapy. Asking them to keep a kind of diary, writing out their reactions, observations, and dreams between sessions, may get them to approach treatment more seriously. Each interview may be organized around discerning and exploring basic patterns that are revealed in the patients' notes or observations. Patients should leave every session with a general problem to focus on until next session. They may then work on this problem, observing themselves and their reactions, noting which environmental or interpersonal situations tend to aggravate or moderate it. This "homework" may catalyze the patients' thinking and get them to assume more responsibility for treatment.

Q. If patients want information about a subject like sex, do you give it to them?

A. First find out why they ask for information and then give it to them or assign appropriate reading.

Q. Should all patients have a physical examination prior to psychotherapy?

A. All patients about to enter psychotherapy should have a good physical examination and, if the practitioner deems necessary, a thorough neurological examination performed by a competent neurologist. The findings will be negative in the vast majority of patients, but the occasional case of early cancer, brain tumor, or other operable maladies that are detected will justify the precaution of routine physicals.

Q. How would you handle patients who appear to have read just about everything on the subject of psychiatry and keep citing the opinions of different authorities that may or may not agree with your point of view?

A. Some patients may have read more on psychiatry than you, but this does not mean that they have integrated what they have read. As a matter of fact, they will probably tend to use the knowledge they have gained in resistance, by intellectualizing what goes on, or by criticizing the technique or formulations of the therapist. At some point in therapy it may be necessary to mention to such patients that, while their reading has given them a good deal of information, this information may be a hindrance to therapy rather than a help. No two problems of an emotional nature are alike, and facts patients have read applying to other people surely do not exactly apply to themselves. They can be fair to themselves only by observing their feelings and attitudes, without speculating what these must be like on the basis of readings. Sometimes it may be necessary to be very blunt and to tell patients that it is important for them to forget what they have read since this seems to interfere with their spontaneity.

Q. What do you do when patients ask a question the therapist is unable to answer?

A. The therapist may say that the question cannot be answered at this time but will be later when the answer becomes more clear.

Q. Is it ever justifiable to lie to patients?

A. Lies eventually reveal themselves and shatter the patients' trust and confidence in the therapist. Truthfulness is, consequently, the keynote in therapy. In an effort to be truthful, however, one should not reveal things to patients that may be harmful to them. It may be essential, therefore, if their security and health are menaced, to avoid answering certain questions directly. If, for instance, patients show symptoms of an impending psychosis, and are dangerously tottering between sanity and mental illness, and if they are frightened by the upsurge of archaic unconscious material to a point where they believe themselves to be insane, it may be harmful to tell them that they are approaching a psychosis. Rather, they may, if they question the therapist, be told that their preoccupation with becoming insane is more important then the symptoms they manifest. These are evidence of great insecurity. Whenever the patients asks a direct question, an honest answer to which may be upsetting in view of existing ego weaknesses, the patients may be asked why they ask this question, and their concern may be handled without upsetting them with a straight reply. It is important to remember that truthfulness must not be confused with necessary caution in divulging information and interpreting prematurely. If patients are insistent on a complete answer to their questions, it may be helpful to point out that therapy involves a mutual inquiry into a problem and an avoidance of premature judgments. One must patiently wait until enough evidence is available before being certain of one's observations. The answer to questions will soon become evident, both to the patients and to the therapist. If for any reason the patients cannot perceive the truth, the therapist will point out why it is difficult for them to understand what is happening. The patients will eventually develop confidence in the fact that the truth will not be withheld but that ideas must be checked and double-checked for their validity before they can be communicated.

Q. Sometimes it is necessary to break an appointment with patients. How can this best be done?

A. Appointments should, if possible, never be broken without adequate notice being given to the patients. Unless this is done, the relationship may be injured and a great deal of work may be necessary to undo the damage. If circumstances make it necessary to break an appointment, the therapist or the therapist's secretary should telephone the patients,

explain that an emergency has developed that necessitates a a revision of the therapist's schedule, and that, consequently, it will be necessary to make a new appointment or to skip the present appointment. In instances where the therapist is ill, or expects to be away from the practice for an indefinite period, patients may be informed that the therapist will get in touch with them shortly to set up a new appointment. If a reasonable explanation is given, there will probably be no interference with the working relationship.

Q. How would you handle patients' resentment because you do not keep appointments on time?

A. The patients' resentment may be justified. Because of ambivalent feelings, patients usually have difficulties trusting any human being completely. The therapist must, therefore, give patients as little basis for distrust as possible, always explaining the reasons for unavoidable irregularities in appointment times so patients will not assume that the therapist is irresponsible. Giving patients an allotted amount of time is part of a reality to which both patients and therapist must adjust. When appointments are forgotten by the therapist, or patients have to sit around and wait for the therapist because the therapist has not finished with a preceding patient, resentments will develop that may interfere with therapy. Of course, there will be occasions when the therapist cannot help being late for a session. Emergencies with a preceding patient may develop, and the therapist may have to run over in time into the next session. Under such circumstances an explanation must be given patients to the effect that an emergency occurred that could not be avoided and that necessitated a delay in starting the session. To impress on patients the fact that they are not being exploited, they may be told also that time taken from their sessions will be made up. In the event a mistake has been made in patients' appointments, and the patients appears for their session at a time allotted to another patient, they must be taken aside and given an explanation to the effect that an unfortunate error in scheduling has occurred that resulted in the patients' being given the wrong appointment time. Another appointment should then be given the patients, during which any resentment resulting from the errors may be handled.

Q. If you are unable to understand what is going on dynamically in a case you are treating, what do you do?

A. Occasions will arise when the therapist may be unable to discern exactly what is going on in treatment. Should this continue for long, it may be indicative of such blocks as unyielding resistance in the patients or of countertransference. In either instance, where the therapist is disturbed by what is happening or where progress is blocked, one or more supervisory sessions with an experienced psychotherapeutic supervisor may be helpful in resolving the difficulty.

Q. When do you increase the frequency of sessions?

A. During the course of therapy it may be necessary to increase the number of sessions weekly for the following reasons: (1) an upsurge of intense anxiety, depression, or hostility that the patients cannot themselves control; (2) violent intensification of symptoms; (3) severe resistance that interferes with progress; (4) negative transference; (5) unrestrained acting-out that requires checking; (6) threats of shattering of the ego unless constant support is given; and (7) when the therapist wishes to stimulate transference to the point of creating a transference neurosis.

Q. When would you decrease the number of sessions weekly?

A. A decrease in the number of weekly sessions is indicated (1) when patients are becoming too dependent on the therapist, (2) when alarming transference reactions are developing which one wishes to subdue, (3) when patients have a tendency to substitute transference reactions for real life experiences, and (4) when patients have progressed sufficiently in therapy so that they can carry on with a diminished number of visits.

Q. How important is adhering to the exact time of a session?

A. From the standpoint of scheduling, adhering to a set time may be necessary. The usual time is between 45 to 60 minutes. But shorter spans, as low as 15 minutes, can be effective in some patients, and certain situations can arise that require extending the scheduled time.

Q. Is advice-giving taboo in reconstructive therapy?

A. Generally. One must keep working on the patients' resistances to the solving of their own problems. The ultimate aim is self-assertiveness rather than reliance on the therapist. On rare occasions, however, advice-giving may be unavoidable.

Q. Should the therapist ever insist on patients' engaging in a specific course of action?

A. Only when it is absolutely necessary that patients execute it and its rationale is fully explained to and accepted by patients.

Q. Should the therapist ever try to forbid patients from making crucial decisions during therapy?

A. Although important changes in life status, like divorce or marriage, may best be delayed until patients have achieved stability and greater personality maturity, it is obviously difficult for the therapist to "forbid" patients to make any decisions. Patients may be reminded that it is important not to take any drastic steps in altering their life situations without discussing these thoroughly with the therapist. If the therapist believes the decisions to be neurotic, the decisions may be questioned, presenting interpretations if necessary. In the event patients decide, nevertheless, to go through with a move that is obviously impetuous, it means that they are still at the mercy of neurotic forces they cannot control, that their insight is not yet sufficiently developed, or that they have to defy or challenge the therapist. The therapist may have no other alternative than to let patients make a mistake, provided the patients realize that they have acted on their own impulses. It is important not to reject patients or to communicate resentment toward them for having made a move against advice. Only when patients are about to take a really destructive or dangerous step is the therapist justified in actively opposing it.

Q. What do you do if patients bring in written material for you to discuss?

A. Occasional written material may be important, but if large quantities are brought in, this practice should be discouraged.

Q. What would you do if patients refuse to talk spontaneously session after session but offer to write out their ideas?

A. If this is the only way patients will communicate, it should be accepted. An attempt must be made, however, to handle the patients' resistance to talk at the same time that they are encouraged to bring in written comments.

Q. What do you do if patients say they fear they will kill someone?

A. One should not reassure the patients or minimize what they say. Rather, they may be told that there are reasons why they feel so upset that they believe that they will kill someone. They may then be encouraged to explore their impulses and fears. If the patients are psychotic or destructively dangerous, hospitalization may be required. If acting-out is likely, the intended victim should be notified.

Q. Should the therapist permit patients to express hostility or aggression openly in the therapeutic situation?

A. Any overt behavioral expressions of hostility or aggression are forbidden, although verbalization of these emotions or impulses is permissible, even indispensable.

Q. Do you ever reassure patients during insight therapy?

A. Reassurance should be kept at a minimum. Gross misconceptions, however, will require reassuring correction, or patients may be in an emotional crisis which needs mitigation. Reassurance should never be given patients when they are in a negativistic state, since this may produce an effect opposite to what is intended.

Q. Are fleeting suicidal thoughts arising in patients during treatment important?

A. Suicidal thoughts are not uncommon during therapy. They often serve a defensive purpose, acting as a kind of safety valve. Vague ideas of suicide may be entertained as a way of ultimate escape from suffering in the event life should become too intolerable. In most instances such ideas are fleeting and are never put into practice no matter how bad conditions become. They are handled therapeutically in the same way that any fantasy or idea might be managed. It is important not to convey undue alarm when patients talk about suicide as an escape fantasy. To do so will frighten patients or cause them to use suicidal threats against the therapist as a form of resistance. Rather, the therapist may listen respectfully to patients and then state simply that there may be other ways out of their situation than suicide. Suicide is an irrevocable act. More suitable ways of coping with the situation will present themselves as they explore their difficulty. If, however, the patients have, in the past, made attempts at suicide, fleeting suicidal thoughts must be taken very seriously. A careful watch is indicated since the attempt may be repeated. Any evidence of hopelessness or resentment that cannot be expressed as such must be explored and resolved if it is possible to do so. Should resolution be impossible and should the danger of suicide continue to lurk, hospitalization may be required. Suicidal thoughts in patients who are deeply depressed must be considered as dangerous, and the patients must be handled accordingly.

Q. What do you do when patients you are treating telephone and insist on seeing you that very day?

A. If possible, this request should be respected, provided the situation is an emergency. Should the therapist be unable to arrange for an appointment, or for a partial appointment, a promise

may be made to telephone the patients at a specified time that day to discuss the situation with them. As early an appointment as possible may be arranged.

Q. What would you say to those patients who ask whether they may telephone or write to you whenever they desire?

A. Lack of time will obviously make it difficult for the therapist to answer telephone calls or to read all the material that patients wish to communicate in writing. The therapist may handle a request on the part of patients to telephone by saying simply that it is much better to take up matters during a session, since the limited time available during telephone conversations may create more problems than are solved. In response to excessive written communications, the therapist may remark that verbalization is to be preferred to writing. Patients may be informed that when emergencies occur, they may feel free to telephone the therapist. If a crisis has developed, patients may be given specific times at which they may call or may be told that the therapist will telephone them at a certain hour. It is usually best to keep such telephone calls at a minimum and to increase the sessions of the patients should a more intensive contact be required.

Q. How would you handle patients who are insistent that you inform them of your whereabouts at all times so that they can get in touch with you?

A. One would deal with this the way any other symptom in a neurosis would be handled. Patients may be told that it is important to find out why they need to know the therapist's whereabouts. It may be that they feel so helpless and insecure that they must be convinced that the therapist will not desert them or deny them help in the event of a catastrophe. Patients may be assured that the therapist will, in the instance of a real emergency, always be happy to talk with them but that it is important to understand what is behind the patients' insecurity in order that they be able to overcome their feelings of helplessness.

Q. In the event patients in psychoanalysis who have been using the couch position manifest anxiety and ask to sit up, would you encourage this?

A. Anxiety may be the product of penetration of unconscious material into preconsciousness, or it may indicate a feeling of isolation from or a fear of the therapist. Encouraging patients to continue their verbal associations on the couch may enable them to gain awareness of important feelings or conflicts. If anxiety becomes too great, however, their request to assume the sitting-up, face-to-face position should be granted. This will generally permit a restoration of stability, especially if supportive measures are coordinately employed.

Q. Should patients be encouraged to use the couch in psychotherapy?

A. In most cases this is not indicated or advisable. The possible exception is in formal psychoanalysis in which free association is employed.

Q. What do you do when patients have reached a stalemate in therapy? They are completely unproductive, and any attempts of the therapist to mobilize activity and to resolve resistance fail.

A. Group therapy with alternate individual sessions often stimulates activity, as may several sessions of hypnosis or narcotherapy. Continued resistance may justify a vacation from

therapy, or, as a last resort, transfer to another therapist.

Q. When is psychotherapy likely to become interminable?

A. Patients whose personalities have been so damaged in early childhood that their personalities have never allowed for a satisfactory gratification of needs or for an adequate defense against stress may feel they require a continuing dependent relationship to function. Transference here is organized around maneuvering the therapist into a parental role. There is strong resistance to a more mature relationship. If the therapist enters into the patient's design, due to needs to play parent, therapy is apt to become interminable.

Q. What does dreaming indicate when it becomes so excessive that it takes up the entire session?

A. If patients deluge the therapist with dreams, the therapist should suspect that the dreams are being used as resistance, perhaps to divert the therapist from other important material.

Q. Which dreams that patients present should one consider of great importance?

A. Repetitive dreams and those with an anxiety content may be of great importance.

Q. What do you do when patients constantly bring up important material several minutes before the end of a session, leaving no time to discuss it?

A. This is usually a manifestation of anxiety. It may be handled by mentioning to patients the fact that the material they have brought up sounds important and should be discussed at the next session. If patients do not spontaneously bring it up, the therapist may do so, handling whatever resistances arise.

Q. How would you handle parents who bring a child to you for therapy, and you are impressed by the fact that the parent needs treatment more than does the child?

A. It may be important to determine how much motivation the parents have for therapy and their level of understanding. Should the parents be unaware of how they participate in the child's neurosis, it may be necessary to inform them that the treatment of their child will require seeing the parents also, both to determine what is going on at home and to help the parents understand how to handle developing problems. In this way the parents themselves may be brought into a treatment situation.

Q. Are interviews of any value with the patients' families or with other people important to adult patients?

A. The therapist may frequently get information from people close to patients that the patients themselves has been unable to convey. Often a conference reveals distortions in the patients' attitudes and behavior that are not based on reality. One or more interviews with important family members may thus be useful. Furthermore, if patients are unable to correct disturbed environmental situations by themselves, the cooperation of a related person as an accessory may be helpful. If patients are reacting destructively to a relative who then responds in a counterdestructive manner, if demands on patients by relatives are stirring up problems in the patients, if relatives are opposing patients' therapy—and it is obvious, help, financial and other, is needed—an interview with the relative, aimed at the

clarification of these issues, may yield many dividends. These relatives may require reassurance to neutralize their guilt about the patients. Sometimes relatives can be prepared for contingencies that may arise in therapy, such as rebelliousness and hostility directed at them by the patients. An explanation that such occurrences are inevitable in treatment, and that they are part of the process of getting well, may forestall retaliatory gestures. The patients' needs for independence and assertiveness may be explained for the benefit of relatives who unwittingly overprotect the patients. Statements to the effect that the patients will get worse before they get better and that it will require time before results are apparent often prevent discouragement and feelings of hopelessness among concerned relatives. Because a therapeutically induced change in the patients' attitudes brought about by therapy may impose new and unaccustomed burdens on people with whom the patients live or associate, preparing these people for the change may avoid a crisis. An interpretation of the patients' actions in dynamic terms will often relieve relatives' guilt and lessen their resentment. For instance, if an adolescent is beginning to act cantankerous and resistive, an explanation to the parent that this behavior is to be expected at the patient's time of life, as a gesture toward cutting the umbilical cord of dependency, that all adolescents are often difficult to live with, and that parents are bound to feel resentful at the behavior of their offspring, may foster greater tolerance. Or a wife distraught at her husband's inattentiveness may be helped to realize that her spouse is responding not specifically to her as a person, but rather to her as a symbol of some actual past or fantasied personage against whom the patient had to build a wall of detachment. This insight may help avoid the creation of the very situations that would drive her husband deeper into isolation.

Q. How would you approach patients should you decide a conference with a relative is necessary?

A. The patients may be told that in psychotherapy the therapist may want to have an occasional conference with a relative or other person close to the patients. The purpose is to get to know the relatives and their attitudes. Following this, the therapist may say, "I wonder how you would feel if 1 thought it necessary to talk with _____ *[mentioning name of person]*?'' The patients may acquiesce; they may question the need for such a conference; or they may refuse indignantly to permit it. If patients are insistent that no contact be made, their desire should be respected. Important material concerning the relative will undoubtedly be forthcoming and may constitute the material of later interviews.

Q. If an interview with family members or other significant people is decided on, are there any rules one should follow?

A. Experience has shown that a number of precautions are necessary when it is decided to contact the family. First, the patients' consent should always be obtained, the only exception being where they are dangerously psychotic or suicidal. Second, confidential material revealed by patients must never be divulged, since the breach of confidence will usually be flaunted at the patients even if the relatives promise to keep the revelations to themselves. Third, in talking to the relatives or friends, the therapist will often have a temptation to blame, to scold, or to enjoin them to change their ways or attitudes toward the patient. Distraught, confused, frustrated, and filled with guilt and indignation, the relatives will expect the therapist to accuse them of delinquencies toward the patients. Permitting them to talk freely, sympathizing with their feelings, and encouraging them to express their ideas about the situation will tend to alleviate their tension. It is important to try to establish a rapid working relationship with them, if this is at all possible. Once they realize that the therapist is sympathetic toward them, they will be more amenable toward accepting interpretations, and more cooperative in the treatment plan. Indeed they may, if they have been hostile to

the patients' therapy or to the therapist, become helpful accessories. Fourth, should they telephone the therapist, they must be told that it is best that the patients be informed about the call, although the specific details need not be revealed. Fifth, if the patients are insistent on knowing what went on in the conference or conversation with the therapist, they may be told that the conversation was general and dealt with many personal and other problems, as well as their relationships with the patients. Sixth, it may be necessary to see these relatives or friends more than once, perhaps even periodically. Seventh, the therapist should not participate with the patients in "tearing down" family members, nor should the members be defended when the patients launch an attack. A sympathetic, impartial attitude is best.

Q. Under what conditions would you advise relatives of patients to get psychotherapy?

A. If the patients are in close contact with neurotic relatives and they are being traumatized by the relatives, psychotherapy may be advised, provided the therapist has a sufficiently good relationship with the relatives to make this recommendation. Therapy may also be advised when a change in the patients' condition makes a new adjustment by the relatives necessary. For instance, a frigid wife, living with an impotent husband, may, as a result of psychotherapy, on the basis of experiencing sexual feelings, make sexual demands on her husband that the latter will be unable to fulfill. For the husband to make an adjustment, he may require psychotherapy.

Q. Is it permissible to treat several members of the same family?

A. The situation often becomes complicated, but it can be done. Whether or not simultaneous treatment is possible will depend on the therapist's ability to handle the inevitable complications. Reconstructive individual therapy with several members of the same family is not easily managed. Treating all or a number of family members together in a group (family therapy) may result in better family adjustment. Marital problems are often advantageously handled in joint marital therapy.

Q. How should one act when one meets patients on the street or at a social affair?

A. A professional therapeutic relationship requires reducing social contacts to a minimum. Occasions will, however, arise when the therapist will run into patients on the street, in public places, or at private social affairs. This may prove embarrassing to both therapist and patients. One cannot handle such situations by running away from them. Once the therapist is recognized by patients, the former may greet them cordially and then proceed with activities as usual. Understandably, at private gatherings, one's spontaneity will have to be curtailed to some extent. The patients' reactions to seeing the therapist in a different role may have to be handled with them during the ensuing sessions.

Q. Should you expect all your patients to like you?

A. Except for very sick patients, a satisfactory resolution of prejudices, suspicions, and resentments will occur relatively early in therapy, leading to a good working relationship. Periodically, however, the patients' feeling about the therapist will be punctuated by hostility, issuing either out of transference or out of an inadvertent error in the therapist's handling of the patients. Analysis and resolution of hostilities as they develop should bring the relationship back to a working level.

Q. If patients continue to dislike you no matter what you do, should you discontinue therapy?

A. A continued dislike is usually indicative of either errors in therapeutic management or of transference that the patients cannot resolve. As long as the dislike persists, little progress can be expected in treatment. Should the patients' feelings persist, the therapist may have to suggest the possibility of transfer to a different therapist. This must be done in such a way that the patients realize that the transfer is being recommended out of consideration for their welfare and not because the therapist rejects them. As a general rule, very few patients will need to be transferred because of persistent negative feelings. If a therapist encounters this problem frequently, the chances are that he or she is doing something in the therapeutic situation that is inspiring the dislike of patients. The therapist should, therefore, seek supervision with an experienced psychotherapist who may be able to help in understanding what is happening.

Q. How should you act to displays of crying or rage on the part of patients?

A. One generally permits these to go on without reassurance until the meaning of the reaction is explored and determined. If the reaction is dangerous to patients or to others, it should be controlled by supportive measures.

Q. Should the therapist engage in a confessional, confiding about his or her life to the patient in an effort to show the patient that the therapist also has some personal frailties?

A. This can be very destructive to the relationship, especially at the beginning of therapy. Patients may use any revelations made as a confession of the therapist's weakness and ineptness and may then decide to discontinue treatment. Patients will usually discover enough frailties in the therapist spontaneously without being alerted to them.

Q. Should you ever admit to patients that you may be wrong about certain things?

A. It is important to admit an error when this is obvious to patients and they question the therapist about it.

Q. If patients ask you if you are ill or tired, would you admit it?

A. If it is true, it may be important to confirm the patients' observation, adding that you do not believe this will interfere with your ability to work with them.

Q. What happens in insight therapy if the therapist's personality is authoritarian?

A. If the authoritarianism of the therapist interferes with the patients' ability to express hostility, and with their assertiveness, it will probably limit therapeutic goals.

Q. Is it possible that a therapist may develop a deep hate for certain patients?

A. If a circumstance like this develops in therapy, there is something seriously wrong with the therapist or the technique used. It is not possible for the therapist to like all patients to the same degree, nor is it possible to avoid disliking some patients temporarily in certain phases of treatment. When this happens, the therapist must resolve the untoward feeling before it interferes with therapeutic progress. If this is not possible, the therapist should

transfer the patients to another therapist and perhaps seek personal psychotherapy.

Q. Does a therapist ever fall in love with patients?

A. If such a situation develops, it is a manifestation of countertransference that will seriously interfere with the therapist's essential objectivity. Failure to analyze such a feeling and to resolve it will make it necessary to transfer these patients to another therapist.

Q. Does a therapist ever develop sexual feelings for patients?

A. It is possible that certain patients may arouse sexual feelings in the therapist. If this happens, such feelings must be subjected to self-analysis and resolved.

Q. Should not the conduct and attitudes of the psychotherapist be as passive and noncommittal as possible?

A. The idea that the therapist should remain detached and completely passive stems from the notion that this attitude will best demonstrate to patients how they automatically project onto the therapist attitudes and feelings that are rooted in past relationships. Not having done anything to incite their attitudes, the therapist is in a better position to interpret transference. The passive, detached attitude also is believed to avoid dependency and to throw the patients on their own resources. Experience shows, however, that the projections of patients, which are sparked by past distortions in interpersonal relationships, will emerge whether the therapist is passive or active. Patients with hostility problems will thus develop hostility toward the therapist who acts detached as well as toward one who acts accepting. If patients have dependency problems, they will get dependent on the most passive therapist. Rather than cripple the spontaneity of the therapist in the dubious quest of interpreting transference phenomena, or of mobilizing assertiveness, it is best for the therapist to act natural and not to assume artificial passivity if the therapist is not normally a passive person. Such an assumption may signify rejection to patients and, in mobilizing hostility, may interfere with the working relationship.

Q. Are not warmth and emotional support necessary for some patients?

A. Yes, especially when the patients' adaptive resources are at a minimum. Unfortunately, some therapists have been reared in the tradition of passivity and nondirectiveness to a point where they provide for patients a sterile, refrigerated atmosphere that, in seriously sick patients, is anathema to a working relationship.

Q. Is the assumption of a studied role by the therapist of any help in insight therapy?

A. It has been recommended by some authorities that the therapist play a deliberate role in insight psychotherapy that is at variance with the therapist's usual neutral, though empathic, position. Such role playing, however, may inspire intense transference that the therapist may be unable to control. As a general rule, the therapist should not transgress the defined role of a professional person who seeks to enable patients to help through self-understanding. An exception to this rule is an extremely experienced and skilled therapist who is thoroughly acquainted with the existing dynamics operative in a patient and who, by dramatizing a part and becoming actively involved in the patients' lives, strives to expedite change. Such activity is not without risks, but it may, in some cases, produce brilliant

results. On the whole, deceptive role playing is not to be recommended. Most patients quickly perceive the artificiality in the assumed part played by the therapist.

Q. What about role playing to provide patients with corrective emotional experiences?

A. One of the reasons that role playing with that aim is frowned on is that it is sometimes employed with incomplete evidence about what requires correction. Premature assumptions about factors responsible for patients' pathology, and about the dynamics of existing interactions with others, may be nothing more than guesswork. To act merely on such impressions is not only unscientific but also may be counterproductive. What could be most propitious is to observe patients in their actual life settings to study their interactions with people and examine their dreams, fantasies, and verbal associations. Since it is not possible to be with patients 24 hours a day and to observe them in their habitual environments, therapists have to rely only on fragmentary observations within the therapeutic situation. Some therapists believe that the therapist is playing a designed role with the patient in any case and that a specifically designed role offers the greatest opportunity for taking advantage of the limited time available. My own feeling about the active providing of patients with corrective emotional experiences is that good therapy in the medium of nonjudgmental and empathic attitudes, as well as reasonably accurate interpretations of transference, will do this without the therapists' disguising their true selves by playacting in a deceptive manner. This is not to depreciate artificial role playing when it is needed to practice more desirable responses or to probe repudiated attitudes and fantasies. But here the patients are aware that no deception is being employed and that the therapist is not putting on a false front by engaging in theatrical maneuvers.

Q. If the therapist acts consistently permissive and accepting, will this not in itself eventually reduce the patients' irrational responses to authority?

A. The behavior of the therapist, no matter how well controlled will, to some degree, always be subject to distortion in terms of the patients' conceptual framework, which, in turn, is based on their previous experiences with authority. This is not to say that gross deviations of behavior on the part of the therapist will not bring about appropriate reality-determined responses. A brusque, disinterested, detached, or hostile manner will produce untoward reactions in most patients. It must not be concluded, however, that absolutely correct activity and behavior will always bring about good responses, since patients may interpret the therapist's actions as a hypocritically conceived lure.

Q. Should deprivations ever by imposed on patients?

A. Occasionally, it is necessary to enjoin patients to deprive themselves of certain sources of gratification to help the exploratory process. Thus, patients with destructive sexual acting-out tendencies may be urged to control their sexual impulses so that tensions may accumulate that will facilitate an analysis of their problem. If patients are shown the reason for their need to give up certain pleasure promptings, they will be less inclined to resent the therapist.

Q. How would you handle overanxious and completely unreasonable patients who act more like children than adults?

A. It is essential to remember that though patients may be chronologically adults, emotionally they

may not have progressed beyond a childhood level. One may expect, therefore, childish tantrums, ambivalent feelings, unrestrained enthusiasms, and other reactions. If one can respect patients despite their unreasonableness, one will best be able to help them.

Q. What do you do when your relationship with patients starts getting bad?

A. All other tasks cease, and one must concentrate on bringing the relationships back to a satisfactory level. It is useless to explore patterns, to interpret and to engage in any other interviewing tasks so long as good rapport is absent. Essentially one must go back to the first phase of therapy and focus on reestablishing a working relationship.

Q. Why is the handling of transference important in reconstructive therapy?

A. Since much of the suffering of patients is produced by destructive transference involvements with people, part of the therapeutic task in reconstructive therapy is to put a halt to such reactions and to replace them with those that have a foothold in reality. If, for instance, patients respond automatically to authority with violent hate, as a result of an unresolved hatred toward a parent or sibling, their reactions may have a disorganizing effect on their total adjustment. Patients usually do not appreciate that this response to all authority is undifferentiated. They may not even be aware of their hate, which, considered to be dangerous in expression, becomes internalized with psychosomatic or depressive consequences. Liberation from such reactions is essential before patients can get well. This can best be insured in therapy by bringing them to an awareness of their projections. Several means are available to the therapist in executing this goal. First, on the basis of functioning in the role of an objective and impartial observer, one may help patients realize how many of their reactions outside of therapy have no reality base. Second, by watching for instances of transference toward the therapist, one may demonstrate to patients, often quite dramatically, the nature of those projections that constitute basic patterns.

Q. What is the difference between "transference," "transference neurosis," "parataxic distortions," and "positive relationship?"

A. Stereotyped early patterns, projected into the relationship with the therapist, were called by Freud "transference reactions." When these became so intense that patients acted out important past situations, this was known as a "transference neurosis." No satisfactory name was given to repetitive early patterns occurring with people outside of the therapeutic situation until Sullivan invented the term "parataxic distortions," which included all stereotyped patterns that developed inside or outside of therapy. A "positive relationship" usually refers to a good working relationship with minimal transference contamination.

Q. Isn't the accepted idea of transference as a manifestation of purely infantile or childish attitudes or feelings a restricted one?

A. Probably. A broader concept of transference would consider it to be a blend of projections onto the therapist of attitudes and feelings that date back to infancy and childhood, as well as more current attitudes that have had a formative influence on, and have been incorporated into, the character structure.

Q. Do all patients have to go through a transference neurosis in order to achieve very deep, structural

personality changes?

A. There is much controversy on this point, but experience shows that some patients can achieve extensive personality growth without needing to live through a transference neurosis.

Q. What activities on the part of the therapist encourage neurotic transference responses?

A. Dependency may be stimulated in patients by such therapist activities as overprotecting patients, making decisions for them, and exhibiting directiveness in the relationship. Sexual feelings in patients may be provoked by seductive behavior displayed toward the patients, by socializing with the patients, and by physical contact of any kind. Fearful attitudes and hostile impulses may be mobilized if the therapist acts excessively passive, detached, authoritarian, overprotective, hostile, pompous, or belligerent. It must, however, be remembered that transference may arise without any provocation whatsoever on the part of the therapist. This is the case when needs are intense and can be voiced and expressed due to the permissiveness of the therapeutic relationship.

Q. What is the best way of handling transference?

A. There is no best way; methods depend on the kind of therapy done and the therapeutic goals. Transference may not be explored or handled in supportive therapy. In reeducative therapy it may be immediately interpreted in an effort at resolution whenever it becomes apparent as resistance. In some types of reconstructive therapy it may be allowed to develop until it becomes so disturbing that the patients themselves achieve awareness of its irrational nature. In Freudian analysis it may be encouraged to the point of evolution of a transference neurosis.

Q. Are so-called "transference cures" ever permanently effective?

A. Structural personality changes rarely occur. A "transference cure," however, may permit patients to relate better to their life situations. This facilitates the development of more adaptive patterns that can become permanent.

Q. How does countertransference lead to an improper assessment of neurotic traits in patients?

A. Countertransference may cause the therapist to make incorrect interpretations of the patterns exhibited by patients. Thus, the therapist may, if welcoming hostile outbursts, regard these as manifestations of assertiveness rather than as destructive responses. If the therapist relishes a submissive, passive attitude on the part of patients, he or she may credit this to cooperation and to the abatement of neurotic aggression rather than to a neurotic need for compliance.

Q. Should you ever emphasize positive aspects of the patients' adjustment?

A. Therapists too often tend to regard patients as a repository of pathologic strivings, emphasizing these to a neglect of constructive traits, mention of which is very important in reinforcing constructive behavior.

Q. Is acting-out always a bad sign?

A. No. It may be a transitional phase in therapy indicative of a shift in the psychic equilibrium. Thus repressed, fearful individuals, realizing that they have been intimidated by an archaic fear of physical hurt for assertiveness, may become overly aggressive and act-out their defiance of authority as a way of combating their terror. Proving themselves to be capable of this expression without experiencing the dreaded punishment may enable them to temper their outbursts. In the same way, sexually inhibited people may become temporarily promiscuous, almost as if liberation from fear is tantamount with indulgence in sexual excesses. Incorporated also in the acting-out process are unresolved impulses and conflicts, in relation to early authorities, that have been mobilized by the transference. When the therapist becomes aware of acting-out, it is important that it be discouraged in favor of verbalization. As verbalizations replace impetuous acts and as understanding progresses, a more rational solution is found for neurotic drives and impulses.

Q. How do the value prejudices of therapists interfere with treatment?

A. Whether intentional or not, therapists will accent in the interview attitudes and feelings that are in line with their value systems, and will minimize those that are opposed to it. If, for instance, therapists have a problem in their relationships with authority, manifesting submission and ingratiation, they may overvalue these traits. They may then tend to discourage assertiveness or aggressiveness when patients seek to take a stand with authority. Therapist may credit this philosophy to "good common sense" and justify it in terms of the benefits that accrue. This may seriously inhibit patients from working through neurotic feelings toward authority. On the other hand, if therapists themselves react to authority with aggression and hostility, they may inspire defiance or promote aggressive attitudes toward authority figures, which may seriously endanger the patients' security.

Q. What do you do with patients who break or cancel appointments consistently?

A. This can be a disturbing problem since consistency in attendance is vital to good therapy. Should confrontation and discussion fail to resolve this problem, the therapist may suggest discontinuance of therapy. If, as in a clinic, the therapist is obliged to see patients irrespective of the latter's motivation, the therapist may insist on the patients' calling for an appointment when they want to be seen. In this way the burden of stopping therapy is put on the patients, and if there is any motivation at all, the patients may "shape up."

Q. Shouldn't therapists be trained in all therapeutic approaches?

A. The most effective therapists are those who can implement whatever therapies are indicated, whether these are of a supportive, reeducative, or reconstructive nature. If therapists have a broad understanding of various therapeutic procedures, know how to execute them, and are sufficiently flexible in personality so as not to be tied to a single treatment process, they will score the greatest therapeutic successes. This, however, is an idealistic situation. Most therapists learn only one kind of technique, which enables them to handle only a certain number of problems—those which are amenable to their technique. They may also be limited by their character structure so as to be unable to use certain techniques. For instance, a therapist may be an essentially passive person and, on this account, be unable to employ the directiveness and authoritativeness of approach essential for symptom removal, reassurance, guidance, persuasion, environmental manipulation, and other supportive therapies. On the other hand, the therapist may be so extremely authoritarian and dogmatic that patients may not be allowed to make mistakes, work out their own problems, or

establish their own sense of values, so essential in reconstructive therapy.

Q. Is there any consistency in therapeutic focus among therapists appraising the same patients?

A. A therapist's judgment concerning existing core problems involves speculations that are not always consistent with what another therapist may hypothesize. Given the same data, different therapists will vary in choosing what is significant. In a small experiment I conducted, three experienced therapists trained in the same analytic school witnessed the first two sessions conducted by a fourth colleague through a one-way mirror. Each therapist, including myself, had a somewhat different idea of what meaningful topic was best on which to focus. But such differences, in my opinion, are not significant. Even if one strikes the patient's core difficulties tangentially, one may still register a significant impact and spur patients on toward a better adaptation. After all, reasonably intelligent patients are capable of making connections and even of correcting the misperceptions of a therapist when a good working relationship exists and the therapist does not respond too drastically with wounded narcissism when challenged or corrected.

Q. Is not insight a basic factor in all therapies?

A. Insight on some level is helpful in all therapies. Even in supportive therapy, an understanding of the existing environmental encumbrances may eventually lead to a correction of remediable difficulties or to an adjustment to irremediable conditions. In reeducative therapy knowledge of the troublesome consequences of existing behavioral patterns may ultimately sponsor a substitution with more wholesome interpersonal relationships. In reconstructive therapy insight into unconscious conflicts, and their projected manifestations into everyday life, encourages patients toward actions motivated more by the demands of reality than by the archaic needs and fears of their childhood. Obviously, insight alone is not equivalent to cure.

Q. What is the difference between the level of insight effectuated in reeducative therapy and the kind in reconstructive therapy?

A. In reeducative therapy an inquiry is conducted into conscious and preconscious drives, impulses, feelings, and conflicts with the object of suppressing or changing those that disorganize behavior and of encouraging others that expedite adjustment. In reconstructive therapy the exploratory process deals with the more unconscious drives and conflicts. Due to the intensity of repression, one must implement the inquiry through examination of, and the inculcation of insight into, derivatives from the unconscious as revealed in verbal associations, dreams, fantasies, slips of speech, and transference. The object in reconstructive therapy is to liberate individuals as completely as possible from anachronistic values, attitudes, strivings, and defenses and to remove blocks to personality growth.

Q. What is the best kind of therapy to use when the sole object is symptom relief or mere control of certain obnoxious personality traits?

A. The objective in the treatment effort may be limited to the restoration of habitual controls to individuals, to the mediation of any continuing environmental stress, and to the modification of strivings and goals that are inimical to the patients' well-being or that are beyond their existing potentialities. Through the use of supportive and conditioning

techniques, and by fostering an awareness of some of their character distortions and strivings, these objectives may be accomplished in a satisfactory way. There are, however, some conditions when character structure is so disturbed, and when elaborated crippling mechanisms of defense are so tenacious, that even the objective of mere symptom relief presupposes an extensive exploration of aspects of personality that have been repressed. This will necessitate reconstructive approaches.

Q. Is it possible to do reconstructive therapy on the basis of once-a-week sessions?

A. The effectiveness of therapy is dependent upon factors more important than the number of times each week patients are seen. Reconstructive therapy is possible in some patients on the basis of sessions once weekly; it is not possible in others. Great skill is required to bring about reconstructive changes when there are long intervals between visits. When a transference neurosis is to be created, four to five sessions weekly will be needed.

Q. What is the difference between an apparent and a permanent recovery as related to reconstructive therapy?

A. An apparent recovery is mere restoration to the premorbid level with the strengthening of the defensive techniques that have served, prior to illness, to maintain the ego free from anxiety. A permanent cure involves a real alteration of the ego to a point where those compromising defensive attitudes and mechanisms are no longer necessary to keep it free from anxiety. Under these circumstances, individuals are capable of gratifying their basic needs and strivings without undue conflict. Recovery in psychotherapy is permanent only insofar as it produces a real change in the character structure of individuals and a reorientation of their relationships with others and themselves. Due to the operation of resistances that blanket offending impulses, and because of repressions that keep from awareness the most important problems of the individual, reconstructive psychotherapy offers the greatest chance of overcoming a severe emotional difficulty.

Q. What would you consider an acceptable minimal goal in reeducative therapy?

A. The least we can do for patients is to bring them to as great an awareness of their problems as is reasonably possible, to enable them to lead as useful, happy, and constructive lives as they can with their personality and environmental handicaps, to help them overcome remediable life difficulties and adapt to irremediable ones, and adjust their ambitions to their existing capacities.

Q. What is the difference between a "normal" and "neurotic" person?

A. "Normality" is a social designation that embraces characteristics not entirely consonant with a definition of mental health. Average "normal" people in a culture possess many neurotic drives that are sanctioned and perhaps encouraged by society. Although these drives nurture some anxieties, "normal" individuals are still capable of functioning and of making a satisfactory social adjustment. If people are no longer able to adjust themselves and begin to manifest excessive anxiety and maladaptive mechanisms of defense, they may be classified as "neurotic." In therapy the objective may be to restore the individual's social adjustment and their "normal" neurotic tendencies. A more extensive objective, however, would be a correction of all neurotic traits, even those condoned as "normal," which is more idealistic than realistic.

Q. If ideal goals of complete reconstruction are impossible, what would be reasonably good goals in reconstructive therapy?

A. It is manifestly impossible for any one individual to reach the acme of emotional maturity in every psychic and interpersonal area. One may decide that a satisfactory result has been achieved when patients lose their symptoms, abandon their disturbing neurotic patterns, deal with their difficulties spontaneously without needing help from the therapist, manifest productivity and self-confidence, show absence of fear following expression of assertiveness, and exhibit an improvement in their interpersonal relationships with increased friendliness and respect and lessened suspiciousness, detachment, aggression, and dependency.

Q. In interviewing patients, should a therapist disclose intimate personal facts as a way of positively influencing the therapeutic relationship?

A. Studies of the effects of self-disclosure on the part of the therapist are inconclusive insofar as their influence on the relationship is concerned. The results cannot be predicted in advance. Depending on their personalities, patients may respond to a therapist's revelations positively ("My therapist is marvelously human," "He does not present himself as a flawless god," "She trust me by revealing these intimacies") or negatively ("This person has such weaknesses that I'm not sure she can help me," "If he can't help himself, how can he help me?"). Some research studies do indicate that therapist self-disclosure facilitates patient self-dis-closure and greater therapist trustworthiness (Bierman, 1969; Sermat and Smyth, 1973). My personal view is to use self-disclosure very sparingly and only when it does not point to severe neurotic problems in the therapist. It may, for example, be employed to show how a therapist handled a problem or situation akin to that confronting patients, thus enhancing modeling.

Q. How do therapists' personalities influence their techniques?

A. Therapists eventually evolve their own therapeutic method, which is a composite of the methods they have learned, the experiences they have had, and their specific personality traits. For instance, analytically trained therapists, inclined by personality to be authoritarian, may be unable to maintain the traditional silence and passivity demanded by classical psychoanalysis. To do so robs them of spontaneity; it provokes tension and prevents them from exhibiting the kind of relaxed objectivity that is most helpful in treatment. They may find it necessary to abandon passivity and to permit themselves to participate more actively in the treatment process. Their patients will perhaps respond to this change in a gratifying way and react more positively than when the therapists were behaving in a stultified manner. This success may encourage the therapists to be themselves, and they will probably find that their results continue to justify their alteration of technique. For them, then, the shift is justified since it liberates them from acting in an artificial, inhibited way. Yet other therapists may not be able to do the same thing; for instance, those who by personality are more retiring, quiet, and unobtrusive. For them the passive technique will probably work well; to attempt to force activity would be as artificial as to expect active therapists to assume a feigned passivity.

Q. How do you explain the misunderstanding that exists among the different schools of psychiatry and psychology?

A. In so virgin a territory as the uncharted psyche, a diversity of theories, interpretations, and methods may be expected. A great deal of animosity has, however, unfortunately come to the surface among groups with divergent points of view. Splinter societies have erupted, justifying their break with the parent body on the basis of discrimination and lack of academic freedom in the older organization. Sparked at first by the impulse to create groups possessed of scientific liberalism, a number of the splinter organizations have, upon achieving independence, then practiced the same intolerant bigotry that initiated their secession, developing their own dogmas and rejecting original thinking among the members. Such entrenched and reactionary attitudes are to be condemned in any scientific group.

Q. Should a good therapist be able to cure or help all patients?

A. No matter how highly trained the therapist may be, some patients will be able to be helped more than others. There will be certain patients therapists will not be able to treat—patients whom other therapists may successfully manage. On the other hand, therapists will probably be able to cure some patients with whom other therapists have failed. Therapists will make some mistakes during the course of therapy with all of their patients, but these mistakes need not interfere with ultimate beneficial results. Finally, therapists will be rewarded by a large number of successes, but they will also have their quota of failures.

Q. Does it follow that psychoanalytically trained therapists will do better therapy than those who have not been analytically trained?

A. It is fallacious to assume that non-analytically trained therapists are incapable of doing many kinds of psychotherapy as well as those who have been analytically trained. If therapists plan to do reconstructive psychotherapy, however, using dream interpretation, transference, and resistance, they will be helped by sound training in reconstructive therapy, including a personal analysis.

Q. Must the therapist be completely free from neurosis?

A. It is doubtful that any person in our culture is entirely free from neurosis, no matter how much personal psychotherapy has been undergone. To do psychotherapy, however, therapists must be sufficiently free from neurosis so that their own personal problems do not divert the relationship from therapeutic goals.

Q. Will personal psychotherapy or psychoanalysis guarantee good functioning on the part of an adequately trained therapist?

A. In most instances it will. Serious personality difficulties may in some cases not be resolved to a point where individuals will be able to function as therapists, however, although they might work satisfactorily in some other field. In other words, where their egos have been so damaged through a combination of constitutional predisposition and traumatic life experiences, individuals may not, even with extensive psychotherapeutic help, be able to achieve that kind of personality flexibility, objectivity, sensitivity, and empathy that are prerequisite for functioning as an effective psychotherapist.

Q. Why should not psychotherapy or psychoanalysis be able to resolve the neurotic problems of psychotherapists, since they actually are not as sick as most patients and should benefit

greatly from psychotherapeutic help?

A. The motivation to carry out psychotherapy, which is what inspires many therapists to seek personal therapy, may not be sufficient to enable therapists to endure and to work through the anxieties underlying their character distortions. For instance, the individuals may, prior to their determination to become therapists, have been functioning in a more or less detached manner, removing themselves from disturbing interpersonal situations periodically when these had become too difficult to handle. Under ordinary circumstances, and in average relationships, they would be able to function quite effectively with this kind of a defensive attitude. This detachment, however, may seriously affect their capacity to operate in a therapeutic interpersonal relationship, in which they will constantly be brought into contact with critically disturbed people who will seek to extract from them constructive responses they may be unable to give. A tremendous amount of personal psychotherapeutic work may be required before therapists will be able to give up their detachment as an interpersonal defense. If they do not have sufficient anxiety to incite them, however, to seek new modes of adjustment, they may not have the incentive to tolerate the great amount of work and suffering that will be involved in effecting a reconstructive change in their own personalities. Consequently, in their personal therapy, they will keep warding off the deepest character change and may go through their treatment without significant modification of their detachment. The fact that many therapists have exposed themselves to extensive personal therapy or psychoanalysis and have emerged from it without any basic character changes is no indictment of psychotherapy. Rather, it is an indication of how difficult it is to treat certain kinds of emotional disturbance without adequate motivation. In other words, the desire to become a psychotherapist is not in itself sufficient motivation to promote deep character change.

Q. What can therapists do whose personality problems interfere with their executing good psychotherapy even after they has gotten extensive personal therapy and supervision?

A. If a qualified supervisor finds that the supervisees' problems are interfering with their therapeutic effectiveness, the supervisees may be advised to seek further personal psychotherapy. Should no change occur, it may be necessary for the therapists completely to give up psychotherapy as a career. They should not regard this as a personal defeat or as a sign of devaluated status, since they will probably be able to function very effectively in another role. For example, psychiatrists may decide to do diagnostic, institutional, or other kinds of work that do not bring them into an intimate therapeutic relationship with patients. Caseworkers can confine activities to an agency organized around areas other than therapeutic services. Psychologists can restrict functions to diagnostic testing, research, vocational guidance, and counseling.

Q. Don't you believe that every therapist should learn the principles of preventive mental health in addition to knowing how to do psychotherapy?

A. Mental health needs are only partially served by an exclusive program of psychotherapy. This is because the impact of emotional problems on the lives of people so often reflect themselves in disturbances in work, family, marital, interpersonal, and social relations without causing collapse in adaptation characteristic of neuroses. The providing of help for these preclinical problems requires an ability to consult with, and to supervise, community workers and professionals such as social workers, teachers, nurses, physicians, psychologists, correctional workers, and ministers, who are unable to handle such problems alone. It is advisable that every therapist be acquainted with the principles of preventive mental health

and know how to communicate well with community agencies and the ancillary professions.

Q. What do you do if you make an outlandish error like forgetting patients' ages or marital status?

A. Being human, therapists will, from time to time, unintentionally commit some blunders. They may forget patients' ages, details about their families, or items in the history that patients have already recounted. Distracted, the therapist may even forget the patients' first names. Sometimes a more flagrant blunder may occur, such as calling patients by the wrong name, or asking them if they have dreamed recently, when they already have in the first part of the interview recounted a dream. Should such slip-ups happen, there is no need to conceal them or to be too apologetic. Therapists may merely say: "Of course, you told me this" (or "1 know this") or "It just temporarily slipped my mind." Patients will not make too much of such errors if a good relationship exists. At any rate, it may, if it seems indicated, be important to explore the patients' feelings immediately upon commission of a mistake.

Q. Should psychiatrists do physical examinations if necessary?

A. Psychiatrists will probably not be as skilled in diagnosis as the internists to whom they can refer patients needing medical treatment. A physical examination in any therapy other than psychoanalysis, however, theoretically need not interfere with the therapeutic process, if the patients' reactions to it are examined and explored. It may bring many interesting and important feelings to the surface.

Q. Should two therapists, each working on separate members of the same family, confer?

A. A conference may be helpful to clarify the patient's interactions with the other member and to check on data significant to both. Usually, however, this is not routine. If it is done, each therapist should be mindful of personal competitiveness with and need to impress the other therapist and of defensiveness regarding the patient's progress.

Q. What is multiple therapy, and does it have a use?

A. Multiple therapy is the treatment of a single patient or a group by two or more therapists. It is preferred by some therapists in the management of difficult patients, such as psychotics and psychopaths. Differences in opinion and transference reactions between the therapists will require careful handling, sometimes within and sometimes outside of the therapeutic session. There may be advantages in employing multiple therapy in cases that do not respond to conventional treatment.

Q. Does not behavior therapy circumvent transference and other resistances?

A. Behavior therapy possesses ingredients that are common to all psychotherapies. Inaugurated almost immediately is a relationship, patients responding to the therapist as an idealized authority who holds the key to their well-being. The trinity of faith, hope, and trust, while not openly expressed, are aspects that cannot be avoided. The placebo element is as much a component of behavior therapy as it is of any other kind of treatment. Factors of motivation and dyadic group dynamics undoubtedly come into play and act as accelerants or deterrents to progress. If readiness for change is lacking, one might expect a negative result in behavior therapy. Subtly, transference will be set into motion, no matter how assiduously

the behavior therapist attempts to avoid it, and resistances of various kinds will rear their obstructive heads at almost every phase of the therapeutic operation. Some behavior therapists refuse to acknowledge the presence of these intercurrent elements, though this obviously will not negate their influence.

Q. If psychological tests indicate that particular patients are very sick, shouldn't you approach them carefully in therapy, and isn't this a sign that your goals have to be superficial ones?

A. One may be forewarned about the strength of the individuals' egos from psychological tests, but this should not prejudice the treatment process. One of the disadvantages of testing is that it puts a label on patients the therapist may be reluctant to remove, even though the therapist's clinical judgment disagrees with the test findings. The therapeutic relationship is a better index of how deep one may go in therapy and the extensiveness of goals to be approached than any psychological test or battery of tests.

Q. Isn't it difficult at present to develop a real science of mind because of the many divergent ideas about psychodynamics?

A. The subject of psychodynamics opens up many founts of controversy because authorities with different orientations have different ways of looking at psychopathological phenomena. Irrespective of orientation, one can always find data that seems to substantiate one's particular point of view. The same interview material may thus be variously interpreted by several observers. Some regard it as confirming their theory that neurosis is essentially a clash between instinctual strivings and the environment. Others as enthusiastically demonstrate cultural forces as the primary provocative agent. Still others may find in the material evidence that neurosis is fostered by disturbances in the integrative functioning of the ego. Such divergent ideas are not too serious; they are to be regarded as the inevitable forerunners of a real science of mind. In the study of the uncharted psyche, theories in abundance were bound to emerge, supporting many rifts and controversies. Fortunately, the beginnings of amalgamation are occurring, an honest effort to blend the findings of the various schools into a body of knowledge shorn of prejudice and bias.

Q. Is it possible for a therapist to be supervised by several different supervisors who espouse different theoretical viewpoints?

A. Unavoidable, particularly in an eclectic atmosphere, is the fact that student therapists will be supervised by several supervisors whose approaches reflect wide theoretical differences. It is to be expected that these divergencies will mobilize insecurity in students who are seeking a definite structure in theory and process. The function of the good supervisor is to help students see that different views merely expose contrasting aspects of the same phenomenon. These multiform facets may seemingly conflict with each other, though they are actually constituents of a unified whole. One must handle the students' disappointments that everything does not harmonize and fit together into a master plan. Should their anxiety prove too great, students may need special, even psychotherapeutic, help. Appreciating that other points of view exist is one of the most important contributions of the supervisor. Only a supervisor who is sufficiently secure not to regard differences in approach as interferences and can view them as a challenge toward further scientific inquiry will be able to render the kind of help that students need and have a right to expect.

Q. Can dependent patients progress in therapy beyond the goal of achieving freedom from symptoms?

A. It is sometimes contended that if patients seek guidance and an authoritarian relationship in therapy their mental set will prohibit their entering into the participatory mode of activity essential for deeper therapy. Their desire for paternalism, it is said, will block essential collaboration. This is not always correct. The majority of patients, even those who have read tomes on psychoanalysis, seek a relationship with a strong, idealized parental figure who can lift them out of their distress. The stronger the anxiety, the greater the expectation. The task of the therapist is to promote a shift in motivation toward expanding the patients' inner resources and working cooperatively with the therapist. A fundamental task in all therapy is to promote the conviction in patients that they have the inner resources to resolve feelings of helplessness. Good technique in psychotherapy takes this factor into account. Understandably, there are some characterologically dependent souls and borderline patients so inwardly damaged that they will need a dependency prop in order to function. No amount of therapeutic work will deviate them from this aim. But even here the therapist owes it to the patients to make an effort to promote greater self-sufficiency. Patients may diagnostically be written off as candidates for reconstructive psychotherapy in view of the depth of their disturbance, their habitual infantile relationships with people, wretched past conditionings with emotionally ill parents, uncontrollable acting-out propensities, paranoic ideas, and so forth. On this basis, a supportive relationship is provided the patients, only to find that they press for deeper self-understanding. Yielding to this pressure, the therapist may institute reconstructive treatments, helping some to rise out of their dependent morass and to use their understanding toward great self-actualization.

Q. Are there any diagnostic signs that will indicate how patients will actually respond to psychotherapy?

A. Very few diagnostic or other rules can be laid down to anticipate patients' responses to therapy. The only true test is the way patients take hold of the opportunity offered them in psychotherapy to approach their lives from a different perspective. Trial interpretations may be instituted to determine how patients will respond in the relationship. Will they deny, resist, fight against, or accept the interpretation, and will they act on it?

Q. What is the effect on patients of passivity in the therapist?

A. Passivity on the part of the therapist may produce frustration and anxiety, which, if not too intense, may mobilize patients to think things through for themselves and to act on their own responsibility. Should excessive hostility and anxiety be engendered, however, or should patients interpret the therapist's passivity as rejection or incompetence, it may have a paralyzing effect on their progress. This is particularly the case when patients, in their upbringing, have been victimized by a neglectful or uninterested parent who put too much responsibility on their immature shoulders. The therapeutic situation then will merely tend to recapitulate the early traumatizing experience and reinforce the sense of rage and helplessness.

Q. Should a trial period be instituted in psychotherapy to see how patients will react?

A. Freud [1913] originally recommended that a trial period of a week or two be instituted to see if patients are suitable for psychoanalysis. A trial period is more or less inherent in all psychotherapeutic endeavors. Patients and therapists mutually survey one another to see whether they feel comfortable and confident about working together. Patients test

therapists. Does the therapist like them? Does the therapist have confidence in them? Does the therapist trust them? The therapist subjects patients to an empirical scrutiny. Can he or she interact with the patients? Are the patients properly motivated, and if not, how can incentives be developed? Are patients operating under misconceptions about treatment? How far will they be able to go in therapy—toward symptom relief? Toward reconstructive personality change? The therapist may, during this trial phase, make a few interpretations to test the patients' receptivity, flexibility, and capacities for change. At the same time that ground rules are established; a working hypothesis is laid down, and the beginnings of treatment are instituted. Reformulations of this early hypothesis will have to be made periodically in accord with the patients' reactions, resistances, and rate of movement.

Q. Shouldn't therapists always remain neutral?

A. Therapists as human beings have feelings, values, prejudices, and needs. They will reveal these to patients sooner or later, if not verbally then nonverbally, both directly in their interpretations and indirectly in their silences, pauses, content of questions, and emphasis. While ideally therapists should avoid prejudicial pronouncements, they should not deceive themselves into thinking that they can always maintain a neutral stand. Nor is this desirable. It may be quite suitable to apply value pressure where it is needed and sometimes, as in patients' acting-out proclivities, it is the only tactic that makes sense. Though maintaining the philosophy that patients have an inalienable right to their points of view, decisions, and behavioral twistings and turnings, therapists do not need to accept the validity of some ideas and actions. There is no such thing as true "neutrality" in therapists. Otherwise they would not care whether patients remained sick or got well. Therapists have opinions and prejudices. They will display these in one way or another, if not one day then the next.

Q. Are there differences among psychoanalysts regarding the use of activity as opposed to passivity in psychoanalysis?

A. Polemics have been organized around the matter of activity versus passivity. On the one hand there are purists like Glover who defend the sanctity of the passive classical procedure. There are nonpurists, like Franz Alexander, who insist that the rejection of activity can only lead to therapeutic stagnation. Activity is generally eschewed in the classical technique on the basis that it tends to produce a refractory and insoluble as opposed to an ameliorative transference neurosis (Mitchell, 1927). Since the time of Ferenczi (1950b, 1950c) who instituted "active" approaches, many analysts have introduced manipulations that to Glover (1964) exceed the limits of pure analytic practice on the basis that "deliberately adopting special attitudes and time restrictions for special cases changes the character of therapy in these cases, converting it into a form of rapport therapy." Although such methodological innovations may produce excellent results and even be the best therapy for cases inaccessible to the customary technique, they should not be confused with "psychoanalysis" in which one analyzes and does not manipulate the transference. Supporting rigidity in approach, Glover avows that "flexibility in both psychoanalytic theory and practice has in the past been a frequent preamble to abandonment of basic principles." Passivity and the adoption of a "blank screen" are advocated as the best of deliberately nurtured attitudes to reduce complications. On the other hand, there are analysts who disagree with Glover, recommending modifications in method from the manipulation of the transference to the open exhibition of interest in and modulated demonstrations of affection toward the patient (Bouvet, 1958; Eissler, 1958; Nacht, 1957, 1958). Commenting on the fact that few cases of simple transference neurosis are seen in practice, Lorand (1963) points out that

psychoanalytic technique today "is quite different from that of earlier periods of analysis." Unless active interference is used in certain cases, for example in character disorders and infantile patterns of behavior, the analysis may stagnate or break down. Obviously, it is impossible at all times to adhere to the basic rules of psychoanalysis. Directiveness and active interference are sometimes essential, especially during stages of resistance "where the standard technical methods are of little help." Such variations in technique within the framework of classical psychoanalysis may be used to further therapeutic progress. The "dosing" of interpretations may also be necessary to activate the unconscious, to eliminate defenses as well as to prevent their too ready emergence. In a past contribution, Glover (1955) himself considered *complete* neutrality a myth and wondered whether adhering to the rule of not making important decisions was really desirable. When deviations from classical technique are in order, however, they must, he insisted, be dictated by the needs of the situation and not by countertransference. In practice, modification of analytic rules is frequently necessary. But whether we should label such deviations as "psychoanalysis" is another matter. There would seem to be some justification in restricting the term "psychoanalysis" to the classical technique and to entitle procedures incorporating modifications and active interventions as "modified psychonanalysis" or "psychoanalytically oriented psychotherapy."

Q. What is the theory behind cognitive therapy, and does it have utility?

A. The theory underlying cognitive therapy is that people are dragooned into maladaptive actions by distortions in thought that they can both understand and control; within themselves they possess capacities for awareness of such understanding and solution of their difficulties. Therapeutic techniques organized around this hypothesis are directed toward correcting deformities in thinking and developing alternative and more realistic modes of looking at life experiences. It is said that this is a much more direct approach to problems than other approaches since it draws on patients' previous learning encounters. Interventions are aimed at rectifying misconceptions and conceptual flaws that are at the basis of individuals' difficulties. This technique involves explorations of the stream of consciousness with the object of modifying the ideational content associated with the symptoms. Among the basic assumptions here are that the quality of therapists' thinking will inevitably influence the prevailing mood and that the *meaning* of a stimulus to patients is more important than the nature of the stimulus itself.

There is a good deal of overlap of cognitive therapy with behavior therapy. Albert Ellis (1962, 1971) in his rational-emotive therapy pioneered cognitive approaches in a behavioral setting. Meichenbaum (1977) attempts to blend cognitive-semantic modification with behavioral modification. Aaron T. Beck (1976) has written extensively on cognitive therapy and has claimed advantages for it in treating depression over all other therapeutic methods, including drug therapy. A new magazine, *Cognitive Therapy and Research* (Plenum), is devoted to explicating the role of cognitive processes in human adaptation and adjustment. Whether cognitive therapy is useful for therapists depends on their skill and conviction and the special learning capacities of individual patients.

63
Recording in Psychotherapy

Satisfactory recording is conducive to good psychotherapy. It acts as discipline for the beginning therapist. It is helpful even to experienced therapists, facilitating the following of the progress of a case and helping in the rendering of a report. It is indispensable for purposes of research (Wolberg, LR, 1964b).

Except in those clinics where an ample budget provides dictating facilities and secretarial services, records of patients receiving psychotherapy are apt to be pitifully sparse. To some extent this is due to the absence of an organized routine recording system. Additionally, note taking during the treatment session is distracting to therapists and annoying to some patients. Of utmost value, therefore, would be a recording system that is both simple to follow and not too disturbing to patients.

Most patients expect that some kind of record will be kept. They usually accept note taking during the initial interview and do not object to occasional notes being written during later sessions. If objections are voiced, these may be dealt with by an explanation to the effect that the keeping of a record is helpful in following patient's progress. Should the patient continue to object to notes being taken during sessions because this is much too distracting, or should the practice distract the therapist, a note may be entered into the record following each session. If fear is expressed that confidential material may be read by another person, the patient may be informed that under no circumstances will the record be released, nor any information divulged, even to the patient's family physician, unless the patient gives written permission for this. Excellent outlines and suggestions for recording may be found in the books by Menninger (1952b) and Beller (1962).

CASE RECORD

The case record should minimally contain the following data: (1) statistical data

sheet, (2) initial interview, (3) daily progress notes, (4) monthly progress notes, (5) termination note, (6) summary, and (7) follow-up note.

Statistical Data

Basic statistical data include the following:

1. Patient's name

2. Address, home and business telephone

3. Age

4. Sex

5. Marital status, how long married, previous marriages, ages and sex of children

6. Age and occupation of mate

7. Education

8. Occupation, salary, sources of income if unemployed

9. Military record

10. Referral source

These data may be entered on a separate sheet or on a form (see Appendix A), or the first sheet of the initial form interview (see Appendix C). A more complete statistical form, which is useful in clinics, is illustrated in Appendix B.

Sometimes the patient may be asked to fill out certain questionnaires to help get statistical data without taking up too much of the therapist's time. Short forms are included under Appendix D, which is a Personal Data Sheet, and Appendix E, which is a Family Data Sheet. In using these forms, the Personal Data Sheet is given to the patient to fill out immediately prior to the initial interview. The Family Data Sheet is filled out after the therapist has accepted the patient for treatment.

Initial Interview

The data to be included in the recording of the initial interview are the following:

1. Chief complaint

2. History and development of complaint

3. Other symptoms and clinical findings

4. Patient's attitudes toward family members

5. Previous emotional upsets

6. Previous treatment

7. Estimate of existing insight and motivation

8. Tentative diagnosis

9. Tentative dynamics

10. Disposition of the case

A convenient initial interview form is included under Appendix C, the first sheet of which is for statistical data.

Daily Progress Notes

At the end of each session, the date and a brief note, which may consist of no more than one sentence, should be entered on a progress note sheet. This should contain the dominant theme of the session. Other entries may include the following:

1. Present state of symptoms or complaints (absent, improved, the same, worse)

2. How the patient feels (anxious, placid, depressed, happy)

3. Important life situations and developments since last visit and how they were handled

4. Content of the session

5. Significant transference and resistance reactions

6. Dreams

Since the wording of the patient's dreams is important, it is best to write dreams down during the session while they are related by the patient.

Appendix F is a convenient form for progress notes.

Monthly Progress Notes

A summarizing monthly progress note is of value in pulling together the events of the month. This may be a succinct recapitulation of what has been going on in treatment. In clinics where supervision of the total caseload is essential, a monthly progress summary (such as illustrated under Appendix G), which is routinely reviewed by the supervisor, may make for a more efficient kind of reporting.

Termination Note

A termination note is important and contains the following:

1. Date of initial interview.

2. Date of termination interview.

3. Reason for termination.

4. Condition at discharge (recovered, markedly improved, moderately improved, slightly improved, unimproved, worse)

5. Areas of improvement (symptoms, adjustment to environment, physical functions, relations with people)

6. Patient's attitude toward therapist at discharge

7. Recommendations to patient

8. Diagnosis

A termination form will be found under Appendix H.

Summary

The summary should contain the following information though curtailed.

1. Chief complaint (in patient's own words)

2. History and development of complaint (date of onset, circumstances under which complaint developed, progression from the onset to the time of the initial interview)

3. Other complaints and symptoms (physical, emotional, psychic, and behavior symptoms other than those of the complaint factor)

4. Medical, surgical, and, in women, gynecologic history

5. Environmental disturbances at onset of therapy (economic, work, housing, neighborhood, and family difficulties)

6. Relationship difficulties at onset of therapy (disturbances in relationships with people, attitudes toward the world, toward authority, and toward the self)

7. Hereditary, constitutional, and early developmental influences (significant physical and psychiatric disorders in patient's family, socioeconomic status of family, important early traumatic experiences and relationships, neurotic traits in childhood and adolescence)

8. Family data (mother, father, siblings, spouse, children—ages, state of health, personality adjustment, and patient's attitude toward each)

9. Previous attacks of emotional illness (as a child and later). When did patient feel completely free from emotional illness?

10. Initial interview (brief description of condition of patient at initial interview, including clinical findings)

11. Level of insight and motivation at onset of therapy (how long ago did the

patient feel that treatment was needed? for what? awareness of emotional nature of problem, willingness to accept psychotherapy)

12. Previous treatments (when did the patient first seek treatment? what treatment was obtained? any hospitalization?)

13. Clinical examination (significant findings in physical, neurologic, psychiatric, and psychologic, examinations)

14. Differential diagnosis (at time of initial interview)

15. Estimate of prognosis (at time of initial interview)

16. Psychodynamics and psychopathology

17. Course of treatment:

   (a) Type of therapy employed, frequency, total number of sessions, response to therapist

   (b) Significant events during therapy, dynamics that were revealed, verbatim report of important dreams, nature of transference and resistance

   (c) Progress in therapy, insight acquired, translation of insight into action, change in symptoms, attitudes, relationships with people

18. Condition upon discharge (areas of improvement, remaining problems)

19. Recommendations to patient

20. Statistical classification

A summary form with spaces for the

above items will be found under Appendix I.

Follow-up Note

A note on follow-up visits, or the inclusion of follow-up letters from patients, helps the therapist to evaluate the effectiveness of treatment. A follow-up letter may be mailed

out 1,2, and 5 years after therapy. A form letter such as the following may be used:

> Dear_:
>
> In the past year I have wondered how things were progressing with you. Would you drop me a note telling me how you feel, and indicating any new developments. You may perhaps want to comment on your experience in treatment and how this was of help to you.
>
> Sincerely yours,

Case Folder

A manila folder is advisable to hold the case record of the patient. The name of the patient is written on the flap, and, if the patient is being treated in a clinic, the case number is also entered. Some therapists prefer a folder that has several pockets that may be used for correspondence in relationship to the patient, as well as for detailed notes. Under Appendix J, there is a folder the writer has found useful in private practice as well as in clinic practice. Printed on the front of an ordinary folder are spaces for entry of the date of each visit, payments made, and certain items that are pertinent to the treatment of the patient. It is a simple matter of only a few seconds to check on the total number of visits, the number of broken or cancelled appointments, the payments that have been made, and the dates of completion of the statistical data sheet, initial interview, monthly progress notes, consultations (psychiatric, medical, psychological, and casework) if these were obtained, tests administered by the therapist, or others, termination note, summary and follow-up notes. There is space also for entry of supervisory sessions if these were obtained in relation to the patient. Printed on the back of the folder are lines for entry of dates for more visits if the space on the front of the folder is not sufficient.

Miscellaneous Enclosures

Included in the case record, in addition to the above data, are other notations and forms used by the therapist, such as psychological test results, notes on medical and other consultations, detailed notes made by the therapist, written comments and notes by the patient (see Appendix S), and correspondence in relation to the patient.

The flexibility of computers in selection, orderly storage, and rapid recovery of data —beyond the capacities of human performance—puts them in the forefront as instruments for research in the mental health field, not only for the calculating of results in experiments designed around specific hypotheses but also in delineating trends and significant information and in generating new hypotheses (Cappon, 1966). Computer programs capable of carrying out principle components factor analysis with varimax rotation may measure clinical change with greater objectivity and probable reliability than other methods (Cole, 1964). By proper programming it may be possible to ask computers to make decisions between alternate futures, thus expediting the predictability of human behavior.

Electrical Recording in Psychotherapy

The employment of videotape recorders (see also Videotape Recording) has also introduced a new dimension into psychotherapeutic recording, with vast potential for teaching and the expediting of treatment (Alger and Hogan, 1969; Berger MM, 1970; Czajkoski, 1968; Danet, 1969; Melnik and Tims, 1974; Stoller, 1967, 1969; Torkelson and Romano, 1967). Therapists, viewing themselves interacting with their patients, may learn as much as they do in a good supervisory session (Geocaris, 1960; Beiser, 1966; Moore, FJ, et al., 1965). The initial shock value of seeing oneself performing inadequately, however, usually induces one to change for a limited time only. Therapists will soon adapt themselves to their television image unless there is a reworking of the material by a supervisor to reinforce learning. Observance by the supervisor of therapists in actual operation with patients is feasible by videotape, the contrast between what the therapists' reports of what they believe has been going on and the recorded events lending itself to emotional learning in the students. Supervisors also may be able to sharpen their own techniques in supervision by videotaping some of their supervisory sessions. Finally, beginning therapists may learn the process of interviewing and the management of various stages in treatment by watching videotapes (or sound movies) of expert therapists working with patients.

Although useful, written records and sound tape recordings alone are limited in bringing about an awareness on the part of patients of incongruous or paradoxical communication patterns. Sound films (Scheflen, 1963) and videotapes are more useful. Alger and Hogan (1966), employing videotape recordings in conjoint marital therapy, have pointed out that many levels of communication, as well as discrepancies between levels, become readily apparent to patients watching themselves immediately after interacting during a session. Differences between the televised actions and remembered responses are beneficially registered on patients. In individual therapy the videotaped interview may help patients see themselves as others see them. This is an excellent way of demonstrating to patients how they communicate. Use of the playback technique has proven valuable for many syndromes, including speech problems and alcoholism. A view of themselves in a drunken state may help motivate some alcoholics to stop drinking. Videotaping may be of value in group and family therapy.

Obviously, it is impossible to record all of the treatment sessions of patients even if therapists possess the proper equipment. Apart from the expense of recording materials and the problem of storage of the recordings, transcription of serial recorded sessions is costly. Occasional recordings that are saved until they have served their purpose will, however, be found valuable. From a practical viewpoint, audio cassette tape recordings may serve the purpose of preserving the verbal interactions of patients and therapists. Although not nearly as valuable as videotapes, they are less expensive and are easily transcribed.

If therapists are not resistive to recording sessions, generally there will be relatively little difficulty in gaining patients' permission and cooperation. The apparatus is placed unobtrusively (it must not be concealed) in the room. When patients enter the room (usually when recordings are to be made, it is best to introduce this possibility to the patient at the initial interview), they may be approached in a way somewhat similar to this:

> *Th.* Hello, I'm Dr___

> *Pt.* Hello.

Th. Won't you sit down in this chair so we can talk things over?

Pt. Yes, thank you.

Th. (pointing to the tape recorder) Don't mind this machine. Sometimes I record an important session during therapy. It saves me the need to write everything down, so I can pay attention better to what is said.

Pt. I see.

Th. (smiling) Does this scare you?

Pt. Oh, no, if it's useful, I've never been recorded.

Th. Of course, what is recorded is completely confidential between us, but if you object for any reason, we don't really have to record.

Pt. No, I don't mind.

Th. If, for any reason, it interferes in any way or bothers you, tell me and I'll turn it off.

Pt. All right, I really don't mind.

Th. All right then, would you like to tell me about your problem so we can decide the best thing to do for you?

The recorder may be turned on at this point, or, if it has been on, no further attention should be paid to it. During later sessions it may be started prior to the patients' entering the room, so that the first comments may be recorded. If the recording is to be used for teaching purposes or transcribed for publication, a signed release is usually necessary. If, for any reason, patients object to the machine, it should immediately be turned off and not used again unless the patients' permission has been obtained.

Recording is being revolutionized by advances in computer technology. Machines can never replace the heuristic propensities of humans. But machines can supplement decision making and contemplative facilities by sorting, storing, categorizing, and retrieving vast amount of information with astonishing rapidity, efficiency, and accuracy. As new developments in switching, information theory, and automatic coding techniques become incorporated into computers, the machines' capabilities will undoubtedly be expanded to include preparation of software programs for instructions fed into the machines. For 30 years, computers have been indispensable instruments in medicine, aiding in diagnosis by categorizing and analyzing symptoms and physical findings (Brodman and van Woerhom, 1966).

New means of cataloging, storing, and dealing with complex variables have made it possible to employ the modern computer in psychiatric hospital systems Glueck and Stroebel, 1975b; (Laska et al., 1967) and even statewide systems (Sletten et al., 1970). In clinical practice, attempts have been made to computerize data regarding the history of patients, their mental status, and symptom clusters in an attempt to aid in diagnosis, prognosis, progress evaluation, and treatment outcome (Colby et al., 1969; Spitzer and Endicott, 1969). The making of computer diagnosis has been especially challenging and has attracted an increasing number of experimenters (Glueck and Stroebel, 1969; Maxwell, 1971). Glueck and Stroebel (1975b) have estimated that classification-assignment techniques are now available to permit accuracy in diagnostic labeling comparable to that of expert clinicians with an accuracy nearing 100 percent, but they point out that there is a lack of ability "of any classification system to achieve more than 70 to 75 percent interrater reliability in the prediction of psychopathological criteria."

Some attempts have also been made to refine computerized analysis of the electroencephalographic and neurologic findings, and innovative tactics have been

evolved for various other types of data recording. The development of automated files help expedite the tabulation and retrieval of diagnostic, treatment, progress, and disposition information. Simple and effective methods for computer programming immeasurably help administrators, auditors, researchers, and ultimately clinicians by simplifying the massive amount of memoranda included in the traditional case record, enabling the scanning of essential elements of a case without needing to spend endless hours looking for pertinent facts.

The programming of computers to process the data of psychotherapy requires that therapists reduce the complex interpersonal transactions that take place to mathematical symbols that can be coded. Because the full encoding of human pursuits is not now, and probably never will be, complete, only limited parameters can be assigned to the circuitry of electronic computers. A number of interesting experiments have been reported. For instance, Colby (1963) has described the simulation of a neurotic process by a computer, and Bellman (1957, 1961) has, through dynamic programming, attempted to contribute insights into the interviewing process. A computer-assisted simulation of the clinical encounter is described by Harless and his associates (1971, 1972) and Hubbard and Templeton (1973).

More mundane operations that are being performed by computers include work with psychiatric records and other data related to the patient's history, symptomatology, and responses to therapy that may speedily and systematically be "memorized," synthesized, and retrieved. Feeding into the machine the recorded history, the psychological test results, and the symptoms of the patient, computers will quickly process these facts against the statistics of relative possibilities of diagnosis, prognosis, and treatment approaches (Rome et al., 1962; Swenson et al., 1963).

In clinical practice, attempts have been made to computerize data regarding the history of patients, their mental status, and symptom clusters in an attempt to aid in diagnosis, prognosis, progress evaluation, and treatment outcome (Colby et al., 1969; Spitzer and Endicott, 1969). The making of computer diagnosis has been especially

challenging and has attracted an increasing number of experimenters. Classification-assignment techniques are now available to permit an accuracy in diagnostic labeling estimated as comparable to that of expert clinicians.

For the most part, computers in psychiatry have been used mainly in clinics, hospitals, and group practices for purposes of office automation. In this capacity they have improved productivity greatly, providing access to satellite offices and to vast data banks. For word processing, data processing, electronic mail, record keeping, billing, accounts payable, accounts receivable, preparation of insurance forms, and other office functions they are proving indispensable. This is invaluable when extensive reporting is necessary to qualify for third-party payments and in response to demands for better accountability and quality of care. A number of computer service bureaus now exist to provide fiscal-administrative help to mental health facilities in line with these demands. Software packages are available that help streamline office management, accounting, scheduling, billing, insurance form preparation, and online inquiry.

With the evolvement of efficient, low-cost microcomputers, clinicians are increasingly using computers for data organization and management of their practices. The possibilities are enormous and, for certain functions—as when vast amounts of data must be recorded, processed, stored, retrieved and printed—there is no equal to the efficiency of a computer. Whether computerization can be cost-effective for the therapist in solo practice is another matter. Simple office tasks such as billing and the balancing of checkbooks can be done more rapidly by hand. Although patient records take a good deal more time to process in a computer, they can be meticulously kept and easily and accurately updated. The preparation of reports and manuscripts can efficiently be accomplished through word processing. Programs such as Word Perfect and Microsoft Word, once mastered, can be a godsend for a therapist writing a paper. If a literature search on a certain topic is necessary, a communications program using a modem enables rapid access of data bases that will produce in minutes a printout equivalent to days of painstaking exploration in a library. The National Library of Medicine has a computerized literature retrieval service, MEDLARS (Medical Literature Analysis and Retrieval System),

consisting of 20 data bases that are accessible from terminals at more than 2000 U.S. institutions. Among the most commonly used component is MEDLINE, which has about four million references to journal articles and books. An area that is now being developed is artificial intelligence, with the goal of answering questions beyond the MEDLAR system that are often diagnosis related and "perform at the level of a human expert in the area that they're programmed for" (JAMA 252: 2337, 1984). Other commercial databank services for literature searches include SCIMATE, Knowledge Index, BRS Catalogue, and Psychoinfo Database, the latter developed by the American Psychological Association and which has more than four million references and abstracts. In research, the computer is irreplaceable for statistical analysis, data management, graphics plotting, creation of tables, and indexing references.

Apart from word processing and research, the clinician may find sundry other uses for the computer. Among the software programs now in use are ones for automated history taking, clinical records management, patient interviewing, mood assessment, treatment planning, medication monitoring, outcome monitoring, projective testing, and patient-therapist simulation. Therapists may through rating scales be helped in estimating the mental status of patients, evaluating prognosis, predicting outcome, making a diagnosis, assigning special treatments, and tracking progress in therapy (Glueck and Stroebal, 1980).

The question arises as to whether computers can improve quality control of patient care. In medical practice this has been shown to be feasible (Poliak. 1985). In psychiatry this also is possible in some areas. Thus, where psychotropic medications are prescribed, anticipated cross-reactions with miscellaneous drugs the patients habitually take for existing physical ailments— as well as tabulation of dosage, complications, and side effects —can be expeditiously accessed. Sophisticated software programs oriented around the DSM-3 classification system may be helpful in diagnosis and thus in the selection of appropriate treatment. As a diagnostic helpmate, computers are acceptable to patients and do at least as good a job as clinicians and at lower cost (Sawyer, 1966; Scharfstein, et al., 1980). A number of programs are also available for diagnostic psychological testing.

Automated testing with the Minnesota Multiphasic Personality Inventory (MMPI), Beck Depression Scale, and Strong Campbell Interest Inventory permits rapid administration and scoring with as good patient compliance as with traditionally administered tests. Moreover, the level of accuracy is relatively high in culturally diverse clinical settings (Ensel, 1980; Labeck et al. 1983; Green, 1982; Colligan and Offord, 1985). The application of a computerized information system to the psychotherapeutic care of individual patients and families is obviously more complicated. Psychiatric problems involve much more complex data than do medical conditions. For example, in nephrology the data base consists of limited physical signs, symptoms, laboratory findings and relevant therapeutic information. In any psychiatric problem, however, there is a host of interrelated biochemical, neurophysiological, intrapsychic, interpersonal, social, and philosophic systems, each of which is tremendously complex and influences treatment progress.

Computers have been programmed to give clinicians reliable information about such variables as symptom change, work and social adjustment, sexual functioning, and risk of suicide (Greist et at., 1973).

Computer interviewing is efficient, reliable, accurate, and highly acceptable to most patients. Up to 85 percent of markedly disturbed patients may be interviewed by computers at the time of admission to a hospital (Erdman et al., 1981). A number of programs lend themselves to consultation, performing as effectively as clinicians in making clinical decisions. For example, Greist et al. (1973) have evaluated an online computer program that makes predictions about suicide risks that are more accurate than those of clinicians. A number of computer software programs have been designed to meet the needs of handicapped people. Thus successes have been secured in cerebral palsy, learning disabilities, and hyperactive and autistic children to improve attention and performance. Computers are increasingly being used in psychoeducation to dispense information about topics such as birth control and sex, and it is often easier and less embarrassing for patients to learn via computer rather than a human lecturer. If therapists are looking for silent, nonarguing cotherapists, they may find it in computer programs such as BARRY which engages patients in dialogue; this can be of help in

monitoring the depth of depression and adherence to the medication schedule. Computers can be programmed to help interview patients regarding substance abuse (alcohol, tobacco, drugs) in a relatively relaxed atmosphere.

By interacting with the computer, clinicians can obtain or substantiate DSM-III diagnoses with a high degree of reliability. Facilitating this is the software program "Psychiatric Diagnostic Assistance." Helpful also in making clinical decisions are such programs as MYCIN, CADUCEUS, AND PUFF. A rapid screening for most mental disorders is now possible (Carr et al., 1981; Fischer, 1974). Attitudes, beliefs, and intimate important bits of information may be revealed by patients to the computer in many cases more readily than to a human interviewer (Greist and Klein, 1981) which is an important aid in treatment planning. Suggested treatment programs already exist in relation to agoraphobia, obsessive-compulsive neurosis, and depression, and more are being developed. Computerized information regarding new psychotropic drugs, changes in administration of existing medications, and side effects and their management can be a valuable aid in pharmacotherapy. The best known data bases for drug information (interactions, contraindications, warnings) are Medline, International Pharmaceutical Abstracts, and the University of Wisconsin Lithium Information Center. Other uses for computers are the updating of available pamphlets, books, and other materials for bibliotherapy and psychoeducation; information regarding social, recreational, and therapeutic resources in the community; and location of self-help groups. Computer-elicited case histories have been shown to be more than 90 percent accurate and reveal data of importance in the management of patients, some of which were not divulged to human interviewers (Carr et al., 1983; Greist et al., 1973, 1977; Lang et at., 1970).

Experiments with computers to enhance psychotherapeutic operations have resulted in the development of a number of interactive programs. Computer mediated psychotherapy systems are to an extent organized around the symbolization of the computer as another human being with which one can interact. People often do this with animals who as pets substitutely serve an important but limited interpersonal function. The computer can become much more anthropomorphized than an animal when it is

programmed to communicate in language the person can understand. The earliest example of a computer therapist is provided by ELIZA, a program devised by Weizenbaum (1966, 1976) a Massachusetts Institute of Technology computer scientist, which simulated a Rogerian non-directive therapist (Colby, et al. 1966). If we observe subjects "talking" to ELIZA we can see how easily transferential phenomena can be elicited, and we may speculate about the usefulness of computers as therapeutic instruments for cognitive and value change above and beyond their proven educational value (DeMuth, 1982).

Attempts have been made to do this (Colby, 1980; Rokeach, 1975; Cole et al., 1976; Friedman, 1980; Spero, 1978; Hedlund, 1979; Selmi et al., 1982; Trappi, 1981; Wagman, 1980; Wegman and Kerber, 1980; and Zarr, 1984). The consensus of opinion by these authors is that despite the threat of dehumanization, there will be important future uses for the computer as an adjunct in organized psychotherapy programs. Caution nevertheless dictates not to compare the brainpower and skill of a computer to that of well-trained and empathic therapists. Granted that some computer behavioral, cognitive, and relaxation programs may be conveniently and economically administered, computers have not yet reached the stage where they have made psychotherapists obsolete.

Computer fantasy games, fashioned after the popular computerized games for youngsters, Dungeons and Dragons, and Adventure (Adams, 1980; Clarke and Schoech, 1984) have been developed for child and adolescent patients which allow them to control the actions of characters on the display monitor with whom the patients identify (Allen, 1984). Children may even construct the main characters in the game—identifying them with the angels and monsters in their own inner world— give them names, and design their dodges and achievements. A tremendous amount of material becomes available to the therapist through such modern play therapy and this can provide an opportunity to question, encourage, and support the children in working through fantasies, needs, and defenses. The responses of the children may be saved on disk for later replay, to procure associations, to invite more reality oriented revisions, and to improve decision making.

The program ELIZA and the interactive fantasy games devised for children with

emotional problems open up the vast possibilities of the computer as a way of influencing behavior that can serve as an adjunct to psychotherapy. As has been mentioned before, the computer can never replace the professional who provides the warmth and empathy of a skilled human relationship (Spero, 1978) but in some ways it can do selective tasks better—for example, educational reinforcement. Required is appropriate software prepared by creative innovators. Some leads in this direction have been provided by a number of experimenters. Reitman (1985) has described a self-help program for impotence oriented around cognitive restructuring that has produced excellent results. Thirty-eight other programs of psychoeducation, sex education for children, sex therapy for varied sexual problems, and therapy for couples' problems are being developed. Lang et al. (1970) have developed a program for desensitization of phobias that has produced results equal to that of a clinician. Schneider (1984) has devised a four-week "Quit-by-Mail" antismoking program with clients treated at home who mail to the author's clinic diary sheets of smoking control progress and responses to smoking questionnaires. These data are entered into a computer, and a personalized reply, prepared by the computer, is mailed back to clients. Initial successes have been encouraging.

Because verbal psychoeducation is an important aspect of a well-organized psychotherapy schema, it has been more and more incorporated into some therapeutic designs. It is, however, costly and inefficient when it is employed by therapists themselves especially in short-term psychotherapy where time is limited. Bibliotherapy has been of some use in providing supplementary readings, but often these cover a subject too diffusely and do not zero in on the specific problems of patients. It is posited that improved computer methods will revolutionize education with replacement of present-day teaching technologies by computer systems that permit active personalized conversational dialogue between student and instrument, thereby eliminating the highly inefficient lecture techniques that reduce the student to an immobilized, passive, and resistant receiving station. An actual attempt in this direction, the teaching of interviewing by employing a suitably programmed computer to simulate an initial psychiatric interview, has met with some success (Bellman et al., 1963, 1966). Here trainees assume the role of therapists, and the computer, properly programmed, replies as patients would

respond. The computer may be programmed to represent a range of problems and patients. Jaffe (1964) has described specific techniques for interview analysis through the aid of computers with special methods of coding interpersonal phenomena; such computers have potential research applications. Wedding (1984) has developed a technique of mailing letters to patients after the third or fourth session that reiterate and elaborate many of the points brought out in therapy—occasionally even anticipating points to be made in the future. A personalized letter typed on the computer is merged with psychoeducational data and specific instructions relevant to the problems of the patient avoiding irrelevant and counterproductive information. The planning of vocational and educational counseling can be vastly enhanced through the use of a computer in an automated "Educational and Vocational Guidance System" (Murray, 1984). A modem provides a telecommunications link between the computer and a data base, such as the "Guidance Information System" of TSC, a Houghton Mifflin Company. The advantages of computer-assisted instruction for patients over written materials and verbal educational methods have repeatedly been demonstrated.

The interactional aspects of computer instruction permit learners to proceed at their own pace, minimizing the transference reactions common in interviewing that may interfere with learning, getting immediate feedback to data provided by the computer, allowing for greater flexibility in learning, and providing great stores of relevant information. A tremendous amount of literature has accumulated detailing the advantages and drawbacks of computer-assisted information systems (Flynn and Kuczeruk (1984), Misselt (1980), Schoech (1982).

Microcomputers are being used in remedial training for correction of memory, perception, concept formation, and problem-solving deficits resulting from brain impairment (Kurlychek and Gland, 1984). Rehabilitation professionals are also employing computers to assist their work with handicapped learning-disabled children and adults. Patients who have suffered a stroke may be asked to acquire and use an inexpensive computer in their homes for cognitive rehabilitation (Brady, 1984). Programs are available to enhance attention, initiation/inhibition skills, cognitive discrimination, and

differential responses.

These examples of computer use in psychotherapy merely provide an inkling of what the future has in store for this remarkable instrument. Zarr (1984) has pointed out the need for enthusiasm and belief in computers' effectiveness as a requirement in computer-mediated psychotherapy. He also believes that the best uses are in brief and focused therapy, especially of a cognitive behavioral type. Excellent accounts of future trends in uses of computers in mental health may be found in the books by M. D. Schwartz (1984) and Crawford et al. (1980).

The optimistic reports are to some degree offset by some emerging problems. For example, attempts made to develop checklists of symptoms and levels of function to enhance psychiatric record keeping have been thwarted by both technical difficulties and resistance by clinicians who find it difficult to accept computers. The old hardware problems that involved a batchmode use of mainframe systems with difficult-to-manage punched cards have more or less been eliminated by the use of interactive mainframe and microcomputer systems. A number of problems have not yet been resolved, however, such as the programming of computers to simulate clinicians' summaries of input data, or to make inferences about diagnosis, prognosis, and treatment. What appears essential is refinement of the data that are most suitable for psychiatric summary statements.

Prevailing complaints are that the need to adhere to a preset and rigid reporting system that requires the skills of a human clinician cannot be subtly managed by a computer. Moreover, because the variables of human behavior are so complex and diverse, the computer reports to date have failed to differentiate patients who present even dissimilar clinical pictures. Sometimes a failure occurs in entering key pieces of information, and this results in wrong diagnoses. Gradually, greater sophistication is entering computer usage, but there still remain the difficulties of clinical compliance and acceptance.

Among the reasons computers do not enjoy greater popularity among clinicians than they do are the difficulties inherent in mastering them. Not only must users learn a new

language, acquire typing skills, and technical know-how but also plow through complicated reading. Many instructional manuals are not monuments of conceptual clarity or good writing. It takes a great deal of time and patience to master operations that are more complex than simple word processing. Learning to develop new computer programs is difficult, but if interest is there are and time of no essence, the effort can be rewarding. Examples of such use is provided in an article by Klepac (1984). The complexity of the data elicited in psychotherapy makes it difficult to organize data for purposes of computerization, although some preliminary attempts have been made toward providing greater regularity in this direction. Mergenthaler (1985), for example, describes an attempt to integrate information technology following guidelines of fundamental research in psychoanalysis.

Therapists first entering the world of computers may be bewildered by the vast variety of hardware equipment and software programs available. It is best in purchasing a computer to deal with a reliable agency locally to which a machine may be returned for repair or adjustment if necessary. The most popular computers are IBM instruments, or IBM-compatible clones that are less expensive; in the latter case, purchasers must be sure that repair facilities will not be too difficult to find. Apple (including Macintosh) computers are excellent, but buyers should ascertain beforehand that any software purchased is suitable for these machines. If possible, a computer with at least 640 K of RAM (memory) and a hard disk should be purchased, but 256 K of RAM and two drives for floppy disks may be adequate for most purposes. A monochrome monitor is eminently suitable, but some therapists prefer a color monitor, even though this is more expensive, because color makes some interactive programs more interesting. A good dot-matrix printer will be needed for speed and, if desired, near-letter-quality printing. A stand to support the printer and covers for the fanfold paper rounds out the basic equipment. Accessory purchases can include a modem (with at least 1200-band speed) for accessing outside data bases and equipment for use with compact disks.

Elaborations of computer programs are proceeding at an enormous pace, covering the entire field of practitioners', interests. Thus software programs, such as psQ "Practice

Partner" (psyQ systems, 1730 Rhode Island Ave., N. W., Washington, D.C. 20086) and "Insight Billing Software" (Applied Innovations, Inc., South Kingstown Office Park, Wakefield, RI02879) are sold with the object of managing the paperwork requirements of mental health practitioners in relation to preparation of billings, daily schedules, accounts receivable, insurance forms, and special reports.

Some programs exist that prepare a DSM-III diagnosis as required by third-party payers. In the "P.D.M. 2000 computerized Diagnostic Interview Schedule" (p.r.n. systems, 222 N. Midvale Blvd., Suite 1, Madison, WI 53705) patients are interviewed on a computer, the data are processed, and a "clear, concise, and documented written report of suggested DSM-III diagnoses" is offered. A "computerized textbook" is available in "Decision Base," which diagnoses all DSM-III disorders, takes histories, and programs other functions (P.W. Long, M.D., II 1206-750 West Broadway, Vancouver, B.C., V5Z Canada). One program, MORTON, administers the Beck Depression Inventory for diagnostic purposes. Tests such as the MMPI are executed with a written narrative describing the personality dynamics and interpreting the scale scores. (Behaviordyne, Inc., 994 San Antonio Road, P.O. Box 10994, Palo Alto, CA 94303-0997; Applied Innovations, Inc., South Kingstown Office Park, Wakefield RI 02879). A computerized stress-inventory program generates a stress profile for diagnostic purposes and suggests changes (Preventive Measures, Inc., 1115 West Campus Road, Lawrence, KS 66044). A "Chronic Pain Battery" screens for psychopathology (Pain Resource Center, Inc., P.O. Box 2836, Durham, NC 27705). "Q Fast" converts questionnaires and surveys into interactive computer programs useful for practioners and researchers who administer tests, and "Psychostat" is a complete statistical package (Stat Soft, 2833 East 10th St. Suite 4, Tulsa, OK 74104).

The "Gordon Diagnostic System" administers game-like tasks for diagnostic and treatment recommendations for attention-deficit disorders and hyperactivity (Gordon Systems, P.O. Box 746, DeWitt, NY 13214). Software programs are being developed for automating test-report writing, statistical analysis of data, projective drawing tests, diagnostic screening batteries for children and adults, and many other purposes. A number of other microcomputer software programs are designed for initial evaluations,

session summaries, treatment planning, termination and discharge, summaries, child and adolescent diagnostic screening, intelligence test interpretation, and Rorschach data summary and report (Psychologistics, Inc. P.O. Box 3896, Dept. A, Indialantic, FL 32903).

For therapists interested in research, a statistical analysis package is available (Walonick Associates, 6500 Nicolet Ave. S., Minneapolis, MN 55423). "PsycINFO" has prepared a compact disk (which will require special equipment) providing summaries of the world's literature in psychology from more than 1400 journals. For quick, convenient searches there is "PsycLIT" (The American Psychological Association, 1400 North Uhle Street, Arlington, VA 22201). The use of microcomputers to provide direct access to databases has increased markedly in the past few years. It is not unusual for clinicians to keep terminals in their offices and also in their homes. New user-friendly computer literature search systems are available from various sources. BRS/Saunders Colleague is a medical literature and information-retrieval service accessible 22 hours daily containing both bibliographic and full-text references. Some of the data bases are MEDLINE, Medical and Psychological Previews, Psyclnfo, Excerpta Medica, the full text of the *American Journal of Psychiatry* and also of the *Comprehensive Textbook of Psychiatry,* 4th edition. Colleague, another data base, can be menu driven or accessed by direct commands (BRS/Saunders, 555 East Lancaster Avenue, St. Davids, PA 19087.) KNOWLEDGE INDEX is DIALOG'S after-hours, simplified search service, available weekends and evenings. It is intended for the weekend user and the at-home user. Its data bases include Mental Health Abstracts, MEDLINE, and Psyclnfo (available through local DIALOG offices or DIALOG Information Services, Inc., 3460 Hillview Avenue, Palo Alto CA 94304). Health-sciences librarians can provide further information.

Some periodicals that may be of interest to therapists are (1) *Computers in Psychiatry/Psychology* (26 Trumbull Street, New Haven, CT 06511; quarterly, $40 a year), (2) *Computer Use in Social Science,* (CUSS Network, Graduate School of Social Work, University of Texas, Box 19129, Arlington, TX 76019; quarterly, $10 a year). Recommended books are (1) J. D. Lieff, *How to Buy a Personal Computer Without Anxiety.* Cambridge, Mass., Ballinger Publishing Co., 1980; (2) J. D. Lieff, Computer Applications in

Psychiatry. Washington, DC, American Psychiatric Press, Inc., 1987; (3) M. D. Schwartz: *Using Computers in Clinical Practice,* New York, Haworth Press, 1984. To use telecommunications for accessing data bases, a subscription to systems such as "Source" or "Telenet" is recommended. Mental health software catalogues may be obtained from (1) American Association for Medical Systems (AAMSI, 1101 Connecticut Avenue N.W., Suite 700, Washington, DC 20036); (2) Psychological Software Specialists, 1776 Fowler, Suite P, Richland, WA 99352; (3) Computers in Psychiatry/Psychology 26 Trumbull Street, New Haven, Connecticut, 06511; and (4) National Health Information Clearinghouse, Dept. GGG, P.O. Box 1133, Washington, DC 20013. Recommended reports and articles are (1) M. D. Schwartz: "Resources for Computer Users." *Hospital & Community Psychiatry* 35:537-539, 1984; (2) J. L. Hedlund et al.: *Computers in Mental Health: A Review and Annotated Bibliography.* NIMH Clearinghouse, Room 1 SC-17, 5600 Fishers Lane, Rockville, MD 20857; (3) J. H. Johnson: Computer Technology and Methodology in Clinical Psychology. Psychiatry and Behavior Medicine, Vol. 13, No. 4, Aug. 1982; (4) *Applying Computers in Social Service and Mental Health Agencies: A Guide to Selecting, Equipment, Procedures, and Strategies.* Administration in Social Work, N.Y., Haworth Press, 1981.

There are critical stages in the development of personality in which crucial incidents and experiences have a destructive impact that are not registered during another period. The stages of weaning, habit training, bodily exploratory activities, entry into school, puberty and adolescence, marriage, pregnancy, child rearing, and retirement and old age pose special problems that influence psychotherapeutic interventions when these are needed.

CHILD AND ADOLESCENT THERAPY

Psychopathology in children must at all times be viewed against the backdrop of developmental norms. Moreover, it must be considered in relation to existing family and social distortions that deprive children of needs essential to their growth or subject them to rejection, violence, or overstimulation with which they cannot cope. Among common noxious influences are parental absence, rejection, seduction, overprotection, or cruelty. Contemporary disruptions in family life, such as a detached and disinterested father, subjection to television bombardments of violence and sexuality, poverty, lack of intimate family ties, and racial conflicts at school, exaggerate the normal problems inherent in growing up. Fears of separation, resistance to socialization, defiance of discipline, sibling rivalry, and Oedipal crises may also interfere with the resolution of developmental disturbances. Emotional difficulties in childhood usually express themselves in symptoms of excessive irritability, hyperkinesis, fearfulness, daydreaming, obsessions, compulsions, bed-wetting, or excessive masturbation. Sleep, speech, eating, and learning disturbances are common, as are psychophysiological manifestations such as tics, spasms, vomiting, diarrhea, headaches, asthma, ulcers, and colitis.

During the first three years of life, excessive and continuous crying unrelieved by

attention from the mother signals a state of unresolved tension (Cramer, 1959). Inordinate rocking, thumb sucking, head rolling, sleeplessness, food refusal, vomiting, retention, soiling, temper tantrums, ritualistic behavior, defiance, stammering, and unusual aggression often indicate disturbances in the child's environment, particularly in the relationship with the mother. In a small number of instances, these are manifestations of organic physical or neurological ailments.

During the fourth and fifth years extravagant fears, nightmares, excessive masturbation, and enuresis reflect sexual identity difficulties. Overactivity, tantrums, negativism, and destructiveness constitute another type of patterning for conflicts developed during this period. Such difficulties are often nurtured by sexual and hostile acting-out in parents and by their seductive use of the child to satisfy their own neurotic needs.

Neurosis during the sixth to ninth years of life frequently manifests itself in failing adjustment at school, the outcroppings taking the form of school phobias, truancy, aggression toward fellow pupils and teachers, and learning disabilities. Outright neurotic symptoms may appear in other types of phobias, tics (blinking, grimacing, jerking of the head and extremities), stammering, compulsions, and conversion phenomena. Excessive withdrawal and daydreaming or aggressiveness and antisocial activities (e.g., stealing, exhibitionism, fetishism, peeping) interfere with social adjustment. Frank, unbound anxiety may erupt. Eventuating psychophysiological disturbances may derange various organ functionings.

In the preadolescent (latency) stage, between nine and twelve, there may be enhanced aggressiveness, fighting with siblings and friends, and occasional depressive states stimulated by disappointments and failures.

During adolescence, potential problems incorporate the full spectrum of psychopathology from behavior disorders to psychoneuroses to psychoses. The emotional disorders that are most common in adolescence, however, are adjustment difficulties, personality disturbances, scholastic failure, school phobia, enuresis, psychosomatic

complaints, delinquency, anorexia, bulimia, and identity disorders.

In the tumultuous growth period of adolescence, with the extensive alterations in the physical, biochemical, and emotional makeup characteristic of this epoch, therapists must, in judging the degree of disturbance, take into consideration the normal anxieties and concerns that plague individuals.

Adolescents have a need for both uniqueness and difference, a desire to conform and a fear of being different from others of their age and sex. Strong and strange impulses dominate the body as the sexual glands mature and the adolescent comes under the influence of erotic thoughts and feelings. New demands are made by family and community; no longer is the youth considered a child. Swings into independence and aggressiveness are followed by refuge in childish dependency and passivity. The need for recognition vies with the impulse to defy. Drives for success and prestige are paramount, while conflict rages over issues of religion and death. A fluctuating sense of values and confusion in identity add to the adolescent's turmoil.

Constructive solutions will be needed. The adolescent must first dissipate dependency ties sufficiently to enter into a more assertive and independent attitude toward the world. This is especially necessary in a society where the burden of one's own support and ultimately that of one's family will fall on the individual's shoulders. Second, the adolescent must learn to control sexual feelings so that there will be a proper balance between restraint and expression. Evolvement of adequate sexual role identification is mandatory. Third, one must change from the subordinate manner of a child to the dominant habitude of a grownup, to feel equal with other adults. Fourth, one must develop a cooperative attitude toward authority, without feeling victimized or excessively hostile. Fifth, one must learn to be assertive and creative and to assume leadership on occasion, without ulterior motives of control or power. A proper educational and career choice must be made.

In primitive cultures the adolescent struggle is less intense than in civilized societies because there is much more continuity in the behavior patterns of child and adult.

Primitive economies are less complex and consequently afford an easier and earlier emancipation from parental support. Child marriage and premarital intercourse are more or less condoned. This sanction affords the growing child an outlet for energies. Civilized societies impose barriers against which the adolescent will struggle. While relatively mature biologically, the adolescent cannot become economically self-sufficient until well along in adult life. A large proportion of today's young people are forced by the requirements of their chosen careers to enter into a long and expensive period of study that must be financed by their parents.

Hostility and resentment are frequently the outcome of the conflict between the impulse to break dependency ties and the need for material help and support. Although adolescents feel an urge to lash out at their parents, most realize that such action will result in retaliatory measures that threaten personal security. In addition, the hostile urge clashes with some of the adolescent's ideals. Thus a youth is at the mercy of many ambivalent and conflicting values and goals. Sometimes the child is driven by contradictory impulses reflecting both the secret sexual and delinquent wishes of one or more parents that they have projectively and covertly conveyed to their offspring, as well as guilt feelings of the parents that have prevented the parents from personally expressing these impulses. The child here acts as a messenger for the parents, who stealthily relish the exploits of their offspring and then heap blame on the child.

Under the best of circumstances the adolescent period is a chaotic one and is characterized by a recrudescence of problems that had their origin in childhood and were never adequately resolved. Often parents have not been aware of these problems, and they are dismayed and frightened by the eruption of severe behavioral disturbances in a previously exemplary child. The early adolescent (12 to 15 years) is plagued by regressive thrusts that conflict with the new growth demands of this stage. The child ambivalently veers between submission and rebellion, sociability and isolation, friendships and enmities, overactivity and retreat, depression and overexcitement. Delinquency and acting-out are common. The struggle in this period is a process of resolution of sexual identity, object ambivalence, and needs for separation and individuation. In middle

adolescence (14 to 17 years) there is some resolution of sexual conflicts with greater ability to relate. Narcissistic defenses alternate with more mature coping mechanisms. Homosexual episodes, depersonalization, anxiety, and runaway tendencies may occur. In late adolescence (17 to 21 years) separation-individuation accelerates, object choice solidifies, identifications strengthen. Identity crises, depression, and adjustment difficulties continue, however, often encouraged by available peer groups involved in sexual and deviant exploits.

In summary, *adjustment reactions* to growing up are a normal byproduct of socialization. They occur in all children. The reactions become exaggerated in those who are subjected to extraordinary stress, or whose developmental needs are not being met by parents, or who are being grossly mismanaged, improperly disciplined, or subjected to cruel and abusive treatment. The constitutional makeup of the child will influence the severity of reactions and the ability to cope with the stress being experienced. The responses of the parents to the child's reactions will also influence the outcome. If they are kindly and caring adults, capable of maintaining control of the situation and their own emotions, the child may be helped through the critical adjustment years. If they are not so equipped, minor maladjustment reactions may explode into severe behavior disorders that can persist and influence adversely later stages of the child's development. The ultimate outcome may be a pathological neurotic or psychotic reaction for which treatment will be needed.

General Principles of Child and Adolescent Therapy

Choice of techniques in child therapy is complicated by a wide variety of available interventions. These are usually determined more by predilections of the clinician than by precise diagnostic assessments. This, in the words of Harrison (1979), has produced a state of "undisciplined chaos" in the field. Experience is the mother of compromise and the great leveler of differences in therapeutic operation. For example, whereas in past years there was a tendency to segregate behavioral from psychodynamic approaches, a fusion of these methodologies has more and more dominated the practices of many child therapists.

Family therapy, with its transactional system orientation, has become an indispensable mode and is often executed coordinately with behavioral-psychodynamic-medicinal approaches and environmental therapy. It seems obvious that therapists cannot neglect any links in the behavioral chain among children any more than they can neglect them in adults, and this will necessitate the use of interventions designed to influence different zones of pathology. With the present knowledge, therapists can match a number of syndromes with appropriate interventions provided a proper diagnosis can be made.

The basic rule in treating disorders in childhood is providing an adequate climate in which developmental needs are met, opportunities for impulse gratification supplied, and proper discipline and restraints imposed. Alterations of the milieu are usually required and the cooperation of the parents and family may be essential even to the point of exposing them to individual or family therapy. Unless this is done, work with the child alone may prove to be fruitless, the parents and other family members sabotaging the child's efforts at adjustment. Indeed a sick child may be the vehicle for holding a family together.

Therapeutic interventions will accord with the accepted theoretical model. Thus, if deviant behavior is regarded as originating through reinforcement of unhealthy patterns by the family, treatment tactics will be organized around modifying the consequences of such patterns through behavior therapy (Ross, A, 1972). Should a psychoanalytic family interaction model be adopted, a search for pathogenic conflicts and their resolution through insight and working-through in the patient-family-therapist relationships will be embarked on. If constitutional organic neurological factors are considered most significant, developmental and language lags that interfere with the normal timetable in the evolution of essential functions will be looked for. Prescription of medications and the institution of adequate training routines will follow.

The existence in childhood of relatively undeveloped personality functions, strivings for independence and.mastery that inevitably conflict with dependency yearnings, heightened motor activity and fantasy life, lowered frustration tolerance, greater needs for

discipline, and extraordinary plasticity of the developing ego will require innovations in therapy technique. Environmental manipulation, crisis intervention *(q.v.),* family therapy *(q.v.),* drawings *(q.v.* art therapy), the use of play materials *(q.v.* play therapy), and the employment of greater activity and supportiveness with efforts at symptom control are more or less standard aspects of child treatment. The key to management is a proper diagnosis with assessment of the potential of the child as well as the role the mother and family will play in organizing a therapeutic milieu.

The majority of child therapy clinics use therapeutic methods that stress the interpersonal therapeutic relationship, focus on the presenting problems, and encourage therapist activities of a friendly, active, and supporting nature to provide a corrective experience for the child. Psychotherapy is considered a new and unique growth experience that is family centered with the focus of concern on the child (F. H. Allen, 1962, 1963).

In mental health clinics for children that emphasize careful evaluation, diagnosis, and treatment planning, both the child and parent are given attention. Thus at the beginning of therapy, parents require help in expressing their feelings about the plans being made for therapy. Prior to bringing their children into a treatment situation, parents are aided in ventilating their hopes, doubts, and fears. Discussions consider the part they can play in preparing their offspring for treatment. In these early interviews the role distortions of the parents with each other and their children usually become apparent. It is essential to involve both parents, when possible, in the planning to avoid distorting the family drama further. The beginning phase of treatment with children is diagnostic for the therapist. The therapist witnesses how the children react to a unique experience of acceptance and empathy, their degree of accessibility, the content and manner of their communications, and the ways that they express or conceal feeling. At the start, children will probably perceive the therapist as they do other adults—hostile, dogmatic, overprotective, or omnipotent. Expectations, fears, and desires for magical cure are sooner or later projected onto the therapist. Recognizing this the therapist encourages the child to express and then to test out misconceptions in the hope of inspiring a more

realistic life orientation. Dealing with the child's need to transform the therapist into a good or bad parent, steady maintenance of one's identity helps to provide for the child a truly differentiating experience. But even in the first interview a therapeutic process may begin. Winnicott (1969), using the child's drawings, has demonstrated that therapists can score a significant imprint on the child and increase their understanding in just one interview.

Emerging from this diagnostic phase is a therapeutic plan determined by the children's physical condition, the evaluative studies of the psychologist, the ability of the children to form a relationship with the therapists, and the cooperation of the parents. A definite schedule is set up, usually once weekly, the children and parents having separate and sometimes concurrent appointments. In a team plan different team members may see the parents and the children.

Changing paradigms of therapy have placed an accent on *child behavior therapy*. Its briefness, ease of administration, and effectiveness in behavior and habit disorders have enabled therapists to help some children, particularly those who because of deficiencies in motivation, cooperation, intelligence, and verbal skills have not been able to use traditional interview and play techniques. The focus is on altering the environmental circumstances that initiate and support deviant patterns. No effort is made to probe for conflicts or to promote insight. There is little emphasis on the importance of the child-therapist relationship except to establish sufficient rapport to enhance the acceptance of social reinforcement. The traditional diagnostic categories are not considered of great importance.

Initially, a behavioral assessment is made of the problem, consisting of an exact description of its nature, its history, its frequency, the circumstances under which symptoms occur, the reactions of the parents or teachers, and the consequences to the children. Many pertinent techniques on behavior therapy are delineated in Chapter 51. The selective method used with particular children will depend on the specific behavior to be altered. Bijou and Redd (1975) have outlined some useful methods. Monitoring

procedures are set up to provide data about progress, and parents are trained in proper responses, and at home to act as accessory behavior therapists.

Thus, in children who have tendencies that are upsetting to others (such as pushing, fighting, hitting), a program may be organized that grants rewards (candy, a token or points exchangeable for something the children like to receive or do, praise) for each instance of desirable social behavior. Coordinately, an aversive contingency may be employed whenever the obnoxious behavior occurs, for example, removal of the children from the room for a period and placement in a room without toys. Or the children may be penalized for conduct by taking away some tokens or points.

If children are psychologically withdrawn or show shy or phobic behavior, they are rewarded with praise and attention when they manifest sociable and non-phobic behavior. They are ignored when they do not. Reinforcements are gradually spaced and delayed, and requirements for reinforcement gradually are made more stringent to shape behavior. Modeling appropriate behavior may be utilized both for the children and the parents, the latter observing how the therapist responds through a one-way mirror if one is available. Systematic desensitization may also be employed. Thus, a school phobia is treated by gradual introduction to the school environment for slowly increasing periods, each success being rewarded.

The acquisition of new and desirable behavior repertoires will call for contingent positive reinforcement for initial improvements then for increasing intensities of the new behavior. Inappropriate normal responses (e.g., of speech, conduct) may gradually be extinguished and displaced to suitable situations by adequate reinforcements.

These operant techniques are also applicable to hospitalized adolescent patients. Their effectiveness is illustrated by the experience in the Adolescent Service of the Boston State Hospital (Lehrer et al., 1971). A token economy is tailored to individual needs or problems. Patients are given points that can be redeemed for money, school attendance, and participation in various activities. Points buy food (hot dogs, pizza, hamburgers, soda, or ice cream). Then patients are permitted to play a jukebox, games (pinball, table tennis,

board games) as well as purchase various items in a special teenage lounge that has a soda fountain and grill. Points are also exchangeable for parties, dances, camping expeditions, and so on. Points are taken away for infraction of the rules. Serious violations, such as assaultiveness and abuse of property, lead to restriction of all activities until the patients have worked out with a psychologist strategies for controlling their behavior and proper point payment for any damages that they have done to property.

Some therapists use the findings of dynamic psychology to conceptualize the development and problems of children. The therapeutic focus of *child psychoanalysis* follows this model and brings to the children's awareness the anxieties, unconscious wishes, and defenses that produce their difficulties. Since children do not respond to therapy as adults do, classical technique must be modified taking into account the children's tendencies to project problems onto the environment and the lack of motivation for therapy. The parents and other important members of the family also have to be brought into the therapeutic situation through parent guidance, family therapy, or individual therapy in accordance with what is required in each individual case. Because children express themselves most readily in play, play therapy is seen as an important tool for probing conflicts and for interaction with therapists. The analysis of children's problems was originally explicated by Sigmund Freud in his "Analysis of a Phobia in a Five-Year-Old Boy." The two main orientations that emerged were those of Anna Freud (1928, 1945, 1946) and Melanie Klein (1932, 1961). According to Anna Freud, children as young as three years of age may be analyzed. Free association and the couch position, however, cannot be employed. Instead the children's activities in movement, play, and random talk are used for interpretation, as are stories, dreams, and the children's reactions to the therapist. Caution in making interpretations is essential since the egos of children are not as firmly developed as those of adults. Generally children do not develop a transference neurosis, instead reflecting more of the immediate situation than the past. The cooperation of the parents should be enlisted as an adjunct to their children's treatment but no attempt is made to offer direct advice. In Melanie Klein's technique, children as young as two may be treated. Unlike Anna Freud's method, the deepest interpretations to fantasies revealed by children in play are given, starting with the first

interview. These are concerned with Oedipal wishes, awareness of parental intercourse, the desire to destroy the mother's body, and the desire to incorporate the father's penis. Since the reality situation is not considered significant, the cooperation of the parents is not sought; indeed, it is considered an unnecessary inconvenience. In recent years the formulations of self-psychology (Kern-berg, 1980; Kohut, 1977; Mahler, 1968) have been applied to work with the more seriously disturbed children and adolescents (Marohn et al., 1980). Interesting descriptions of the psychoanalytic process in children may be found in the writings of Aichorn (1936), Bios (1962, 1970), Born-stein (1949), Erikson (1963), Fraiberg (1965), Gyomroi (1963), Isaacs (1930), and Winnicott (1958). There is some disagreement among analysts regarding how thoroughly the unconscious should be probed.

Instead of an expressive-exploratory approach it may be decided to employ a supportive-educative-suppressive type of therapy to bolster repression of offensive conflicts and active promotion of more constructive behaviors. Here combinations of therapies are commonly used such as environmental manipulation, promotion of emotional release, family therapy, educational techniques, behavior therapy, and play therapy as means of maintaining communication and releasing fantasies that may be explored. Examples of play therapy are Winnicott's (1977) squiggle game and Gardner's (1971) storytelling methods detailed in a number of books published by Creative Therapeutics of Craskill, N.J. In play therapy, psychotherapists may employ psychodynamic concepts and in essence integrate psychoanalytic with behavioral, educational, family, and environmental-manipulative approaches, an integration which is probably for the majority of cases the most rational mode of operation.

Children and adolescents are less motivated for therapy than adults and a good part of the time may have to be spent by therapists developing a relationship with the recalcitrant youngsters. Children are more likely than adults to project their difficulties onto the environment, acting out their needs and conflicts while avoiding inner exploration and self-observation and inhibiting the constructive use by the therapist of transference as a therapeutic tool. On the other hand, the children's natural use of play as

a form of communication enables trained therapists to harness some of the bubbling energies that seem so chaotic. Working with the material elicited during play therapy calls for a great deal of skill, particularly in knowing how and when to interpret defenses, conflicts, and the underlying impulses (Harrison et al., 1984; Fraiberg, 1965). In adolescents the capacity for self-observation is somewhat more developed than in children. This is balanced by the ambivalence and confusion of identity that are hallmarks of this developmental period. Because adolescents tend to project their conflicts and to act out explosively at times, therapists may have to abandon their preferred roles as participant observers and intervene when the acting-out assumes dangerous proportions.

Technical modifications are necessary in adolescents that take into account the identity struggles going on within them (Es-man, 1983). Because adolescents are so resistive to receiving help of any kind, an empathic, active, non-challenging approach is more effective than a confrontational one, which inexperienced therapists are tempted to employ, especially when the adolescents test them by acting-out. Periodically, therapists may have to substitute game playing for interviewing. Patients may find it difficult during puberty or early adolescence to discuss sexual concerns, and to lessen anxiety, therapists of the same sex may be preferable. Between 15 to 17, adolescents are somewhat less in a tumult and become more amenable to an exploratory approach, but here the relationship with therapists must be sufficiently firm to support this effort and to handle the adolescents' inevitable countertransference reactions. Therapists who have had difficulties in their own adolescence are likely to adopt an anti-therapeutic stance in working with patients exhibiting defiance, or resistance. Short-term psychotherapy may be especially suited to adolescents (Proskauer, 1971; Rosenthal and Levine, 1971) focused on certain problems that patients choose to handle. Because children's and adolescents' pathology occurs before the maturational cycle is complete, because dependency on parents and family is still high and economically necessary, involvement of the parents and/or family is, as has been mentioned before, essential for good therapy. Family therapy is especially of value when dysfunctional transactional family processes exist, when scapegoating of patients is suspected, when the patients' difficulties are related to a pathological family structure, and when urgent intervention is required as a consequence

of a family crisis (Berlin, 1970; Williams, 1973). Adolescents with borderline problems may require a special approach using some of the insights from object relations theory (Masterson, 1972).

Attempts to use more formal psychoanalytic therapy in late adolescence are more successful than in earlier years. A search is made for fixations and problems in the infantile period and in early childhood that reappear in direct or disguised forms as well as the defenses against regression, castration anxieties, and superego guilt. From these therapists may better understand how hitherto adjusted children become converted into disorganized, willful, or violent adolescents. Youthful patients are, however, usually resisting participants in probing noxious early experiences and reactions, not seeing the connection with what is happening in the present.

Gladstone (1964) describes three major groupings of adolescents for whom different treatment approaches are applicable. The first group consists of acting-out character problems and offenders who will require extreme therapist activity to promote a relationship, a firm setting of limits, and a constant emphasis on human values and their communication in the relationship. In another study, Gladstone points out how this may be done. The second group includes neurotic disorders and dependency problems. Here observant and interested objectivity is offered patients, emotional catharsis is encouraged, there is a probing of underlying conflicts toward insight, and there is a minimum of interference from therapists in working out the conflicts. Illustrations of such tactics are provided by Josselyn (1952, 1957). The third group is composed of withdrawn schizoid reactions. With such patients are best employed supportive techniques, experience sharing, continuous correction of distorted perceptions with efforts at reality testing, and educational correction and filling in of learning deficits. Silber (1962) gives examples of these procedures.

Group therapy (q.v.) with children has been described by Slavson (1949, 1952) and has become an accepted way of dealing with problems in childhood, both as a principal therapy and as an adjunct to individual therapy. Of note, too, are Moreno's methods of

using psychodramatic play with groups of children (Moreno, 1965).

The size of children's groups must be kept below that of adult groups (Geller, 1962). For instance, in the age group six years and under, three children constitute the total. Both boys and girls can be included. Single-sex groups are those (1) from 6 to 8 years, which optimally consist of 3 to 5 members; (2) from 8 to 12 years, which may have 4 to 6 members; and (3) from 12 to 14 years, which also have 4 to 6 members. Mixed-sex groups at the oldest age level are sometimes possible. Play therapy is the communicative device up to 12 years, the focus being on feelings and conflicts. It is obvious that the ability to communicate is a prerequisite here. Beyond 12, discussions rather than play constitute the best therapeutic medium. Techniques include confrontation, analysis of behavior in the group, and dream and transference interpretation. Both activity (during which acting-out may be observed) and discussions are encouraged at various intervals. Interventions of the therapist should be such so as not to hamper spontaneity. Discussion is stimulated by the therapist, and silences are always interrupted. Ideally, individual therapy is carried on jointly with group therapy, particularly at the beginning.

Group therapy may be helpful for adolescents even though resistance is prominent. Identity crises and confusion respond better to group treatment than to any other approach (Rachman, AW, 1972a & b). The therapist must function in roles other than that of psychotherapist—for example, as guide counselor and teacher (Slavson, 1965). A behavioral group approach is often helpful, for example, with disturbed adolescents in a hospital, such as was previously described, as well as in a residential setting (Carlin and Armstrong, 1968). The introduction of several young adults of ages 21 to 24 helps foster healthier transference reactions and provides identification models. The therapist amid the impulsive behavior in the group (which is spontaneous among adolescents) cautiously introduces interpretations.

Some therapists find a cotherapist (preferably of the opposite sex) useful (Evans, 1965; Godenne, 1965). Countertransference phenomena that often occur in cotherapy include excessive attraction to young patients of the opposite sex, fear of "liking too much"

certain patients of the same sex (due to homosexual fears), projection of feelings and frustrated impulses in relation to the therapists' own mates onto the cotherapists or patients of the opposite sex, competition with the patients of the opposite sex for the cotherapists, competition with the cotherapists for the group's admiration and support, and transfer of emotions originally felt for children of the therapists onto members of the group.

The *drug therapy* of children with behavior disorders, schizophrenia, and chronic brain syndromes has included the use of a number of substances (Fish, 1963, 1965, 1966). The most important drug influence has been registered on psychomotor excitement, a control of which reduces other symptoms, such as perceptual and thought disorders. As a result of being calmed down, the children may become amenable to group activities, educational offerings, and psychotherapy (Fish, 1960a & b).

Generally no drug is given until it is proven that environmental manipulation and psychotherapy have had no effect on the prevailing symptoms. Diphenhydramine (Benadryl 12.5-25 mg 3 or 4 times daily; average dose 100-200 mg daily, maximum dose 300 mg) is valuable in behavior disorders with hyperactivity in children over 20 pounds of weight and in anxiety reactions in children under 10 years of age. Since it produces drowsiness, it may be employed as a bedtime sedative. Other drugs that can be used are chlordiazepoxide (Librium) for children over 6 years of age, 5 mg 2 to 4 times daily, increased if necessary to as much as 10 mg 2 to 3 times daily; and diazepam (Valium), 1 to 2.5 mg 3 or 4 times daily, increased gradually as needed and tolerated for anxiety. Promethazine (Phenergan) for severely disturbed children (Bender and Nichtern, 1956) acts as a sedative when 25 mg is given at bedtime or 6.25 mg to 12.5 mg is given three times daily. Phenothiazines may be tried for primary behavior disorders, as well as schizophrenia and organic brain disease where milder therapies are ineffective. Chlorpromazine (Thorazine, 1 mg per pound of body weight daily, or 50-100 mg daily) is used in excited states; should an emergency necessitate intramuscular injection, 0.25 mg per pound of body weight every 6 to 8 hours as needed are given. Trifluoperazine (Stelazine, 0.15 mg per pound of body weight daily, or 1-15 mg daily) is used sometimes in

apathetic, withdrawn children. Taractan (in children over 6 years of age) in dosage of 10 to 100 mg daily, Navane (in adolescents) in dosage of one to 40 mg daily, Haldol (in adolescents) 0.5 to 6 mg daily, and Moban (in adolescents) in dosage of 10-50 mg daily may be tried, in that order, where phenothiazines are ineffective. Haldol may be effective also in tic disorders and Tourette's disease. The employment of Ritalin and Dexedrine will be described later in drug therapy for attention-deficit disorders. Barbiturates should not be given to children. Should hypnotics become necessary, Benadryl or chloral hydrate may be used. The latter is prescribed as Noctec syrup (each teaspoon equals 500 mg) in a single dose depending on body weight up to a total of 750 mg. In depressive disorders in adolescents where psychosocial treatments have failed, imipramine (25-75 mg daily) may be tried, recognizing that cardiovascular symptoms may occur. MAO inhibitors are not recommended. Antidepressants have also been found useful in separation-anxiety disorder, attention-deficit disorder with hyperactivity, enuresis, and obsessive-compulsive disorder (Rancurello, 1986). The use and dosage of imipramine (Tofranil) in enuresis is described in the section on habit disorders. The use of stimulant drugs in attention-deficit disorders is detailed later in this chapter.

The Management of Aggression

The management of aggression constitutes an important aspect of working with children. Methods of handling aggression range from extreme permissiveness—even to the undesirable extent of allowing physical attacks on the therapist—to rigid disciplinary measures and physical restraint.

Aggression is representative of many diverse conditions. It may be a reaction to frustration of a fundamental need or impulse. It may be a means of coping with overwhelming inner fears stirred up by terror of a menacing world. In the detached child it may signify an averting of close relationships with people; in the child with power strivings, a way of gaining control; and in the masochistic youngster, a technique of provoking others to a point where they retaliate in kind. In some children it is the only form of relationship to another human being that they know, and it constitutes a frenzied

appeal for companionship or help. Aggression may be a camouflage for a deep feeling of inner helplessness, and as such it is motivated by the conviction that the only way to escape hurt is to overwhelm others. It may be a manifestation in compulsively dependent children of disappointment in the adults to whom they cling, on the basis that the children's whims are not being satisfactorily gratified or because more favors are being shown to others than to themselves. Before adequate therapy can be instituted, it is essential to know the symbolic significance of aggression to the children and the situations under which it is most likely to appear.

A number of children who exhibit behavior problems in the form of direct or subversive aggression never seem to have developed an inner system of moral restraint or the ability to tolerate an average amount of frustration. Neglected children—those reared without proper guidance or discipline or those brought up by parents who themselves fear aggression and are consequently unable to take a stand with the child—frequently develop a defective repressive mechanism that is incapable of inhibiting rage or of directing it into socially approved channels. Such children usually have no fear of, or respect for, authority. They are narcissistically oriented and use aggression as a coercive tool to force others to yield to their will. There is little contrition or guilt associated with their destructive acts, and the children usually take the attitude that people or objects on which they vent their rage are worthy of its consequences. Retaliatory measures have little deterrent influence and actually may incite the children to further bouts of aggression.

In treating children showing this form of aggression, a permissive environment is worse than useless. This is because a sympathetic tolerance of the children's rage plays into the children's contemptuous attitudes toward authority. Actually, the children themselves see no necessity for change, and a permissive atmosphere merely perpetuates aggressive strivings.

The ideal objective in these children is to build up a superego capable of exercising control of their inner impulses. Much as growing infants develop a conscience from

external restraints and prohibitions, so the children with diminutive superegos need discipline to nourish this impoverished portion of their personality. A kindly but firm expression of disapproval, and even irritation in response to destructive behavior, are much more rational approaches than its sanction or tolerance. The children must be taught that there are limits to their conduct beyond which they cannot go, that they have responsibilities for their daily acts that they must face, that definite things are expected of them, and that they have to live up to these expectations. When, in the therapeutic setting, limits to the children's conduct are first established, the children are apt to react violently; but as firm discipline continues, they will themselves discover that they are much more comfortable knowing that there are boundaries beyond which they cannot go. This is not to say that they yield themselves readily to such circumscription of their freedom. The usual reaction is to engage in a prolonged struggle with the therapists to break down the limits imposed on behavior.

The therapeutic situation differs from any previous atmosphere because the children soon begin to feel in it a warmth and expectation such as they have never before experienced. Indeed, while in the realistic world their impulses have brought them a measure of gratification they have also isolated them from people. They gradually begin to understand that therapists are adults who are not threatened by their aggression and do not yield to it or withdraw love even in the face of the most provoking tantrum.

As the children continue therapy, affection for the therapist gradually increases. Eventually, the children seem to go through a stage in development similar to that of the normal evolution of the conscience, namely, they feel it essential to win the therapists' approval and love. Whereas punishment and threats of abandonment have had little influence on the children's aggression, the fear of losing the approval of the only adults who have become significant to them has an extremely potent effect on the ability to inhibit rage. Needless to say, the process during which the children reintegrate themselves with authority, in which they identify themselves with loving adults and seek to win the latter's love and approval, is a long and tedious one. But the conscience, even in normal children, never develops precipitously; rather it extends over a period of years. One must

not get too discouraged if the youthful patients have temporary setbacks in relationships with authority, including therapists.

There is another type of aggression in the form of a power striving that resembles the aggression in children with an undeveloped superego, but it has an entirely different dynamic significance and calls for a radically different kind of approach. The superego, instead of being diminutive, is hypertrophied and takes on a terrifying and punitive aspect. The image of authority is that of a fearful and destructive force that can overpower and mutilate the children if they yield to its control. The way that the children cope with their helplessness is by overwhelming others with their power drive and aggression.

The object in therapy here is not so much to reinforce and solidify the superego, but rather to undermine it and replace it with one that does not threaten the children for the exercise of their impulses or functions. It is consequently necessary to tolerate aggression as much as is possible within reasonable limits of safety and decorum. Unlike the case of the first type of aggression, a permissive environment is essential. The permissive atmosphere at first often incites power-driven children to exaggerated acts of aggression. These seem to be defensive techniques by such children to avoid yielding their vigilance against authority.

Power-driven children often have difficulty in expressing softness, love, or tenderness. These emotions conflict with their self-ideals, and this is especially the case in children reared in environments where toughness and strength are the only admirable qualities in life. During therapy in a permissive situation, such children gradually begin to let down their guard. One sees them working cautiously with creative materials, and there often emerges from deep within the children a great deal of esthetic feeling that has been buried previously under a crust of hardness. The amount of anxiety that accompanies the expression of tender emotions is amazing. As the attitude toward authority gradually undergoes a change, the children usually find it more permissible to enjoy softer impulses. In a hospital ward, for example, many children who have been egocentric and destructive may be seen, after a while, making active attempts to help the crippled and defenseless

children in dressing, in their habit training, and in other routines. During the period when I was in charge of a boys' ward in a large mental hospital that housed violent and intractable boys who had not been able to get along in any other setting, I noticed this phenomenon repeatedly.

Another form of aggression frequently encountered is that in dependent children, who cling to the therapist or to other children in a submissive and ingratiating way. The aggression is stimulated by a feeling in the children that they have not received a sufficient amount of attention or love. The demands of dependent children are often so inordinate that it is impossible to live up to their expectations. There is involved an element of magical wish fulfillment, and rage occurs when wishes are not automatically granted. There is another important reason for aggression in the dependent child, and this emerges from their conviction that independence is being crushed by the people upon whom they lean. As long as dependency remains the keynote of living, assertiveness, activity, and creative self-fulfillment are constantly subdued. Great hostility may be underneath the outer core of submissiveness and ingratiation, and the children may regard the adults who care for them as overpowering beings who prevent them from attaining to self-sufficiency. This is one reason why aggression is precipitated without any apparent cause in those children who receive unlimited privileges and favors. It is essential for personnel who deal with children to understand this, because the eagerness of adults to overprotect dependent children may actually rob the children of the necessity of participating actively in their own growth.

Dependent children may burn up their energy cajoling or forcing others to carry them, because they feel too helpless to accomplish things through their own efforts. Therefore, a program must be instituted in which the children learn to accept responsibility for daily routines of living. Self-growth is attained primarily through achievement. It is understandable that the children will exhibit episodes of aggression when they sense that others insist that they stand on their own feet. It is important not to yield to the children's aggression when it is obvious that the children are trying to force the therapist to care for them.

Finally, it is necessary to consider the aggression exhibited by shy and detached children. Such children are usually referred to a clinic or to a hospital because of neurotic symptomatology, psychosomatic complaints, or severe psychoses. Aggression, here, is at first not expressed, and the outward behavior of the children is usually of a compliant and innocuous nature. Detached children are threatened constantly by life and by people. They maintain their safety either by submitting to others or by building a defensive chasm that separates them from the world. In individual play therapy they will sit quietly awaiting instructions with little show of spontaneity. In a group of other children they will isolate themselves and play alone. They possess an enlarged and punishing superego as well as a great undermining of self-esteem. Beneath the shell of compliance are great quantities of hostility that they fear expressing openly. The object in treatment is to get them to mingle intimately with other children, to engage in competitive activities freely, and to express their aggression without counteraggression on the part of surrounding adults. This necessitates an extremely permissive environment.

Detached children are driven by a spontaneous force to assert themselves with other children and with adults, but their efforts in a normal environment are usually frustrated. In the permissive environment of the clinic or hospital these children gradually experiment with self-expressiveness. In play therapy they may reach a point where they break through their reserve and begin working with pliable materials that they can manipulate or destroy. Later on, they may begin to penetrate from the periphery of the group to its center, participating in activities that bring them into contact with others.

As the children realize that they will not be hurt in closer relationships with others, they may engage gradually in mild competitive activities. Later, they may actually take a stand in life, defending their own rights and demands. At this point a tremendous amount of aggression is released, and they may become very destructive or assaultive. The aggression frequently is in the nature of a test to provoke adults around them into acts of retaliation in order to prove to themselves that their previous concepts of the world as menacing were justified. Furthermore, as the permissive environment begins eating away at their repressive images of authority, they may begin experiencing feelings of love

toward the therapist. They may become so overwhelmed with terror out of fear of getting close to anyone they may direct their aggression at the therapist with little external provocation. Therefore, some tolerance of the children's aggression is therapeutically indicated.

Aggressive acting-out children have been helped by behavioral reinforcement programs. Rewarding desired behaviors with complete ignoring of unacceptable behavior has resulted in significant improvement. Working with parents and teachers to educate them regarding the meaning of the disturbed behavior is indispensable as a way of helping the children retain their gains. If behavior therapy does not help the problem, a program of psychotherapy (which may be a long-term one) with the children and parents will be required.

The Hyperkinetic Child (Attention-Deficit Hyperactivity Disorder (DSM-III-R Code 314.01)

Whenever therapists encounter an aggressively hyperkinetic child, it is important to rule out organic syndromes that may manifest themselves purely as a behavior disorder (Wender, P, 1971). Symptoms of aggression, frustration intolerance, hyperactivity, and disturbed behavior occurring prior to 6 years and even 10 years of age may be a consequence of damage to the brain brought about by such etiological factors as a high forceps delivery, severe infantile infectious illness (e.g., whooping cough, measles), and frequent spells of high fever without apparent cause (Levy, S, 1966). Before making a diagnosis, however, it will be necessary to rule out ordinary physiologic hyperactivity, reactive and neurotic behavior disorders, childhood schizophrenia, and mental retardation. Childhood depression also may mask itself in hyperactive and psychosomatic reactions (headache, abdominal pain). A rule of thumb has been applied to the effect that if children do not have enough control over themselves to sit still while watching their favorite television programs, an organic brain problem should be suspected. In true hyperactivity of organic origin there is a limited attention and concentration span, emotional lability along with impulsiveness, an inability to delay gratification, and poor frustration tolerance. Minor neurological signs and an abnormal electroencephalogram

may be present. Often a learning disability is the reason children are referred for treatment. Because of sadistic, uncontrollable behavior, the children may be ostracized by other children and may be excluded from school. This undermines self-esteem and sponsors paranoidal ideas and more violent behavior.

Therapy is difficult and prolonged and is best administered by child therapists, preferably those who have had experience with hyperactive children. Work with both children and parents is essential. The latter must be counseled and educated regarding the nature of the problem and the need to refrain from applying the labels of "good" and "bad" to the children. It is often difficult for parents to accept the diagnosis of organicity and to control their desperate fears and guilt feelings. The cooperation of a neurologist may be helpful. Tutoring for special learning difficulties may be essential, as may exercise programs to improve motor skills. A comprehensive treatment approach is thus best. Feighner and Feighner (1974) describe one such program consisting of a complete evaluation of the child, pharmacotherapy, behavior modification, curriculum counseling, training for parents and teachers, parent-child interaction videotaping, and feedback sessions while coordinating the treatment of the children with the family.

Drug therapy is usually symptomatically effective, the object being to stimulate the braking mechanisms of the brain to inhibit the motor overactivity. The drug that is most popular is methylphenidate (Ritalin), which is used in children over six years of age. Before breakfast and before lunch, 5 mg is given, gradually increasing by increments of 5 to 10 mg weekly up to a total of 60 mg if necessary. Usually 20 to 40 mg will be effective. If there is no improvement in one month, the drug should be discontinued. Other drugs that may be employed are the amphetamines. Dextroamphetamine (Dexedrine) may be given to children over three years of age as tablets or elixir. In children of 3 to 5 years, 2.5 mg is given daily, increased at weekly intervals by 2.5 mg until an optimal response occurs. In children over six years of age, 5 mg is given once or twice daily, raised weekly in increments of 5 mg until the best response is obtained, which is usually below 40 mg. Pemoline (Cylert) is an alternative drug and is given in dosages of 37.5-112.5 mg. All of these medications may be reduced or discontinued over weekends or during school

vacations. After the patients reach puberty, the drugs may not be needed at all. Hyperactive children in a classroom setting may be helped by the stimulant drugs Dexedrine and Ritalin to control their behavior by improving attention and completion of classroom assignments. Behavior therapy is also effective in reducing fighting and quarrelsomeness, improving frustration tolerance, and controlling temper outbursts. Much of the behavior therapy can be done at home, the parents being trained in operant-reinforcement techniques. Target behaviors to be controlled are listed, their frequency and provocative stimuli charted, and contingent positive reinforcements of appropriate conduct and negative reinforcements of misbehaviors consistently applied (Safer and Allen, 1976). Self-instructional, self-control training may also be possible in some children (Meichenbaum and Goodman, 1971).

Coordinately, other adjunctive modalities previously mentioned should be employed. Parent groups meeting in six weekly sessions have proven beneficial. Reading materials should be assigned to parents, such as the article by M. A. Stewart (1970). Teacher groups also have their use. Play therapy, contact with teachers, videotape sessions with the parents to play back interactions, remedial tutoring, and special exercises are other useful techniques.

In the medium of their relationship with their therapists, the children are encouraged to explore their feelings and attitudes. The poor impulse control and the motor incoordination of the children during treatment may stir up countertransference reactions in the therapist, at home in the parents, and at school in the teachers. A passive neutral attitude will create insecurity in the children. On the other hand, counteraggression will add fuel to the fire. A firm, kindly attitude is best. Should the children become violent, they should physically be removed from the disturbing situation so as not to perpetuate their behavior. Slowly, with proper management, mastery of behavior may be established, and there will be an ability to cope with increasingly challenging situations.

Hyperactive reactions may occur in situations other than in minimal brain

dysfunction and present the same symptoms as the latter—for example, in children with unsocialized aggressive behavior, anxiety disorder, sociopathic personality disorder, and psychosis. In such cases stimulant drugs may not be effective or may actually exaggerate the symptoms. Appropriate diagnosis is essential in treatment planning. Individual, family, group, and behavioral approaches are productively employed in these conditions, but stimulant medications are definitely contraindicated.

Residual-attention-deficit disorder in adults, characterized by emotional lability, restlessness, and impulsive outbursts that are not due to schizotypal or borderline personality disorders also respond to methylphenidate (Ritalin) and pemoline (Cylert) (Wender et al., 1985).

Juvenile Delinquency (Childhood or Adolescent Antisocial Behavior, DSM-III-R Code Y 71.0)

A famous writer presented the problem of juvenile delinquency in these words: "Our youth now love luxury. They have bad manners, contempt for authority, disrespect for older people. Children nowadays are tyrants. They no longer rise when their elders enter the room. They contradict their parents, chatter before company, gobble their food, and tyrannize their teachers." These are the words of Socrates, written in the fifth century B.C. In the thousands of years that have passed since Socrates, we are not only still grappling with how to control youth's defiance of convention, but also with serious infractions of law that are represented by offenses of violence, stealing, fire setting, vandalism, dangerous drug use, rape, and other crimes.

Delinquency among children who belong to asocial gangs is common in economically depressed areas. Here a cultural-transmission theory has been posited by such authorities as Tannenbaum (1938) and Topping (1943). Other authorities insist that the quality of family life is what is of greater etiological significance. Susceptible children are those from families in which there is no cohesiveness, no clear-cut authoritative model with which to identify, and little or no constructive supervision and discipline (Glueck and Glueck, 1950). Delinquent groups are powered by forces in opposition to the social world. (Cohen, AK, 1955). Collective solutions are evolved that, though antisocial, gain mutual support

and identification. Work with delinquents, therefore, must take into account both the disruptive family organization and the deprived environment from which they come. Therapeutic directions are milieu oriented. These focus on a broad community approach, enlisting the aid of religious leaders, social agencies, and police groups. Economic help, counseling, and casework for the delinquents' families and rehabilitative group work with the delinquents themselves are given within the strictures of the available personnel and budgetary restraints of the involved community. Individual psychotherapy generally fails unless comprehensive environmental approaches are employed. A peer group can be the treatment of choice. Nevertheless, the need for individual therapy with a therapist who can act as a role model should not be minimized. Therapists directing adolescent groups require training and experience in working with adolescents.

Delinquency does not confine itself to children from deprived and lower socioeconomic families. It affects upper- and middle-class groups as well. A. M. Johnson and S. A. Szurek (1952) have shown that the inability of parents to set limits due to poorly integrated impulses and "superego lacunae" (Johnson, AM, 1949), and the goading of children to act out unconscious perverse and hostile parental strivings that were unresolved in the parents' own relationships with parental figures, produced delinquent behavior. "It is possible, in every case adequately studied, to trace the specific conscience defect in the child to a mirror image of similar type and emotional charge in the parent" (Johnson AM, 1959). A specific superego defect may thus be created in the children that reflects the parental flaw. Szurek (1942) insists that many cases of psychopathic personality are products of unconsciously determined promptings from both mothers and fathers that encourage amoral and antisocial behavior. The child "victims" chosen are the recipients of subtle insinuations and suggestions that may often, even though the parents are not aware of their presence or implications, be detected by a good clinician during an interview. Indeed, psychotherapy with delinquents may have to be focused on the parents rather than the children since they will tend to undermine the children's treatment should the children stop responding to their messages.

Modifications of technique are obviously very much in order in working with a

family neurosis, and this was years ago pointed out by Aichhorn (1936). Aichhorn's methods, employed during the residential treatment of delinquent adolescents, inspired the founding of special residential units organized around providing emotionally corrective experiences (Brady S, 1963; Redl, 1959). Bettelheim (1950), E. Glover (1956), Noshpitz (1957), Szurek (1949), and Szurek, Johnson, and Falstein (1942), among others, have introduced methods that have proven of value in dealing with the problems of delinquent children and their families.

The treatment of delinquency is eminently unsuccessful, however, no matter what strategies are utilized. This is in large part due to the effect on the people handling the children. The children's expectation of rejection and punishment promote rampancy and rowdyism, to which the human targets of this turbulence respond with retreat, outrage, and often brutality. The self-fulfilling prophecy of the children that they will be hurt creates a feeling of hopelessness and distrust. They move from one situation to another with the same result. Ultimately, the children may be placed in a *residential treatment unit* organized around the philosophy of a structured therapeutic community (Alt, 1960; Balbernie, 1966, Noshpitz, 1975). Various orientations exist among different centers. Thus, a center may operate as a school, casework agency, or hospital with appropriate personnel such as teachers, caseworkers, nurses, and physicians. Psychotherapy of a group and behavioral nature is usually available in such units depending on the philosophies and skills of the therapists.

Residential centers have increased in numbers, but unfortunately not in quality. An exception is the unit in England known as Finchen Manor described by Langdell (1967), which was organized for selected multiproblem families. An effective unit requires a special design. *(Roche Report,* 1966). Most present-day units are not well organized or operated effectively for ideal management of delinquent children. Moreover, residency is too short term, less than the minimum of two years usually required for any change to register. In addition, there is a lack of coordinated services (provision for educational and vocational opportunities, outlets for aggression, need for privacy, and an absence of well-trained staff and other personnel who are both caring and capable of maintaining

adequate control. Too often the aggression of the children leads to rememdies of isolation, punishment, and drug treatment, which, while temporarily effective, do not alter the existing difficulty. A pertinent problem in some settings is the insistence in retaining the medical model in the institution, which is an inappropriate one for children (Linton, 1973). Here the responsible psychiatrists, clinical psychologists, and psychiatric caseworkers are not in as intimate contact with the children as would be childcare workers, teachers, and other people who can be intimately related to the children's daily life and behavior. A reeducational model that involves total milieu planning is more appropriate than a medical model. It has been recommended that a different type of professional is needed for residential units, one who has received comprehensive training designed for the tasks that he or she will pursue. In France, Denmark, and the Netherlands, for example, a new discipline is evolving concerned with mediating child problems ("education orthopedagogue").

A great deal of the failure in treatment is also due to the paucity of aftercare services once the children leave the residential unit. Little continuity usually exists between the residential center and the environment to which the children are returned, which continues to impose on them the original traumas and deprivations. *Intensive home therapy* by medical and non-medical personnel has been employed with some success (Dornberg et al., 1968). Therapist activities will vary from guidance and support to formal marital or family therapy depending on the needs of the family. The home therapists usually work under the supervision of the child therapists who are in charge of the program. Among the conditions for which home therapy is especially indicated are the presence of a psychotic parent at home, refusal of children or parents to accept office treatment, the dealing with double and multiple binds, adverse reactions of a mother to a baby or her pregnancy, and projective mechanisms in parents that activate the children's disturbed behavior.

A *day care center* constitutes a useful modality for some children, particularly those who manifest such problems as severe withdrawal, lack of object relationships, impulse control, and blocked language use (Westman, 1979). Reinforcements are provided for

constructive conduct (North, 1967). Day-care treatment often avoids prolonged hospitalization, providing the children with a therapeutic environment for many hours a week while remaining a part of their families. A disadvantage is the low therapist-to-child ratio, which is ideally one to one. One way of meeting this dilemma is to train ancillary workers, some of whom can be recruited as part of a corps of volunteers.

Learning and Reading Developmental Disorders

A host of academic skill disorders exist under the umbrella of specific developmental disorders that have distinctive DSM-III-R Codes. These include *developmental arithmetic disorders (315.10), developmental expressive writing disorders (315.80), developmental reading disorder (315.00), developmental expressive language disorder (315.31), developmental receptive language disorder (315.31), and developmental articulation disorder (315.39).*

Learning and reading disabilities are the commonest single immediate causes for the referral of children to guidance clinics (Rabinovitch, 1959, Silver, 1975). In prescribing appropriate treatment, psychological tests are in order to ascertain the general intelligence and to assess the potential, achievement level, developmental readiness, and degree of emotional disturbance; neurological examinations are recommended to rule out brain injury and aphasic disorders. Generally there is a close relationship between learning disabilities and emotional disturbance, but the presence of emotional illness itself does not presuppose that there will be failure in school work. A psychological inability to learn or to read is often a symptom that serves a specific purpose, such as to punish the parents, to defy authority, to refuse to grow up, to avoid competition, or to punish oneself. Anxiety that emerges from the children's school failures adds to their inability to attend and to concentrate on work. Even when the problem is organically determined, as when there is damage to the associational patterns controlling visual-motor functioning, such anxiety may act as a prime disorganizing factor. The treatment of learning and reading difficulties will depend upon their cause. Problems rooted in organic brain disorders will require retraining, using visual, auditory, and kinesthetic approaches (Kephart, 1955;

Strauss, AA and Lehtinen, 1947; Strauss, AA and Vernon, 1957). Disabilities provoked by emotional factors will call for psychotherapy, aided, if necessary, by special tutoring and remedial reading.

School Phobias(Separation-Anxiety Disorder, DSM-III-R Code 309.21)

A school phobia is really a family problem and usually involves an immature, indulgent, or highly controlling mother who has been unwilling to separate herself from the child. A prephobic conditioning occurs prior to the school years. Children who have been reared with the idea that the world is an unsafe place, and that a mother is necessary to protect them and make things safe, are particularly vulnerable when thrust into the strange environment of a school. Often the mothers are unaware of their own dependent needs and of their ambivalence toward their own mothers, which they are projecting onto the children.

Once realistic causes for fear have been ruled out, such as stressful situations within the school itself, juvenile terrorists who threaten or attack the child, a disturbed teacher, identifiable handicaps such as reading disabilities and other cognitive dysfunctions, or childhood depression, treatment may be started. The first step is to insist that the parents be firm with the children to the effect that school must be attended. Sometimes the children will have developed a host of somatic complaints (headaches, "stomach trouble," intestinal cramps) to reinforce the stay-at-home position. After a physical examination has revealed no organic problem, the parents will have to handle their fear that they will damage their children by insisting on school attendance. They must be persuaded of the fact that the longer the children stay away from class the more difficult it will be for the children to return. The school personnel may have to be brought into treatment planning to bolster the parents' resolve that the children must go to school even if the children complain and act ill in class.

Some family therapy with the parents is usually necessary to apprise them of their own involvement in the situation (in terms of their personal history and problems) and to give them support in the handling of the children's recalcitrance. The parents have to

bring the children to school at first, and therapists should be available on the telephone to render assistance to these flagging parents who are wilting under the children's intransigence. Occasionally, behavioral desensitization is helpful as an adjunct (Eysenck, 1960a).

If the children's fear is associated with children who terrorize or threaten, this will have to be handled with the school authorities. Should the problem be the children's classroom teachers who are disturbed, the children may do better in another class. Coordinately, psychotherapy may be needed for the children, as well as the parents, and sometimes they may all be seen together. If the children have a serious emotional problem, such as depression, intensive therapy may be required and perhaps some antidepressant medications. The parents may have to continue in long-term therapy after the children's symptoms have come under control to work through their own dependency problems.

Psychotic Children

Apart from *autistic* disorder (DSM-III-R Code 299.00) no generally recognized subtypes are classified in the existent group of "pervasive developmental disorders". In the past they have been loosely lumped in the categories of Atypical Development, Symbiotic Psychosis, Childhood Schizophrenia, and Childhood Psychosis.

The treatment of psychotic children is organized around a design that takes into consideration "the severity of the psychological impairment, the creation of a therapeutic relationship, the formulation of realistic expectations, and the maintenance of therapeutic agility" (Shafii, 1979). Psychoanalytic approaches are of greater use in exploring the dynamics than in contributing to practical management. This will necessitate flexible combinations of pharmacology, behavioral techniques, family therapy, and milieu therapy. Drug treatment has many drawbacks but in active psychotic states it may be essential. What has to be kept in mind is that children require relatively higher doses of psychoactive medication in relation to their weight than do adults and adolescents, that low dosage exposes children to risk with little chance of benefit, and that medications may

result in unforeseeable long-term complications. When deemed necessary, neuroleptics such as chlorpromazine (Thorazine) and haloperidol (Haldol) may be employed with overactive children. Haldol is especially valuable in children with tics and Tourette's disease. Operant conditioning techniques may be indispensable in psychotic children, and especially with autistic children, in whom they may establish some measure of social conformity and reality-based behavior.

Residential treatment of children and adolescents is sometimes essential in youngsters who are out of control and who constitute a danger to themselves or others (Wolberg, LR, 1959). Psychotic children particularly will need hospitalization (Gralnick, 1966) as may severe cases of anaclitic depression (Spitz, RA, 1946), certain delinquencies (Aichhorn, 1936), and severe psychosomatic and organic conditions (Rapaport, HG, 1957).

Childhood schizophrenia (Bender, 1947; Despert, 1948), early infantile autism (Kanner, 1959), and the "symbiotic psychosis syndrome" (Mahler, 1952) are characterized by profound disturbances of behavior on every level of functioning—physiological, psychological, and interpersonal. Withdrawal tendencies and problems in communication make treatment extremely difficult. Therapy aims at establishing a better integrity of body image, a sense of entity and identity, a consolidation of object relationships, and a restoration of defective developmental ego functions (Mahler et al., 1959). Therapists provide for the patients auxiliary egos and encourage a living through of those developmental phases that were thwarted in the patients' actual growth experience. An interesting account of such a working-through with a schizophrenic in an intensive relationship is described by Sechehaye (1956). Due to the primary process nature of the children's behavior and communication, it may be difficult to comprehend the meaning of their verbalizations and actions. Here therapists may have to serve an educational function.

Emergencies

Sometimes emergencies arise in children that the psychotherapist may be called on to resolve. Usually they are the climax of a long preceding period of maladjustment to

which the parents may have been oblivious or indifferent. They are differentiated from the normal developmental crises that call for minimal interventions since they may be the means to conflict resolution. Acute disturbances in adolescents may occur as a result of identity crises. Here a quiet youngster may suddenly become aggressive and destructive. Often we find this among adolescents who have been forced to be "good." As they enter into the turmoil of adolescence they break through their passivity by outbursts of aggressiveness. On the other hand, aggressive and violent behavior, as toward people, may be the result of a psychosis, which will call for entirely different management. To put a youngster with an identity crisis into a psychiatric institution as a result of the crisis will only contribute to the identity confusion.

True emergencies will call for accurate assessment of underlying causes. A detailed history of the children's development and interviews with the parents and perhaps teachers and other significant adults is in order. The therapeutic plan will then be discussed with these people. The plan may follow a crisis interventional model.

One of the most common emergencies is *running away* from home (Jenkins RL, 1973). It is estimated that there are 600,000 to 1 million runaway children yearly in the United States. Often the elopement is to communes of peers who encourage drug and promiscuous sexual indulgence. Some runaways are normal children escaping from a situation of intolerable stress or complete rejection. Some seek constructively to effectuate separation-individuation, which is impossible in a home that continues to infantilize them.

The effect of this gesture may be disturbing to the families, but it calls for an examination of their role in blocking the children's personality growth. Since over 90 percent of cult members leave the group within two years, patience, understanding, and resumption of communication with the children are essential.

Some schizophrenic children resort to disorganized runaway tendencies and may be accepted in a group that seeks to protect them, though they in fact offer little. Commonly, running away is a delinquent response, all the more dangerous since the children may be

attracted to delinquent gangs that wreak havoc in the community. Diagnosis is important since *why* the children run away will determine the kind of treatment that must be instituted. In all runaway problems, work with the families as well as the children is mandatory.

Another emergency is a *suicidal attempt,* which most frequently occurs in teenagers between 15 to 19 years of age. These are often impulsive in nature, precipitated by disproportionately minor provocative incidents that, for the youths, are interpreted as of major importance. What is behind the attempt (conflict over sexual impulses, self-punishment for forbidden impulses or thoughts, projected aggression against a parent or sibling, frustrated dependency, persecutory delusions, toxic drug reaction, hopelessness, depression) will require persistent probing. Whether or not hospitalization will be needed must be assessed. At any rate, environmental rearrangements may be required along with therapy for the children and at least counseling for the parents.

The easy accessibility of *drugs* during period of school attendance or during leisure hours has, particularly in adolescents, produced emergencies brought on both by the discovery of the indulgence by parents and by an overdose of the intoxicating substance. Although casual temporary experimentation with such drugs as marijuana may not be too significant, substances such as amphetamines, barbiturates, codeine, and heroin can lead to serious emergencies and addiction. The use of mind-expanding drugs, such as LSD, substances in glue (glue sniffing), and gasoline is also fraught with dangerous consequences. Usually, combinations of drugs have been taken, and their exact identification is difficult when the children are admitted to a detoxification center, since they themselves usually will not know what they have imbibed. Behind the taking of such destructive drugs may be efforts to escape from depression, boredom, stresses of separation-individuation, and impulses of aggression. Often the only signs that these youngsters exhibit are anxiety, excitement, and overactivity. The temptation for clinicians is immediately to use sedatives. Without knowing whether or not drugs have been taken, and their nature, it is dangerous to contribute to the drug toxicity by adding other substances to an already overloaded nervous system. In recent years there has been a

shift from hallucinogenic and tranquilizing drugs to alcohol, and it may be anticipated that cases of acute alcoholic toxicity will be increasing among adolescents. After successful detoxification, a psychotherapeutic program, often prolonged, will be required.

In *car crash cases* where one youngster is killed and another survives with minor injuries, it is often helpful in the emergency room for the doctor or nurse to communicate to the survivor that it is common in such cases to feel guilty and, if this happens, to recognize that it will eventually be gotten over. Allowing the youth to verbalize feelings while listening sympathetically may be important. Sedatives should not be offered since refuge may henceforth be found in drugs. The parents should also be informed regarding the turmoil the child is likely to experience and to anticipate it.

In the event of *death of a parent* the surviving parent should be encouraged to talk about the departed member openly with the children and not to cover the matter up by denying the validity of the pain that the children are bound to suffer. A great area of prevention can be instituted in the emergency room when an adult with a coronary attack is brought dead on arrival. The surviving parent may have no opportunity to see any other professional people than the personnel in the emergency room, who should try to explain how best to guide the children through their grief. A few minutes spent with the parent explaining the need not to cover matters over with a pall of silence may prevent a great deal of misery, particularly among adolescents.

Other emergencies include school phobias, anorexia nervosa, parental beating of the child (the battered child), sexual and other violent assaults, and deaths in the family. These will call for special handling and perhaps extended treatment (Morrison, 1975).

In the U.S., where the divorce rate is almost 50 percent and father absence (due to separation, abandonment, or divorce) is approaching a national epidemic, the breakup of the family may be considered another crisis in child development. Recent studies (Mallerstein and Kelly, 1982) indicate that the effects of divorce are persistent and pervasive for children as well as their parents, with stress, anxiety, and depression lasting as long as five years after the event. Particularly vulnerable are children under six years of

age, when the presence of the father during the Oedipal phase plays a critical role in healthy development. Both mothers and children need special support to weather this crisis. The stress provoked by separation and divorce may need to be dealt with through special counseling, crisis intervention, divorce mediation, and psychotherapy.

PSYCHOTHERAPY IN OLD AGE

As people mature they are confronted with ravages of aging that make a mockery of the advertised joys of the golden years. Eyes, ears, teeth, joints, heart, and other organs gradually deteriorate and physical energies slowly give way. These burdens are increased by the death of loved ones, as well as the detachment of children who insist on leading overly independent lives. Loss of the great ego supports of job and professional position, along with disillusionment with the false promises of retirement, add to the strains of loneliness and devalued self-esteem. The elderly are subject to multiple personal losses due to their longevity (Goodstein, 1985). As medical advances add years to peoples' lives, diseases of aging (arthritis, cardiac ailments, kidney disease, arteriosclerosis, cataracts, cancer) and associated infirmities complicate the existence of the elderly person. But even more devastating are the ravages of fear and insecurity. Little wonder, then, that depression and growing old are so often inseparable.

Women experience such consequences of aging somewhat later than men do. They must, however, endure the disabling illnesses of their aging mates, whose enhanced dependency needs and importunate demands for attention may make them difficult to manage. For the spouse of a depressed, phobic, hypochondriacal, paranoidal, or mentally deteriorating partner, individual or group psychotherapy may be vital to the couple's welfare.

The loss of a mate through death or divorce during the elderly years is especially traumatic, and bereavement reactions not too uncommonly terminate in suicide. Therapeutic help is often focused on crisis intervention followed by continuing psychotherapy of a combined counseling and supportive nature. The ideal philosophy on which bereavement therapy should be based is that although, in the words of Nemiah

(1984), humans do "have a built-in-clock, and are programmed to a destiny to which we all must yield," a happy and fulfilling existence can still be enjoyed in the years remaining.

The assumption that the elderly cannot benefit by psychotherapy, that their dulled cognition and blunted memory are permanently gone, has been proven false (Cath, 1982). Therapy will require an empathic immersion by therapists into the relationship and the ability to deal with countertransference that often involves the therapists' own terror of growing old. There is resistance also on the part of therapists to being viewed as objects of idealized identification.

The employment of environmental support systems is vital as an adjunct to psychiatry. Unfortunately, our culture fails to provide adequate roles for the many old people who retire or who, because of their age, are pushed aside by younger and more energetic citizens. In making efforts at facilitating adjustment, counseling and casework methods may help resolve problems of housing, finances, health, occupation, socialization, and recreation. Proper information and guidance may be all that an older person requires to continue to maintain self-respect and to shore up feelings of self-sufficiency. In many cases more will be needed. Community health centers for the aged are increasingly being demanded that consider the common problems of medical care, housing, transportation, finances, nutrition, job training, recreation, and hospitalization. Preparation for retirement is urgent, and some enlightened industrial groups have taken responsibility for development of educational and social-action programs to ready their executives and employees for termination of their jobs. The economic burden of medical care has for many been lightened by Medicare, but the rising costs of delivery of health-care services are creating many budgetary problems. The economic, legislative, and administrative bodies of government are accordingly constantly being reminded of the growing problems of dealing with the aged.

A shift in living arrangements alone may eliminate a host of difficulties. Any changes must obviously take into account both the person's desire to live in familiar surroundings and the practical needs of one's situation. Dwelling units especially designed for the

elderly have become increasingly popular, and retirement villages containing medical, recreational, and rehabilitative services are available.

Many aged people are needlessly condemned to the wretchedness of nursing homes or the segregation of poorly run retirement communities. In some cases private-home placement may be a more suitable solution, supplemented with the facilities of community centers that have programs for the aged. On the other hand, if individuals are unable to care for themselves, a hospital or old-age nursing or convalescent home may be what is required.

Finding suitable work for an active older person may restore vitality, interest, and self-esteem. It is totally unrealistic to assume that leisure alone can bring contentment to those who have been occupied productively all of their lives. Nor is it sensible for the community to turn people out to pasture who have acquired skills and knowledge that cannot easily be duplicated.

The problems of retirement make preretirement counseling an important preventive measure. New adaptations will be required. Spouses should be prepared for irritation at being with each other full time. Role playing is helpful in preparing the retirees for what is inevitable—time on their hands, a feeling that they are out of the mainstream of life and "has beens." A search for new meanings to existence will be needed.

Education in an aging society is an important aspect of a comprehensive program. Properly implemented, it supplies information to the older person regarding the physical changes in the body and new emotional requirements that take place with ongoing years. It clarifies confusion about sexuality. It furnishes guidelines for continued creativity and vocational usefulness. It encourages enjoyment of positive assets and minimization of liabilities. Programs of adult education to prepare individuals for aging and to help develop new leisure-time interests must include instruction for people working with older people about various phases of geriatrics. The booklet, *Planning for the Later Years,* issued by the U.S. Department of Health, Education and Welfare (Washington, D.C., U.S.

Government Printing Office) contains some excellent suggestions for health maintenance, nutrition, emotional adjustment, housing and living arrangements, retirement income, work, and legal problems. It may be profitably read by the aging person. Other reading materials for the aged or their relatives are given elsewhere in this volume (see the section on old age in the Addenda, [Selected Texts]). For professional persons the writings of Weinberg (1975), Butler and Lewis (1973), Rossman (1971), and Simon and Epstein (1968) and the publications *Medical World News, Geriatrics* (1973) and *Psychiatric Annals,* (vol. 2, no. 10 and 11, 1972) are recommended.

Among the most useful measures are the development of appropriate recreational facilities in churches, schools, community centers, and the various old-age institutions that encourage hobbies, handicrafts, dancing, lectures, and discussions. Social participation increases morale and counteracts withdrawal and deterioration.

The above measures designed to meet the diversified needs of older people may avert or delay the development of untoward senile reactions. The most common of these are confusional syndromes that come on suddenly, particularly when individuals are moved to unfamiliar surroundings or subjected to situations to which they cannot adjust. Old people have a tendency to prowl around at night and during the day to wander away from home. Providing them with activities to occupy their minds tends to keep them more focused on reality.

Perhaps the most difficult problem in providing a solution to the elderly in family settings is the inability of children to accept the inevitable change in role that will be demanded of them as their parents become more helpless and dependent. The psychotherapists consulted by the families will usually have to involve the entire families in the treatment plan, helping children to face the physical and emotional changes in their parents, and educating them about the need for becoming substitute parents for their own parents in response to the latter's developing dependency needs. What the aged person often requires is "a surrogate-protector in much the same way that he approached a parent as a child. . . . It is possible for the therapist to use this delegated authority to foster

and maintain an illusion that the patient has found a protector and one who will satisfy many psychological needs" (Goldfarb Al, 1964).

Mental disorders in elderly people are characterized by a superimposition of psychological reactions (usually depression and paranoidal projections) on an organic substrate. Assessment of the degree of organic involvement is essential in outlining an appropriate program of therapy. This will require clinical observation, laboratory tests, and an electroencephalogram. Once the degree of affective and organic components implicated is estimated, a comprehensive treatment plan includes physical care, rehabilitation, drugs, and psychotherapy. With good supervision the vast majority of unstable older people may be treated outside of a hospital. Geriatric day treatment is both therapeutic and cost effective (Roche Report (March 15, 1982). Transfer to a mental institution causes great anxiety and agitation and may shorten life. If home conditions are unsuitable or upsetting, institutionalization may be inevitable, and, if proper facilities can be found, the last years of life may be made tolerable if not enjoyable.

Depression is the most common symptom in the elderly. Frequently it is misdiagnosed as dementia, memory loss, or other presumed organic conditions, which disappear when the depression clears up. Depression in the elderly is accompanied by frequent somatic concerns, memory or cognitive defects, and occasionally, paranoidal ideas that may expand into delusions. The treatment of depression in old age differs in some respects from that in younger years (Charatan, 1975). Modest treatment goals are pointed toward symptom relief employing a directive, supportive approach with frequent brief sessions rather then infrequent long ones.

If drugs are needed, it must be remembered that elderly people are extraordinarily sensitive to psychotropic medications, which may produce untoward and sometimes dangerous side effects even with lowered dosage. Pressure to prescribe medications is brought to bear by relatives because of disturbing symptoms such as confusion, somatic complaints, insomnia, nocturnal wandering, behavior disturbance, and especially, depression. Adverse side effects are common especially when cardiovascular, kidney, and

other ailments exist, and when various drugs employed to control these ailments interact with the psychotropic substances. Yet psychotropics properly employed can be useful. For example, depression may be the basis of an elderly person's confusion, impaired memory, and personality change. A misdiagnosis of organic brain disease fosters hopelessness and "giving up" by the patient. Here antidepressants may be valuable, with selection of those drugs that produce a minimum of sedation and cardiotoxic and anticholinergic effects, such as trazodone (Desyrel) nortriptyline (Pamelor), desipramine (Norpramin), and monamine oxidase inhibitors (e.g., Nardil). Neuroleptics like thioridazine (Mellaril) or chlorpromazine (Thorazine) should be used with awareness of their anticholinergic side effects. If sedation must be avoided, haloperidol (Haldol) or fluphenazine (Prolixin) may be selected. The anticholinergic effects of antidepressants and antipsychotics (constipation, blurred vision, dry mouth, difficulty urinating) may be very annoying and can be minimized by choosing the least anticholinergic agents available. A good antianxiety drug is alprazolam (Xanax), which has a half-life of eight hours; it may also be used as a hypnotic and mild antidepressant. Oxazepam (Serax) and Lorazepam (Ativan) are preferred to diazepam (Valium). Other good hypnotics for elderly insomniacs are temazepam (Restoril) with a half-life of about nine hours and triazolam (Halcion), whose half-life is very short (3 to 4 hours). Temazepam has been shown to mix Well with other drugs used by the elderly. Since low blood pressure and ataxia, which lead to falls and disabling injuries and fractures, are often caused by psychotropic drugs, patients must be warned to take special precautions in footwear and walking. Absorption of drugs is delayed when taken with food. Medications should, therefore, be given on an empty stomach at least 30 to 60 minutes before retiring. In treating depression in the elderly, it should be kept in mind that depression can be produced or exaggerated by medications taken for cardiovascular disease, such as reserpine (Serpasil), methyldopa (Aldomet), and beta blockers, e.g., propranolol (Inderal). Substitutes for such medications may have to be found. Severe depressions may require electroconvulsive therapy (ECT) after a thorough physical examination, blood count, urinalysis, electrocardiogram, and x-ray of the chest and spine show no contravening abnormalities. A total of 8 to 10 biweekly treatments is best.

Insomnia may require chloral hydrate (Noctec), Dalmane, Restoril, or Halcion. Barbiturates should be given sparingly, if at all, and central analeptics should never be given in confusional states. There are many other substances in use whose virtues are mixed (Hollister, 1975). These include the cerebral dilators Pavabid, Cyclospasmol, Vasodilan, and Riniacol, the ergot alkaloids (Hydergine), and procaine (Gerovital), although the latter can produce a mild antidepressant effect. Small doses of stimulants such as Ritalin sometimes help fatigue and mild depression. Vitamin supplements are often used, but a balanced diet should eliminate the need for heavy vitamin intake.

The conditions requiring psychotherapy in geriatric patients include all of those in younger groups as well as syndromes arising with the deteriorative, metabolic and systemic disturbances of old age. Relationship and interpretative therapies are employed in combination as needed (Goldfarb Al, 1955, 1959; Meerloo, 1955). The question arises as to whether reconstructive changes in the elderly can be achieved through alteration of the basic character structure and development of new potentialities. Or must therapists be content with a holding operation, with symptom relief and better adaptation in areas of living in which the patients are failing, with at best a reorganization of attitudes and value? Elderly people with a basically good ego structure and in whom organic brain damage is minimal may, if sufficiently motivated, be brought to some reconstructive change (Yesarage and Karasu, 1982). Generally, however, significant alterations in character structure are not to be anticipated. Psychotherapy serves to alleviate the anxieties of aging individuals, providing a means for emotional catharsis, reassuring them about their physical condition, helping them deal with depression, grief, and the death of family members and friends, assuaging frustrated sexual feelings, correcting misinformation, managing problems of retirement and difficulties in living alone, mollifying paranoidal projections, and convincing them that their basic needs will be met because somebody cares. Chronically ill patients who live in fear of death appreciate friends and counselors. In psychotic states, psychotherapy may be coordinated with drug therapy even in those with brain damage (Hader, 1964). Short sessions (10 to 15 minutes weekly or bimonthly) may be all that is required. This usually suffices to support dependency needs and to give patients a feeling of being protected.

Group therapy and group discussions are ideally suited to the needs of elderly people, fostering group belongingness, reducing the sense of isolation, and enabling people to deal with feelings of separation and fears of loss and death (Cooper, 1984). The goals in group methods are to support existing personality strengths, inculcate knowledge of human behavior, expand tolerance and flexibility toward individual differences, accept a changing role in life, deal with personal prejudices, facilitate group cooperation, and promote better interpersonal relationships (Burnside, 1970; Goldfarb Al and Wolk, 1966; Klein WH et al., 1966).

One of the problems, however, is getting older people to break through their isolation and join a group. Often individuals will come to an outpatient clinic in search of help for somatic complaints and will resent being referred to a psychiatrist. A well-explained referral, however, will often be accepted, such as that physical problems and suffering always give rise to tensions that make it difficult or impossible for a physical problem to heal and that group therapy often will help resolve tensions and aid the healing process. Most patients experience great relief as a result of group therapy. This may ameliorate somatic complaints as well as mollify problems of living. Through group interactions the virtues of continuing work, sexual, and exercise activities are discussed and encouraged and social isolation is reduced. Many "organ deficits" vanish when personal life interests and social activities are restored (Levenson, 1982).

Psychotherapy was never designed to cure everybody. With present techniques, therapists are able to effectuate symptomatic improvement in almost all patients, behavioral changes in the majority, and complete cure in some. The fact that reconstructive alterations are possible is an encouraging sign, however, since it contradicts the commonly accepted adage that human nature cannot be changed. With continued empirical research the understanding of personality will undoubtedly be advanced, and with more clinical experience therapeutic methods should become enriched. In the meantime, therapists may follow the old Chinese proverb, "It is better to light one candle than to curse the darkness."

Failures in psychotherapy, apart from the employment of improper interventions, are generally the product of mismanagement of the therapeutic relationship. Most commonly, patients are pushed toward reconstructive goals that are beyond their competence and motivation. Also some may seek extensive personality change even though they are incapable of achieving more than symptom relief.

No matter how ambitiously therapists may pursue treatment, they are confronted with limitations in all patients in their potential for growth. Three kinds of patterns may be clinically observed. First, there are promptings so deeply imbedded in the personality matrix that they seem to pursue an autonomous course. No amount of insight or authoritative pressure seems capable of modifying their expression or lessening their force. These tendencies are rooted in conditionings sustained during early childhood, perhaps in the preverbal period before the individuals were able to conceptualize experiences. They may, if sufficiently intense, disorganize adult adjustment. For instance, separation from a mother for extended periods during infancy may sponsor profound feelings of distrust. Apathy, depression, pressing drives for oral gratification, suspicion regarding the motives of people, and a view of the world as menacing may survive in traits

that distort the most bountiful reality in later years. The ego, structured on an infirm basis, sustains disintegrative proclivities. In most people, however, symptomatic residues of early conditionings, though present, are not so pronounced. Minor as the symptoms are, they still defy change and energize maladjustment.

A second group of patternings develops somewhat later, which are remembered, at least in part, and can be verbalized. Serving spurious neurotic functions, they may in execution promote conflict, this group of patternings is subject to some control through willful inhibition once the individuals appreciate the nature and consequences of their inclinations. While these strivings may continue to press for expression, their mastery by patients becomes an important goal. Many of these strivings are rooted in needs and drives that, in promoting anxiety, are repressed. Their recognition, if the individuals are sufficiently motivated, may enable them to bring these forces under control and, in fortunate instances, to eliminate them completely.

For example, a girl whose assertiveness during the second and third years of life was inhibited by parents wedded to the doctrine that children are to be seen and not heard may discover that when she mobilizes sufficient aggression and rage she can get her own way. "Hell-raising" then becomes a pattern essential to the expression of assertiveness. Recognition that her aggression is resented by her colleagues, and insight into the sources of her affiliation of assertiveness with aggression, may enable her to experiment with modes of assertive display dissociated from acting-out. A boy fondled seductively by a parent may become too stimulated sexually and detach from his sexual feelings. Intimate relationships in adult life may precipitate an incestuous association that inhibits sexual expression. Awareness of the roots of his difficulty may enable the individual to experiment sexually with the objective of establishing new habit patterns. A host of pathological conditionings may, as Freud pointed out, invest the sexual and aggressive drives, and the person may develop inhibitions of function or distorted and perverse modes of expression. Burdened by essentially childish needs, he or she may be fixated in activities that survive as outlets for sex or aggression. To gratify these drives, a toll must be paid in currencies of insecurity and damaged self-esteem. This group of neurotic

promptings, with proper therapy—should the individual strongly desire it—may undergo modification. The patient thus either learns to live with handicaps, once they are understood more thoroughly, or is better able to control them. With reconstructive therapy an individual may be able to develop more mature ways of managing sexual and aggressive feeling and behavior.

A third group of patterns present in all people is relatively flexible. This group is not subject to severe repression and does not press for release against all reason. Developing both during early and late childhood and in adult life, the group constitutes the bulk of the individuals' coping maneuvers. These, the most malleable of tendencies, may be influenced most significantly in therapy.

Disappointment in psychotherapy is often registered when, after an ambitious, carefully designed and prolonged program of treatment, patients continue to resist giving up the first set of patterns and must exercise their will power constantly to keep the second group in check. Faulty habit patterns, disorderly study and work activities, conditioned phobias, and many maladaptive attitudes and values are among such tendencies. All human beings are so constituted that no amount of therapy, as practiced today, can alter some personality components, since they have become so firmly entrenched that they function like organic fixtures. Yet, properly designed psychotherapy offers individuals a substantial opportunity to rectify many destructive personality traits and to achieve a measure of happiness that, prior to treatment, was outside their grasp.

UNTOWARD REACTIONS DURING PSYCHOTHERAPY

The bulk of patients in psychotherapy move along well. Obstructions in progress and inimical emotional outbursts are readily handled. There are conditions, however, that pose hazards even for experienced psychotherapists. Personality structures in which emotional instability is ingrained, having existed since early childhood, will in all probability erupt with greater bursts of violence, responding with insurgency and defying control. Impartial as they may try to be, therapists will be drawn into the patients' onslaught and may be unable to maintain an even tenor, either yielding to unreasonable

demands or counterattacking in retaliation. The greatest incidence of untoward reactions in psychotherapy occurs when the relationship between therapists and patients is faulty. Inexperience and improper conduct of treatment, as well as countertransference, account for a large percentage of unfortunate results, although it is unclear how these take place. The work of Bergin (1963, 1971) and Strupp & Hadley (1977) accents the need for further research into deterioration effects and reasons for failures in psychotherapy.

It may not be amiss to mention the virtue of therapists' seeking consultation or supervision for a case that is not going well. This will necessitate courage and honest self-confrontation in facing the fact that they may be acting nontherapeutically with a patient or be employing interventions that do not satisfy the patient's needs. Talking things out with a colleague will often break through the current obstruction and promote satisfactory future movement.

Constituting treatment failure is the emergence during therapy of certain disturbed reactions. These are most apt to erupt when the customary defenses of the individuals are challenged or blocked, as in reeducative and reconstructive therapy; however, they may break loose in certain patients as a consequence of mere contact with the therapists, however supportive therapists may try to be. Thus, borderline patients who are maintaining a delicate balance in holding onto reality are particularly vulnerable to close interpersonal relationships. Even ordinary human encounters stimulate undue tension and conflict. Underlying morbid traits—kept under control by tenuous defenses—may emerge, often with explosive violence. Depressive manifestations may deepen into suicidal attempts; psychopathic aberrations may be acted out in total disregard of consequences; feelings of unreality and depersonalization may spread into an outright psychosis. During any kind of psychotherapy with borderline patients, the course of treatment is customarily stormy, punctuated by fluctuations in the sense of reality. The patients may interpret the relationship as an assault on their integrity, particularly if the therapists are excessively authoritarian or have unresolved hostile or sexual difficulties that filter through in manner and speech. Borderline patients sensitively divine these from the tiniest cues (Schmideberg, 1959). Emotional crises constitute the usual climate in

which therapy is conducted.

Problems are also commonly encountered in the treatment of somatoform disorders, characterized by intensified recrudescence of symptoms. When such eruptions are minor, there is no great danger; however, severe outbreaks of somatic disturbance may occur, such as a thyroid crisis, violent asthmatic attack, or fulminating ulcerative colitis that may lead to death. Suicide is also a possibility. The most disturbing reactions occur in patients who have habitually had a tenuous relationship with other people and a fragile self-image since childhood. "These individuals easily react . . . with a violent frenzied emotional flood, or with destructive violence at times turned in on themselves, or with a more complete withdrawal and inaccessibility. Any of these reactions may be fused with various disturbances of organ function (oral, excretory, circulatory, and also genital) and may reach the point of abandoning adequate contact with reality" (Mittelman, 1948b).

Patients suffering from brain injuries are apt, during psychotherapy, to manifest outbreaks of euphoric, paranoidal, sexually aggressive, or suicidal behavior (Weinstein and Kahn, 1959). Probing procedures employed in manic-depressive psychosis and involutional psychosis may release great anxiety and resentment and activate latent suicidal drives (Arieti, 1959). A treatment relationship in dependent individuals who mask their hopelessness by a thin overlay of indifference may precipitate a deep depression when the patients realize the realistic limitations in the degree of closeness possible with the therapists. Exploratory activities in reactive depressions, are notorious for exciting intense anxiety (Muncie, 1959).

Paranoid reactions respond adversely to almost any kind of human contact. Thus individuals who are burdened with self-doubt and suspicion may in a relationship of even moderate intensity find themselves responding with strong mechanisms of denial and projection. Ego defenses may then shatter, with emergence of oversensitivity, estrangement, preoccupation, distrust, suspicion, fears of physical and sexual attack, litigious tendencies, homosexual impulses, delusional jealousies, and grandiose delusions (Cameron N, 1959). Schizophrenics who interpret psychotherapy as an intrusion on their

privacy often will be provoked into fearful or aggressive reactions. Personality disorders manifest diverse reactions to therapeutic contacts. Urgent dependency needs may be projected onto the therapists, with excessive clinging, release of intense erotic feelings, and liberation of resentment at the inevitable frustration. Detachment with needs for control may be threatened by the patients' belief that yielding to another person implies a trap from which there is no escape. Masochistic promptings may enjoin the individuals to torture themselves with luxurious symptoms. Homosexual strivings kept in check prior to treatment may suddenly appear, promoting panic. Impulsive characters may exhibit acting-out proclivities without warning, engaging in outlandish and dangerous activities (Michaels, 1959).

Antisocial personalities may when challenged respond with excited and even psychotic behavior. Alcoholics and drug addicts are notoriously treacherous, indulging in defiant and occasionally destructive practices. Some patients with conversion reactions display alarming conduct when an attempt is made to alleviate or reduce their symptoms. A psychotic disorder of a depressive or paranoidal type may supervene (Abse, 1959). In obsessive reactions, frightening extremes of anxiety and rage may from time to time be released, along with guilt feelings and expiatory self-punishment, the therapists being accused of promoting the appearance of these symptoms (Rado, 1959).

RISKS OF PSYCHOTHERAPY

Difficulties will also develop as a consequence of the new adaptations forced on individuals as a result of removal of the problem for which they originally sought help. Sometimes a neurotic disorder constitutes the best compromise individuals can make with life and with themselves. Although they may complain bitterly about the disabling effects of their condition, when they are relieved of it, they may expose themselves to new circumstances that will or will not terminate happily. This, of course, is something for which practitioners cannot be held responsible. There is no crystal ball with which to predict the ultimate outcome of any problem. The responsibility of therapists is to help patients overcome an illness and to enable them to make a constructive future adjustment.

The end issues, however, may leave much to be desired, under which circumstances therapy may be scored as a failure. Thus a patient with migraine gets insight into the fact that she is complying, with strong internalized rage, to the authoritative demands of a widowed mother who seeks to infantilize her only child as an outlet for her controlling needs. Therapy helps the patient to liberate herself from her mother. The latter, unable to accept her daughter's freedom, commits suicide. The ensuing guilt, recriminations, and depression in the patient make her regret having started psychotherapy. An obese girl, helped to diet by psychological treatments, finds herself attractive to men. Unable to cope with the sexual demands made on her by her admirers, she responds with panic. A patient with frigidity dramatically overcomes her sexual indifference. Responding passionately to a seductive male, her episode terminates in pregnancy and the birth of an illegitimate child, which complicates her life detrimentally.

It is often impossible to foresee and to forestall future calamities that follow even traditional medical and surgical treatments. Thus the relieving of anginal pain, through prescription by an internist of a vasodilator, may encourage a cardiac patient to overtax the heart through physical efforts beyond one's endurance, initiating a massive coronary attack. Plastic surgery often exposes patients to responsibilities that their devalued self-image is unable to countenance, sometimes initiating many adverse reactions.

Another example would be refusing to treat travel phobias by psychotherapy to protect patients from the possibility of an airplane crash; this would constitute a foolish if not irresponsible shirking of therapists' duty. The best course to follow is to attempt to anticipate possible consequences of therapy and to work with patients until a reasonable stabilization is reached in their life situations.

FAILURES IN RECONSTRUCTIVE THERAPY

There are certain patients in whom long-term reconstructive treatment is not only useless but constitutes a definite hazard. Such patients, in good faith, enter into treatment with well-trained psychoanalysts, and after years of futile probing reach a desperate dead end. In many instances the hope of cure enjoins patients to engage a succession of

therapists, each espousing a well-documented theoretical system that promises success but ultimately results in failure.

If a hard look is taken at what has been happening, it is often found that the therapists have become incorporated by the patients into their neurotic schemes. It becomes obvious that what the patients are seeking from treatment is not cure, but satisfaction of dependency needs, a relief from the suffering that their conflicts foster, but which they refuse to relinquish, and replacement of amputated aspects of themselves that, with present knowledge, are far beyond the power of science to supply. Freud, astute clinician that he was, recognized that not all people were ready for the long-term pull of psychoanalysis when he advised that only individuals able to develop a transference neurosis be treated with his method. Although the diagnostic boundaries are diffuse, empirically it is possible to designate the kinds of conditions in which failures are common with reconstructive therapy.

The most unacceptable of candidates are patients who seem to be unable to get along on their own. These individuals are possessed of such great fragility in their defenses that they tend to fall apart in the face of even reasonable stress. Often they protect themselves from hurt by restricting needs and circumscribing the zones of their interpersonal operations. Yet their helplessness enjoins them to fasten themselves to some host who, they insist, must supply them with love, support, and other intangible bounties. Such unfortunate individuals have been so damaged in their upbringing that no amount of help, affection, discipline, entreaty, supplication, or castigation seems to repair their hurt. They tend to find and fasten themselves to individuals, movements, and institutions from whom and from which they hope to gain sustenance and strength. They act like exsanguinated people in need of perpetual transfusions.

Diagnostically these individuals spread themselves over a wide nosologic spectrum. They include schizophrenics, borderline patients, alcoholics, drug addicts, and antisocial personalities. They may have obsessive-compulsive, depressive, phobic, and somatoform disorders. Essentially they are characterologically immature, never having achieved inner

freedom and independence. It is as if they have become marooned on an island of infantile affect. Outwardly they may present a facade of assurance, but inwardly they are anchored to pitifully dependent moorings.

When such individuals enter psychotherapy, they soon sweep therapists into the orbit of their dependent designs. The grim objective of making therapists idealized parent figures is not diverted in the least by therapists' technical skills, astute observations, lucid interpretations, management of countertransference, encouragement of emotional catharsis, transference revelations, expert unraveling of dream symbolisms, the uncovering of forgotten memories, free association, structured interviews, firm directiveness, punishment, kindness, support and reassurance, suggestion, hypnosis, drugs, or by any other method therapists may exploit or devise. Therapists who are deceived by the earnestness with which patients dedicate themselves to the therapeutic task will credit the patients' lack of progress to the obstinacy of the patients' resistances, which, the therapists imagine, will eventually be resolved. And the patients, coasting along on the premise that time itself brings the cherished gift of unconscious motive or memory, will become increasingly helpless and will then supplicate for greater professions of dedication from the therapists. The liberated hostility serves no purpose other than to make the mutual lives of patients and therapists miserable in a futile tug of war.

With expanded public education and the exciting promises of fulfillment through psychotherapy, more and more individuals—unable to gratify their pathological dependency promptings in their habitual relationships, or through religion, or by affiliation with special movements—have flocked to the office of therapists seeking the elusive pot of gold that never quite materializes. And because hope springs eternal, the therapeutic diggings go on for years in the vain quest of bringing up treasure that somehow, according to legend, must eventually be exposed. Both patients and therapists enter into this undeliberate deception only marginally aware that the quest is a useless one and that what the patients really seek from therapy is supportive aliment for their emptiness.

The great danger in long-term reconstructive psychotherapy is not only its becoming a never-ending placebo to such characterologically dependent individuals who would otherwise find an object of faith outside of therapy, but, more insidiously, its activation of latent dependency needs in those who have managed their lives, prior to treatment, with a modicum of independence and assertiveness. As treatment continues, the defenses, organized around avoiding dependency, break down and are swept away. This contingency is useful, of course, in patients who have a solid enough core to reconstitute themselves. Indeed, unless the shaky superstructure is removed, the defective underpinnings cannot be strengthened to support more adequate defenses. But what happens in individuals who do not have the materials, let alone the tools, to rebuild their lives? That which once served to carry them through daily chores, albeit not as mature as might be ideal, no longer can be used. The patients have thrown away their crutches, and their legs are now too weak to propel them in any direction. The specter of patients being damaged by prolonged therapy is one that unfortunately haunts every psychotherapist.

Can therapists, by proper diagnosis, select patients for reconstructive therapy more appropriately, eliminating those who are subject to the dependency hazard? Are there ways that poor therapeutic risks can be spotted in advance? Psychotherapists find themselves in a quandary because morally and ethically they are committed to helping people develop and grow no matter how sick. A corollary may, therefore, be appended to the questions: When poor therapeutic risks are detected, are there effective treatments?

Before an attempt is made to answer these questions, the qualities of a good therapeutic risk for protracted reconstructive treatment should be designated. For individuals to benefit from reconstructive therapy, the following conditions should prevail.

1. The presence of a personality disorder serious enough to justify the sacrifices inherent in an extended period of treatment.

2. The presence of symptoms or behavioral difficulties that are intensely annoying to the patient.

3. An ability to accept the conditions related to time and finances, and cooperation to undergo techniques that probe the unconscious.

4. The presence of rigid resistances that cannot be resolved by less ambitious approaches.

5. A level of dependency that is not too high.

6. The ability to tolerate anxiety without severe disintegrative reactions.

7. The presence of some flexible defenses, ample enough to support the patients when anxiety is mobilized.

In advance of starting an actual therapeutic program, there are a few prognostic indicators that may be of value. If the patients have been seriously maladjusted since childhood—have failed to achieve goals ordinary for their age levels; have not had a good relationship with at least one person in the past; are not psychologically minded; are prone to severe acting-out; have been in psychotherapy for a number of years, particularly with a series of therapists without achieving benefits; have been institutionalized in a mental hospital; or manifest symptoms of schizophrenia, manic-depressive psychosis, organic brain disease, severe compulsion neurosis, antisocial personality, alcoholism, drug addiction, severe psychosomatic illness, or obstinate sexual perversion—trouble is likely. Projective psychological testing is helpful diagnostically, but it may not reveal much in relation to the outcome.

The best clues will be supplied by the psychotherapeutic experience itself. If patients show favorable responses to interpretations, evidenced by constructive reactions inside and outside of therapy, and particularly an ability to implement insight in the direction of change, therapists may be encouraged. Material from free associations, dreams, and transference reactions will reveal much that is not apparent on the surface. These are usually good indicators of therapeutic movement. If patients respond catastrophically to interpretations, or if they do not respond at all, if they manifest few or no transference reactions or the transferences are too violent, if acting-out persists in spite of interpretation, if their associations and dreams consistently reveal no constructive

developments—these are warnings that danger may shadow continued intensive explorations.

TREATMENT OF POOR THERAPEUTIC RISKS

When signs indicate patients are poor therapeutic risks, the objective will be to bring them to homeostasis as rapidly as possible with short-term supportive and reeducative approaches. It may be useful to confront patients frankly with the realities of their situation. Remarks may be couched in terms such as these:

> *Th.* You have problems that date way back in your life. It will require some time to reverse these completely. There may be some things we may not be able to alter entirely because they go so far back and are so firmly welded into your personality that they may not budge. But you can still live a comfortable and happy life. Now one of the problems in a situation like yours is that you feel helpless to do things by yourself. You will then get very dependent upon me, and it will set you back. For this reason we will keep our treatment short. Please don't feel that I am neglecting you if I encourage you to do things on your own.

These directives obviously will pass over patients' heads. Even though they may appear to agree intellectually, emotionally they will continue to press for a long-term dependent relationship. In some cases they will really need to be dependent on someone or something the rest of their lives since they cannot get along by themselves. If this is a possibility, therapists may still acquaint patients with the dynamics of their problems in the hope of enlisting their reasonable egos as allies. By showing patients the relationship of their dependency to other elements of their personalities, of how and why they get angry, of what they do with their anger, of how they undermine their self-esteem, of why they detach, they are given a reality explanation for manifestations that they have hitherto considered to be mysteriously ordained.

If patients persist in retaining therapists as their dependency agents—and there are many patients who are able to afford this luxury and some therapists who are willing to play such an exhausting role—therapists may graciously accept the post and inform the patients of willingness to treat them and work with them on their daily problems. The therapist may add, however, that the situation will be very much as in diabetes, where insulin must be taken constantly. There are some emotional problems that are like

diabetes and that will require help on a regular basis. Patients need not be ashamed if this is their situation.

There is hardship in working at depth under these circumstances. The patients will merely regurgitate their insights and recite their dynamics like a catechism. The best practice is to settle back with the patients and handle their immediate reactions with logical, persuasive arguments, attempting to inculcate in them a philosophy of living that will help them to accept their limitations and difficulties with grace. At the same time, deep material is interpreted whenever it is propitious to do so. Should the patients rail at the therapist and objurgate him or her for failing to transform them, the therapist must try to control the patients' frustrated feelings. A simple reply is best here: "Maybe it is impossible for you to change." This may have a startling effect on patients for the good, often shaking them out of their therapeutic lethargy.

Recognizing that there are patients who will require aid the rest of their lives and cognizant of the ever-expanding waiting lists, therapists may attempt to provide these sicker patients with a dependency prop that does not require a tie-up of services. For instance 15-, 20-, or 30-minute sessions may be all that is needed. Medications are prescribed intermittently if necessary, and the patients may be encouraged to join groups. Group approaches offer advantages to patients, since they help them to diffuse transference. Within any group, patients generally will select one or two people as their dependency target, but they know they can draw on the group at large when necessary. It is helpful, therefore, to encourage joining various activity groups, such as social and discussion groups. These may eventually replace the therapists as the prime supportive mainstay.

67
The Psychotherapist in Community Mental Health

There is a story about a unique way of diagnosing mental illness developed in a small community in Scotland. The "suspected" person is placed in a basement room that has a water tap. The faucet is turned on to flood the floor, the person is handed a mop and asked to dry the floor. If he or she continues to dry the floor without turning off the faucet, the diagnosis of "madness" is confirmed. This droll story is sometimes used to illustrate the situation of mental disturbances in the community. By concentrating efforts on managing the pressing disorders of the mentally and emotionally ill, therapists often lose sight of the fact that they coordinately fail to turn off the faucet in the polluted social system that is pouring out more patients than can be treated.

Such a statement assumes that enough is known about what causes emotional illness and that there are means to remedy the causes to turn off the faucet. Such assumptions are only partially true, but there certainly is sufficient knowledge at the present time, if not to dry the floor, to keep the basement from being flooded. The point is that such knowledge is not being used, nor does our society yet support with adequate economic and other means its implementation.

On the debit side it must be admitted that what was posited 20 years ago as "community mental health" is still a relatively unchartered field that embodies a variety of theoretical systems and methodological approaches. Designs for essential services vary with the characteristics and problems of the community being accommodated, with the needs of the individuals and agencies who constitute the consumers or the client systems, and with the philosophies and training of the personnel staffing the center or clinic that is executing the program. The problem areas for reform potentially are limitless, and, obviously, a rigid selection of zones of involvement will be in order. These range from clinical services for severe emotional problems, to counseling or casework for circumscribed personal and environmental difficulties, to educational projects for the

public geared to preventive objectives, to training programs for allied professionals and paraprofessionals, to hospitalization and day care facilities for the mentally ill, to rehabilitative and work adjustment programs for the handicapped, to consultation aids to organizations or groups in the community.

There are many existing models in community mental health that deal with how these services may be integrated, and many more will undoubtedly be developed with changing politico-socioeconomic conditions. Caplan (1974) in explicating some of these models states that "since we are grappling with a highly complex multifactorial field, no single model can be expected to do more than focus our attention and pattern our expectations about one aspect of the field." What would be applicable in one community does not necessarily conform with the special problems and conditions of another community. Mental health workers must consequently maintain flexibility and use whatever models seem pertinent, always altering these as new accomodations become necessary. At the Postgraduate Center for Mental Health in New York City we have worked in different communities and with almost 500 different agencies, institutions, and community groups in cities and counties in New York, New Jersey, and Connecticut. We have found that rigid adherence to any one model of operation can cripple a program and that a great deal more innovative flexibility is required than in working with individual and group psychotherapy.

There are times in the career of most psychotherapists when they are called on to apply their mental health skills to the social system. For example, a local school is experiencing an extraordinary increase in droupouts. A community is being plagued with an epidemic of misdemeanors and crimes perpetrated by juvenile delinquents. A center is being organized to provide recreational and rehabilitative services for older people, and the founders insist that it be oriented around sound mental health principles. A social agency wants to know how to start a mental health clinic. A group of ministers needs help in doing more effective pastoral counseling. Vocational rehabilitative workers request a course in the psychiatric and psychological aspects of work readjustment. A parent-teacher's association desires a lecture on child development illustrated by a good film. A

fraternal society is setting up a series of discussion groups dealing with family life education and needs a discussion leader. The roles that psychotherapists will be expected to play in servicing any of these requests go beyond those they conventionally assume in the clinic or their office. They must take on among other responsibilities those of educator, public health expert and mental health consultant. If they have had the traditional residency and post-residency training, they will not be equipped to do this, the focus of their education being more on clinical than on community functions.

It is beyond the scope of this book to explicate the details of community mental health or the full operations of the mental health specialist. Ample literature exists on these subjects. Mannino, MacLennan, and Shore (1975) have compiled an excellent reference guide to the consultation literature as well as a serviceable list of films and tapes. A full bibliography may be found in *Community Mental Health and Social Psychiatry,* prepared by Harvard Medical School and the Psychiatric Service of the Massachusetts General Hospital (Cambridge, Harvard University Press, 1962), and *Community Mental Health, Selected Reading List 1961-1965* (Canada's Mental Health Supplement No. 50; November-December, 1965), as well as Beliak et al. (1969, 1972, 1975) Bindman (1966), Brace-land et al. (1975), Hume (1966), and NIMH (1967-1970). Nevertheless, some guidelines will be indicated in this chapter that therapists may find of practical value.

Assume for illustration that a therapist receives a letter requesting a consultation from the director of a boys' club that has been organized around activities, such as carpentry and other handicrafts, for adolescents from deprived economic areas. The presenting problem is poor staff morale, which the director credits to the fact that the staff members feel themselves to be ineffectual in dealing with psychiatric problems. Delinquency and drug addiction among many of the boys, for example, continue unabated. The director believes that a course on psychopathology would be good for the staff and may help them to function more efficiently. The therapist replies affirmatively to the letter and sets up an appointment with the director. Prior to the conference, the therapist may make several assumptions:

    1. The director's diagnosis of what is needed, namely a course on

psychopathology, may or may not be what is required to resolve the problem.

2. In entering into the picture, the consultant (therapist) most likely will find among different levels of the administration, supervisory group, and staff workers, as well as among the recipients of the service (the adolescents) a hotbed of interlocking psychopathological constellations. The consultant will, with full justification, be tempted to prescribe psychotherapy for the most disturbed individuals. To do this would probably prove fatal. Limited finances, absent motivation, and the dearth of treatment facilities render psychotherapy impractical. Solutions other than therapy will be required.

3. A series of conferences will be needed with the director, the supervisors, and the staff individually and collectively to determine what they believe is wrong and to observe the way that they interact with one another in the work situation.

4. A series of conferences with the adolescents, particularly the leaders, may be desirable at some time once the picture has crystallized.

5. The entry of the consultant into the organization will probably stir up initial anxiety and resistance on all levels of the organization that will require handling.

6. Being involved in the dynamics of a social system, the consultant will have to keep communication channels open between the administrative, supervisory, and staff levels of the organization. The boundaries of the consultant's operations will require explicit definition; i.e., the director may need to be informed about what is going on but may not have to be involved in the project itself; written communications will have to be sent by the consultant to the director outlining what decisions are reached and what the consultant proposes to do; written agreement to proposals must be received by the consultant; a liaison person must be appointed by the director to represent the administration; and a decision must be made in joint conference who the consultant will work with in the project.

With these assumptions in mind, the consultant and director set up an appointment to meet in the consultants office. The director appears to be an intelligent, interested, and

knowledgeable person, a social worker who has had considerable experience in the field of group work. The director is very active in community affairs and has affiliations with many community organizations. The director is sociable and relates well. The consultant, inquiring about the program, discovers that 1000 boys are being worked with who live in the area of the club. During the summer the club runs a camp outside of the city. The activity program is managed by a staff of expert crafts people who have had no mental health orientation. The initial impression of the consultant is that if the staff had some mental health information, they may be able to use this in their work with the adolescents. For instance, many of the boys are expressing the usual defiant gestures of adolescents, and some of the staff, the consultant believes, are responding with feelings of not being appreciated. Moreover, a good number of the adolescents have severe character disturbances and are engaging in antisocial activities that may be upsetting the staff. Clarification about the dynamics would, therefore, seem indicated.

The consultant makes an appointment to visit the club and arranges to meet with the staff and supervisory groups individually. Several meetings are also held jointly with the staff supervisors and director. It soon becomes obvious to the consultant that the relationship of the staff and supervisors with the director leaves much to be desired. They consider the director an autocrat who overrides their decisions and who does not allow them freedom in their work. They respond to this by sullen withdrawal and disinterest in their duties. Most of the staff believe that they might learn something constructive from a course in mental health principles and practices. The consultant, however, is convinced that little will be accomplished until better relationships are established among the personnel. The director is not at all aware of personal shortcomings in managing the staff or of their hostile reactions to this management. From the way the director had communicated in the initial conference, the consultant could not diagnose what was wrong until the work situation and the ongoing interactions had been observed.

In discussion with the staff, the following plan is elaborated: (1) a group process to enable the staff to verbalize feelings and to become aware of self-sabotaging reactions that paralyze their functions and interfere with their relationships with the adolescents, (2)

conferences with the director to give the director an opportunity to express feelings and to test the director's flexibility, (3) group meetings with the staff, supervisors, and director, during which they are encouraged to discuss how they feel about one another in their work roles. Such sessions help the director play a more cooperative role with the staff and encourage them to talk to the director about their "gripes."

The consultant does not consider the staff participants as "patients" for very good reasons. First, they do not regard themselves as patients; second, the consultant is principally concerned with their work problems and not their neuroses; and third, group process, employing principles of group dynamics, is the instrumentality that will be used, not probing techniques into defenses and unconscious conflicts. The upshot may be therapeutic for all participants, but this is a byproduct. The focus is on conscious feelings in relation to the staffs ongoing interactions. Improved morale results in the staff taking greater interest in the boys, even taking them on outings. The effects are registered in dramatic improvements in behavior both within and outside the club.

Another example of how a therapist-consultant may respond to a community need is contained in the request of a suburban psychiatric clinic for staff training in psychotherapy. Upon visiting the clinic, the consultant finds that the problem confronting the clinic is that all of the available time of the staff members is occupied in treating a stationary caseload that does not seem to be going anywhere. The waiting lists are long; intake has more or less been frozen for months due to the absence of available therapeutic hours.

Examining the records of the kinds of patients being treated, the consultant finds that most of them are chronic cases: borderlines, or dependent-personality patients who have fastened themselves onto their therapists and have settled into what is turning out to be a permanent niche. The director of the clinic believes that what is required is more sophisticated training of the staff in depth approaches so that the basic inner problems of their patients may be influenced, in this way "curing the patients" and resolving the stalemate. An interview with the staff reveals frustration and demoralization because of

disappointment that they are unable to effectuate cures and because of pressures on them to open up more time for new patients.

The consultant sets up conferences with the staff members, and what is finally decided is the following: (1) establishment of a special clinic for sicker patients organized around drug therapy and no more than 15-minute supportive interview sessions once weekly or bimonthly, (2) transfer of the bulk of patients to this clinic, (3) development of a social rehabilitative unit in a neighboring church recreational center to which the patients may be referred for adjunctive social programs, (4) organization of a group therapy clinic and training of the staff in group therapeutic techniques, (5) concentration on short-term therapy as standard for the clinic and staff training in brief psychotherapy, (6) since this plan is long-term, requiring a period of years for its full development, a training program in group therapy and short-term therapy, for which the consultant will help recruit appropriately qualified trainers, (7) work by the consultant, if possible, with this group over the 3 or 4 years of transition, since there will be much staff anxiety that will require handling.

A third example will illustrate how psychotherapists engage in community work. A therapist-consultant is called into a school to determine why so large a percentage of the students are failing their college entrance examinations. Upon studying the school program, and after conferences with the principal, the teachers, and some of the students, the consultant comes to the conclusion that what is needed in the school is a school psychologist who can help students with problems in school and personal adjustment. An expanded budget is presented by the principal to the school board, some of whose members accuse the principal of being lax in running the school. They then oppose the recommendations. A group of irate taxpayers organizes itself into a political-action body and argue that a psychologist in the school will "make the students crazy" or give them "new-fangled foolish ideas about sex." The principal of the school is greatly disturbed and realizes that the community will not accept a psychologist to serve the high school population. The consultant and the principal discuss the problem with the teachers, and it is decided that an educational program is needed for the community. The help of the PTA

is enlisted, and an educational program is planned. A series of community lectures is organized employing mental health films, with discussion groups following the lectures around problems of child development and family life. There results a change in attitude, and the psychologist is accepted into the school system.

It will be seen from these illustrations that the operations of community mental health specialists go beyond those of mere psychotherapist. If they are to live up to community responsibility, psychotherapists will need skills not now developed in the traditional residency and postresidency programs. It so happens that by the nature of education and background, psychotherapists may not know as much about the community and their proper role in it as do certain professionals, such as community organizers, public health officers, and other social scientists. Yet the knowledge of human dynamics and of the irrational forces that prompt people and groups qualifies psychotherapists to understand the disorganizing emotional cross-currents that operate in society. What therapists need, as has been mentioned before, is the acquisition of a completely new set of professional talents in addition to psychotherapy, since psychotherapy as such may not be suited to the client group or will require reinforcement with other techniques.

The lines along which this supplementation may be organized is perhaps best conceptualized in an ecological model of community mental health that draws upon theories and techniques from clinical psychiatry, social science, and public health. Since one objective is the control en masse of emotional disturbance, it is essential to bring into the orbit of techniques methods that not only influence individuals but also families and other groups. A network of coordinated services is consequently employed that acts independent of psychotherapy. By the very nature of the work, psychotherapists who work in the community must collaborate with other professionals in the fields of education, medicine, nursing, welfare, correction, law, religion, and other disciplines. This does not mean a watering down of psychotherapy when it is indicated in individual cases; however, the limitations of psychotherapy in dealing with community problems must be acknowledged. Essential is a broadening of the base of operations to include every measure—psychological and sociotherapeutic—that can help people relate better and

function better.

Actually, present knowledge of dynamics and psychopathology has widened the horizons of illness to include deviant behavior in addition to the traditional neurotic and psychotic syndromes. With this insight has come the need to provide services for disorders up to recently not considered within the province of psychotherapeutic concern. As a consequence, it has been necessary to blend therapeutic methodologies with educational, social, and rehabilitative approaches and to modify ideas and methods within the context of the communities' medical and social organizations.

Alterations in line with community need inevitably includes psychotherapy. In extending the benefits of psychotherapy to the masses, however, it becomes necessary to adapt psychotherapeutic tactics to abbreviated objectives. Short-term psychotherapy devoid of ambiguous abstractions and amorphous theoretical concepts that applies itself to the immediate problems of patients becomes essential. The effect of these modified treatment techniques can be both reparative and reconstructive, although goal compromise may be necessary to meet the practical needs of the millions who require aid. Attention to the populations that are now being unserved or underserved, such as the chronically mentally ill, the aged, children, minorities, alcoholics, and substance abusers, is particularly urgent.

In addition to psychotherapy, the total involvement of the community and its resources in a comprehensive program is unavoidable. One form particularly suited for sicker patients is the "therapeutic community" (Edelson, 1964; Kraft, AM, 1966). The therapeutic community is actually an old concept, dating far back in history. But the ways in which therapeutic communities have operated have varied with the level of our understanding of group and interpersonal processes. Mental health specialists will need to know how to help each member of the community achieve as maximal a development as is within the individual's potential.

Because emergencies in the lives of people most commonly motivate them to seek help, some mental health centers have largely devoted their efforts to working with crises.

According to Caplan and Grunebaum (1972), the following points are essential crisis intervention:

1. Timing: Intensive and frequent visits during the first 4 to 6 weeks are mandatory, rather than spacing interviews at weekly intervals over a long-term period.

2. Family orientation: The integrity of the family should be preserved to help support the member in crisis. Interviews with the family at its home may be required.

3. Avoiding dependency: Undue dependency is avoided by dealing with the current situation rather than focusing on past problems.

4. Fostering mastery: All efforts are made to encourage understanding of a problem and modes of coping with it effectively. This may require intensive short-term education.

5. Outside support: Enlisting the help of available outside support (friends, clergy, and other agencies) facilitates treatment.

6. Goals: The objective is to improve adjustment and immediate coping with the current situation rather than "cure." Trained nonprofessionals may be useful in carrying out the therapeutic plan.

Helping people to deal constructively with crises necessitates less a focus on etiology than on encouraging exiting health-promoting forces of an interpersonal and social nature that are present or latent. Ca-plan (1974) points out appropriately that capacities for adaptation of individuals are bolstered by help from their social networks, "which provide them with consistent communications of what is expected of them, supports and assistance with tasks, evaluations of their performance, and appropriate rewards." Although the intensity of stress and the existing ego strength of individuals is important, the quality of the support that the individuals get from their group is even more important in adjusting to the noxious effects of an environment or in coping with crises. Supportive groups are many, the individuals involving themselves consistently with some of these such as in work, church, and political or recreational associations; or groups may be selected and utilized only in times of need, such as self-help groups, physicians, social

workers, ministers, lawyers, nonprofessionals, mental health aides, and concerned friends who have had and perhaps conquered problems similar to those of the individuals. These helping aids may be exploited spontaneously by the individuals or, if a community is lacking in them, organized and stimulated by a knowledgeable professional. Where they exist and the individuals isolate themselves from them, the task of community mental-health workers may be to motivate the clients to make use of them or to deal with the resistances against their use. Adequate support programs are vital in any comprehensive program of community mental health (Caplan and Killilea, 1976).

COMMUNITY PSYCHIATRY

The reduction of psychiatric morbidity through preventive, rehabilitative, and therapeutic measures is the objective of "community psychiatry" or "social psychiatry." Elaboration of community-based treatment and aftercare services draws upon principles of public health and incorporates epidemiological and biostatistical precepts even though psychiatric techniques are ultimately employed. An ample body of literature has accumulated on community psychiatry: Beliak (1964, 1974); Bernard (1954, 1960); Carstairs (1962); Clausen and Kohn (1954); J. V. Coleman (1953); Columbia University School of Public Health (1961); Dax (1961); Dohrenwend et al. (1962); Duhl (1963); Dunhan and Weinberg (1960); Faris and Dunham (1939); Felix (1957, 1961); Forstenzer (1961); L. K. Frank (1957); H. Freeman and Farndale (1963); GAP (Reports 1949, 1956b; Symposium, 1965); Goldston (1965); Greenblatt et al. (1957); Gruenberg (1957); Hanlon (1957); Harvard Medical School (1962); Hume (1964, 1965, 1966); M. Jones (1952); I. Kaufman (1956); Kupers (1981); Lager and Zwerling (1983); Lamb (1984); Lebensohn (1964); Leighton (1960); Leighton et al. (1957, 1963); Lemkau (1955); Lin and Standley (1962); Milbank Memorial Fund (1956, 1957, 1959); Mintz and Schwartz (1964); NIMH (1961); Pepper et al. (1965); Plunkett and Gordon (1960); Redlich and Pepper (1963, 1964); Rennie and Woodward (1948); Ruesch (1965); Stainbrook (1955); Talbot (1984); Weston (1975); and WHO (1960).

PREVENTIVE PSYCHIATRY

Originally, therapy was focused on caring for seriously impaired mental patients. The emphasis on prevention, however, has shifted attention to patients with less severe emotional ailments, i.e., the psychoneuroses, the character disorders, the minor addictions, and even the milder adjustment problems. Caplan (1965) stressed that it was essential to accept responsibility "for helping those of all ages and classes who are suffering from disorders of all types, wherever they occur in the community." His statement makes clear why therapeutic services shifted away from the desperately mentally ill: there just was not enough money to go around.

A public health model of prevention divides such a program into primary, secondary, and tertiary categories (Caplan, 1964; Zusman, 1975). In *primary prevention,* attempts are made both to modify the environment and to reinforce constructive elements within individuals to aid in their coping capacities and to reduce the incidence of mental disorder. In *secondary prevention,* the aim is to diagnose and to treat patients with existing mental disorders to lower the severity and duration of morbidity. In *tertiary prevention,* the object is to rehabilitate people with emotional difficulties so that they may make some kind of adaptation to their environment.

Efforts at prevention require knowledge of community organization and planning as well as cooperation with other productive community programs that are operative within the community. There are relatively few psychotherapists who have gone beyond their clinical training to acquire required skills to work at prevention. But even if mental health workers have had adequate knowledge and training, there are regressive forces within the community that will resist change and will even attempt to restore the prior pathogenic elements once change is effectuated. Indeed, there are professionals who insist that the present-day community mental health movement is geared predominantly toward social control and toward preserving the politico-economic system and that change will be possible only by the assumption of a radical position, with mental health centers becoming politically involved while using methods that reach large masses of people (Kunnes, 1972). Advocated is turning over the control of policies and priorities of services to the citizenry of the community, the "consumers." On the other hand, it is pointed out by

oppositionists that where such a radical position has been taken, the results have been sadly wanting and that, therefore, a more conservative stance is to be preferred. Therapists can only do for a community what it is willing to accept. This should not dampen enthusiasm about what can be accomplished or discourage efforts at public education that can reduce the resistance threshold.

Primary prevention, though "the most desirable and potentially most effective approach to a solution of the problem of mental disorder in our communities, is clearly more a hope than a reality" (Caplan and Grunebaum, 1972). "In regard to preventive programs there seems to be no empirical evidence that any program is capable of preventing abnormal behavior." The provision of adequate health, housing, police, sanitation, educational, welfare, social, and recreational facilities requires outlays of public funds so vast that any effective provision would threaten other priorities. Increasing taxation and the issuing of bonds to bolster flagging budgets have acted like time bombs that threaten fiscal solvency. Accepting the fact that primary prevention is still a dream, some community mental-health operations have served quite successfully to supply services for secondary and tertiary prevention.

THE COMMUNITY MENTAL HEALTH CENTER

Broadening the base of services to the mentally ill and emotionally disturbed and focusing on early treatment and ambulatory services result in a minimal disruption of personal, family, work, and social life. Essentially, therapists function most effectively as consultants both for the management of individual cases and for the development and implementation of programs. Therapists' major areas of competence, diagnosis and treatment, is of great value here.

Two patterns of community psychiatry appear to be emerging. The first is organized around the community mental-health center, which aims at decentralization, regionalization and local service and is not too intimately related to other health services. The second is the integration of psychiatric services centered around the general hospital, which has consultative, outpatient, inpatient, round-the-clock care facilities but which is

relatively isolated from community welfare and educational services.

The assembly under one umbrella of *all* services for the mentally ill was one of the recommendations of the National Congress of Mental Illness and Health, held by the American Medical Association Council on Mental Health in 1962 (NIMH: *The Comprehensive Community Mental Health Center,* Public Health Service Pamphlet No. 1137, 1964; see also *Community Mental Health Advances,* Public Health Services Publication No. 1141). The Joint Commission on Mental Illness and Health, in its report to Congress in 1961, also emphasized the need for community services as a way of prevention and treatment to avert the debilitating effects of long hospitalization. The Joint Commission recommended expanded services in the community, a shift of focus from mental hospital institutionalization to smaller inpatient units as well as increased community care, a concentration on prevention and rehabilitation, greater cooperation among the different professions toward improving mental health research and treatment, and a more intimate coordination of hospital and community resources (*Action for Mental Health: Joint Commission on Mental Illness and Health.* New York, Basic Books, 1961). These recommendations fostered the organization of community mental health centers that promised the following:

1. Inpatient services, including a 24-hour emergency service

2. A day hospital

3. Outpatient clinic services for adults, children, and families without a waiting period

4. Partial hospitalization for day care and night care

5. Consultation services

6. Diagnostic services

7. Rehabilitative services of an educational, vocational, and social nature

8. Precare and aftercare services, such as placement in foster homes and halfway houses

9. Training of all types of mental health personnel

10. Research and evaluation

These instrumentalities were not to be under one roof or one sponsorship but were to be administered so that a continuity of care was achieved (Downing et al., 1966; Dorsett and Jones, 1967; McKinley et al., 1966; NIMH, 1963a & b).

The concentration of services around a general hospital was recommended by some authorities, and a selected annotated bibliography was prepared by the National Institute for Mental Health detailing how a hospital may function as a psychiatric resource (*The Community General Hospital as a Psychiatric Resource,* Public Health Service Publication No. 1484, Public Health Bibliography Series No. 66).

The experience of implementing the community mental health center program has not been an entirely happy one. Glass-cote et al. (1969) believed that the flaw was in the timetable: "Lack of experience, lack of staff, and lack of definition have all played a role, but they have been less of a problem than bad timing." The urgency to spend allocated funds for construction of community mental health centers over a two-year period encouraged the building of centers prior to planning how they would be used in comprehensive statewide designs. Problems also developed in providing for adequate staffing, a prime key to the adequate operation of a center. Psychiatrists, who were in preponderance, now find themselves in the minority in comparison to psychologists, social workers, and nurses. Much of the fault in fulfilling the original purpose of Congress in creating the program lay in the fact that providing for the mental health needs of all people in all parts of each state with adequate preventive, screening, diagnostic, therapeutic, rehabilitative, consultative, educational, research, and training services was a too ambitious, and perhaps unrealistic, goal that awaited a good deal of experiment over many years before it could be even minimally fulfilled. This is perhaps why unfavorable publicity and reports of failure of the community mental health programs have appeared in the literature. For instance, Ralph Nader *(Medical Tribune,* 1972) has claimed that the programs in action have perpetuated a two-class system of care that is sterile in ideas and

operations. An overcommitment to broad social problems at the expense of the immediate needs of clients "wastes professional staff and is both expensive and unfruitful, thus causing public disillusionment and endangering the whole community psychiatry program" (Wachpress, 1972). Under the circumstances it is remarkable that many community mental health centers have functioned as well as they have *(New York Times,* 1972). It is hoped that profiting from what has happened in the past, with adequate governmental funding and more sophisticated staffing, the centers may ultimately bring to fruition some of Congress's original goals. It is hoped, too, that aftercare programs for patients discharged from mental hospitals will become better financed and organized so that readmissions to hospitals are less necessary. Some of the statistics are presented as impressive. The number of hospital beds for mental patients has been more than halved, and the average stay has been reduced from 8 years to 17 months. Without adequate support systems in the community, however, the benefits of deinstitutionalization are questionable.

EXPANDED FUNCTIONS OF THE PSYCHOTHERAPIST

Since diagnostic and treatment resources cannot be deployed for relatively large groups of patients, and patient-therapist contact being limited, other modes of contact are necessary. Preventive methods entail the detection and remedying of *social forces* and *environmental pressures* that have a potentially pathogenic effect. Consequently it is advisable to include in the treatment plan "the active manipulation of the organizational aspect" of patients' lives (Caplan, 1965). This often requires the offering of individual or group consultation to administrators and others in an organization. Advice may be given affecting any phase of organizational functioning, including policy making. In expanding operations, therapists will, as has been mentioned before, have to go beyond habitual clinical theoretical models.

Community work foists onto therapists responsibilities that differ from those of traditional psychotherapy and are in line with the new tools being used (i.e., consultation, in-service training, and general public education). Guiding people in the organization

(executives, foremen, staff workers) with problems is complicated. Exploiting the theory and practice of community psychiatry, the practical implementation of community research methodology, the planning of services in line with the most efficient use of resources, and the development and administration of community programs are functions that will require specialized training beyond that of the psychiatric residency. Such training will undoubtedly be organized in the future as part of a career program and may be as eagerly sought after as psychoanalytic training had been for the past generations of psychotherapists. One design of training was a model offered at the Columbia Presbyterian Medical Center, which was organized and carried out jointly by the Department of Psychiatry and the School of Public Health and Administrative Medicine through an interdepartmental Division of Community Psychiatry (Columbia University, 1961; Bernard, 1960, 1965). Other training programs have been at the Johns Hopkins School of Hygiene and Public Health (Lemkau, 1955), at Harvard (Caplan, 1959), and at Berkeley (Beliak, 1964). There are some who believe that it is possible to teach community psychiatry in a traditional residency training program (Daniels and Margolis, 1965). Some favor the Community Mental Health Center (Sabshin, 1965). Others have developed programs in relationship to state and local health departments and university, state, and private training centers (Kern, 1965).

Comprehensive Training in Community Mental Health

There is disparity in ideas of who should be trained in community psychiatry and community mental health. Some authorities believe that psychiatrists should have the priority; others believe that psychiatric nurses, clinical psychologists, and clinical social workers are fully capable, with training, of learning skills in community psychiatry (Hume, 1966). Community mental health is, according to Lemhkau (1965), of medical concern, but it is not identical or coincident with psychiatry. It is much broader: it is a community-wide responsibility that sponsors the concept that "the program is to be under professional and lay auspices, and that mental health is promoted and fostered not solely through medical treatment, but also through a variety of institutions and agencies with numerous disciplines joining in the effort."

The multidisciplinary accent on community mental health has exacerbated rivalries and hostilities among the disciplines involved whenever adequate financing for services has become available. With expanded funding, arguments of who can practice—and under what auspices and supervision—will perhaps be as vehement as in the practice of psychotherapy. With added information about epidemiology and biostatistics, and with a greater public health orientation, trained psychotherapists in any of the professions can very well adapt to a community-based design for the mentally ill and, if creative and experienced, may be able to organize, direct, and execute projects of public education in mental health. To do consultation, however, and the in-service staff training and education of allied professionals (ministers, nurses, social workers, physicians, rehabilitation workers, speech therapists, and teachers) in therapeutic techniques (counseling, group process, and so on), even experienced therapists will need to fulfill certain requirements. They will preferably, following their residencies, have completed postgraduate work in a psychoanalytic or psychotherapeutic training center. They will ideally also have completed a structured course in community mental health that draws upon the public health and behavioral science fields. Work in community projects under supervision will have taught them the fundamentals of mental health consultation and how to gear teaching methods to the needs of the different professionals who handle people experiencing problems. It is hardly conceivable that a mental health consultant and professional trainer can be on a level below that of supervising psychotherapist.

One of the chief difficulties for most psychotherapists launching into the field of mental health is that, with the possible exception of social workers, their training, experience, and hence conceptual framework is largely clinical. Although this framework may operate effectively in psychotherapy, it does not apply to many, perhaps most, of the problems encountered in the community. An ideal community mental health worker should in part be a sociologist, anthropologist, psychologist, educator, political scientist, community organizer and planner, psychoanalyst, psychiatrist, physiologist, social worker, historian, pubic health specialist, biologist, social philosopher, researcher, and administrator. Since no therapist has or will ever have a complete combination of skills relating to the above professions, therapists will have to accommodate existing talents to a

complex, difficult, and constantly changing community atmosphere, utilizing themselves as constructively as possible while preserving the open mind of a student and scholar who is in constant search for new information and knowledge. Training is helpful within a community mental health center to equip therapists with the specialized abilities required to work in the community. When therapists have the motivation and are fortunate enough to live in an area where there is a training course in community mental health, the experience may be very profitable.

The kind of training that is most suited for community mental health specialists is, in addition to psychotherapy, experience with group processes and group dynamics, research design and methods, community organization and planning, communication techniques, teaching, various rehabilitation procedures, administration, and legal and legislative processes. A knowledge of public health objectives and measures is also helpful. It is rare that an individual can be interested in all of these fields. Generally therapists concentrate on a special area, such as mental health education, but comprehensive knowledge will enhance functioning even though greatest weight is given one kind of activity. Work in such fields as rehabilitation, law enforcement, industry, recreation, and religion, requires an extensive repertoire of techniques. The broader the education of therapists, the more effective they will be as consultants.

Since substantial therapeutic impact may be made during periods of crisis, contact with individuals in trouble may be of incalculable help if therapists have fundamental information about how to recognize an emotional problem, how to interview, how to conduct themselves constructively in therapeutic relationships, and how to make referrals. Educating such individuals presupposes an understanding of teaching method.

TECHNIQUES IN COMMUNITY MENTAL HEALTH

Mental Health Consultation

Consultation is a basic tool of mental health specialists. It consists of an interaction between a specialist or consultant and one or more consultees (usually agency

professionals) aimed at the mental health components of their work, including program and practices of the consultee organization. In the course of such consultation the consultee is also, according to Gerald Caplan, "being educated in order that he will be able in the future to handle similar problems in the same or other clients in a more effective manner than in the past" (U.S. Public Health Service, 1962).

Mental health consultation must be differentiated from psychotherapy, supervision, professional education, in-service training, and collaboration (Haylett and Rapaport, 1964). In psychotherapy, the interaction is with patients toward resolving symptoms and strengthening personality assets; in consultation, the relationship is with consultees and is geared toward enhancing their knowledge and skills. In supervision, supervisors assume an administrative in addition to an educative role; in consultation, consultants do not play an administrative authority role. In professional education, students are schooled in a skill that equips them to enter a certain profession; in consultation the consultees have already fulfilled the minimum requirements for their profession. In in-service training, the focus is on improving competence in the tasks for which therapists have been hired; in consultation new tasks are envisioned to expand the consultees' functions in mental health areas.

Consultation is usually offered to individuals in key administrative and supervisory positions to maximize the effect and reach the greatest numbers of people, i.e., the working staffs. It is generally done at the consultees' place of work unless consultants possess or arrange for special facilities.

Stages of consultation may be divided into a beginning or "entry" phase, a problem-solving phase, and a termination phase. It is assumed that the consultee is acquainted with the consultant or the consultant's work and is oriented regarding the nature of consultation services. If not, a preparatory interpretive meeting or group of meetings may have to be arranged. A contract is drawn up either verbally or, preferably, in the form of an exchange of letters. The consultant and consultee agree on details about participating personnel, the extent of time of the project, and physical arrangements. It may be

necessary to clarify the consultant's role—for instance, that services are not given directly to the consultee's clients. The next phase is that of problem solving, which is the core of the consultation process. Here the consultee's motivations and readiness for change mingle with the consultant's skill, experience, and capacity to handle emotional aspects of the relationship. This interaction will determine the rapidity with which movement and change are registered. The final phase is that of a mutually agreed upon termination.

The methods employed by the mental health consultant will have to be adapted to the special needs and problems of the agency, group, or individual who is seeking help. Generally, methods derived from the clinical model, i.e., therapeutic work with individuals, are not too applicable to consultation. As an example, suppose that the specialist is engaged by a social agency as a consultant in making their functions more effective. The first step is the "entry process" into the agency—"consultee system," or "client-system" as R. Lippitt et al. (1958) call it. This entails a proper diagnosis of the problem determined by setting up a series of meetings with key personnel. The objective is to help the consultee arrive at an understanding of what is needed and which aspects of the problem to approach immediately and which later on. A problem-solving plan is evolved, and the consultant then focuses on facilitating and enhancing the problem-solving skills of the individuals who will execute the plan. Communication channels are opened up between the various levels of the agency (executive, supervisor, and staff) to handle the effects of feedback, and resistances to change and to learning. The consultant then continues to work with the agency until the plan is proceeding satisfactorily. If the agency is large, the consultant may restrict efforts just to training the supervisory staff, expanding their information and skills so that they may by themselves manage and continue the program that has been instituted. The consultant may have to use some research techniques and engage in 9 or 10 group conference services, getting details of work habits, studying records, and becoming familiar with the functions of the organization. Then attention may be directed to training. If the consultant cannot personally enter into the problem-solving process, help may be obtained from the proper outside resources for this task. Finally, the consultant withdraws from the agency or "consultee system" (Wolberg A and Padilla-Lawson, 1965).

Considerable numbers of writings have accumulated detailing theory and method in mental health consultation. Recommended readings are the following: Argyris (1961); Berlin (1956, 1960, 1964); Bindman (1959, 1960, 1966); Boehme (1956); Brashear et al. (1954); Caplan (1961b, 1963, 1964, 1970); L. D. Cohen (1966); J. V. Coleman (1947); Cooper and Hodges (1983); Covner (1947); Croley (1961); Davies (1960); W. E. Davis (1957); GAP (1956a); Garrett (1956); Gibb (1959); Gibb and Lippitt (1959); Gilbert (1960); Gilbertson (1952); Glidewell (1959); Gordon DE (1953); Greenblatt (1975); Halleck and Miller (1963); Kazanjian et al. (1962); Lamb and Peterson (1983); Leader (1957); Lifschutz et al. (1958); G. Lippitt (1959); R. Lippitt et al. (1958); Maddux (1953); Malamud (1959); Mannino et al. (1975); Mental Hygiene Committee (1950); Nunnally (1957); K. B. Oettinger (1950); Parker (1958, 1962); L. Rapaport (1963); Rogawski (1979); M. J. Rosenthal and Sullivan (1959); San Mateo County (1961); G. S. Stevenson (1956); Valenstein (1955); A. Wolberg and Padilla-Lawson (1965); Zander (1957).

More specifically, the entry phase is characterized by an exploration during conferences of the manifest problems and needs of the consultee. During this phase relationships will be established. If possible, a personal interview is arranged by the consultee for the consultant with the head of the agency to affirm the agency's support for the project. Answers are needed to the following:

1. What is the structure of the agency, including the history, budget, and financing?

2. What is the organizational structure involving the personnel in the agency? What are the authority lines and policy-making bodies?

3. What are the supervisory policies?

4. Are there any apparent personality problems of, and conflicts in relation to, the leadership?

5. Are there any apparent conflicts in policies and aims?

6. What are the existing functions of the agency and are these being fulfilled?

7. What are the proposed future functions, if any, and are these realistic?

8. What is the community setting in which the agency operates? Are there conflicts between policies and functions of the agency and the community? What are the -areas of community support and the areas of opposition? (For example, a school may wish to focus its resources and energies on the most gifted children who are showing learning blocks. The parents' association may be pressing for better tutoring to prepare the students for college boards. Some community organizations, courts, and social agencies, in contrast, may be insistent that juvenile delinquents and retarded children receive special attention, which will conflict with a program for brighter students.)

9. What is the community organization; is there now or will there be a duplication of services? Is there cooperation with other agencies?

10. What are the existing and anticipated conflicts regarding programming and policy changes?

11. What were the previous experiences of the agency with consultants?

During the next (problem-solving) phase of the consultation there is an ordered gathering of informaation about the consultee system, including needs and difficulties. A true working relationship begins to develop. Diagnostic assessments are made and a plan of action is agreed upon. It will be essential for consultants to educate the consultees in handling anxieties and resistances. A periodic review of services and problems may be required and role limitations defined. It is to be expected that some untoward reactions will crop up among the staff, supervisors, and administration when program changes are proposed or implemented. Great tact must be exercised in dealing with these. It may that the staffs proposals for change may not be consonant with the personal philosophies of the administrator, in which case exploratory conferences will be necessary.

In the course of problem solving, transference and countertransference will come into evidence. The consultants' own analysis and experience as psychotherapists will help the consultants deal with these contingencies. Obviously, psychotherapy will not be done; however, inimical reactions may tactfully be interpreted on the "here-and-now" level. Temptation to fall back on clinical methods must be resisted. If the consultees recognize an emotional problem in themselves and request help for this, the consultants may offer

advice about resources. Plunging in blindly and trying to get consultees to accept personal therapy without their desire for this may destroy the working relationship.

What is discouraging to most consultants is the slowness with which attitude change can be brought about. Personality difficulties among the personnel in an agency are the greatest deterrents to change and constructive action, and consultants will have to work with these obstructions painstakingly. Honest, frank communication in the matrix of a working relationship is the best way of dealing with emerging resistances and problems. Consultants must expect that some of the intrusions proffered will be challenged and that discrimination may be exercised that will not always be in the consultants' favor. Questions consultants ask about the organization and its functions may arouse suspicions of "trespassing" and may mobilize guilt feelings in those who fear that their negligence in duty will be discovered. Some may resent being told how to do their jobs. The consultants during conferences should convey no implication of blame or criticism, no "eyebrow lifting." A casual reassuring manner is best punctuated by occasional approving remarks for praiseworthy tasks the consultees are doing. Attempts should be made to build up confidence and trust, realizing that no matter how meritorious or urgently changes are needed, they are bound to be resisted. Even a poorly functioning organization has achieved a shaky equilibrium, which will be defended.

Among the rules to follow are these:

1. Do not be hasty with advice. Community problems are complex and a thorough exploration will be essential before conclusions are valid.

2. Consider carefully the ideas and opinions of the people with whom you are working.

3. Expect power groups to try to involve you; avoid taking sides.

4. Try to see all aspects of a question if there is conflict. Verbalize how the opponents must feel. Let them offer suggestions regarding proposed courses of action.

5. Try to exhibit tact and to retain a sense of humor.

The withdrawal phase of consultation will take place after the problem for which the consultants was retained has been solved, or prior to its solution by mutual consent. An evaluation of the service and plans for future cooperation (e.g., reports, personal contact) are made.

It is apparent that the consultants will need to know something about community organization and planning for mental health, social planning, organizational management, administration, public relations, public health, individual and group dynamics, research, law, teaching, supervision, social psychology, cultural anthropology, sociology, and political action.

At the Postgraduate Center for Mental Health in New York City, an interdisciplinary specialty program trained psychiatrists, psychiatric social workers, and clinical psychologists to function as community mental health consultants only after they had completed a postgraduate psychoanalytic training program (which requires an average of 4 years of didactic courses, personal psychoanalysis, and intensive supervision) and who thereafter spent an additional 2 years, part time, in active consultative work in the community under supervision (Hamburger, 1976; Wolberg A, and Padilla-Lawson, 1962). In practically all cases, students have become so interested in community work that they have participated substantially as community workers after completing their course in addition to operating as therapists in private practice. The model for the consultation process taught has been developed and organized in part around the paradigms of G. Lippitt (1959) and Gibb and R. Lippitt (1959), which emphasize systems theory and group dynamics, and in part around concepts of a mental health "multilevel-planning-activity group (MPAG)" developed by A. Wolberg and Padilla-Lawson (1959), an outline of which is given in Table 67-1.

To apply themselves most effectively in the community, therapist-consultants will have to fulfill a number of roles. Ideally, they should be able to plan, develop, and implement programs for prevention of mental illness, for reduction of psychiatric morbidity, for training of mental health personnel, for agency evaluation and

reorganization, for education of professionals (e.g., physicians, teachers, ministers, lawyers, correctional workers) who deal with people blocked in learning, work, and interpersonal and social relationships, for upgrading of skills of institutional staffs (e.g., schools, industry, social agencies), and for public education in mental health. Obviously, neither the consultants' backgrounds nor available time will enable consultants to be equally effective as community mental health consultant, professional trainer, and public health educator. Consequently, it will be necessary to restrict efforts to areas within the consultants' competence while acquiring further training that will equip consultants to play an expanded mental health role. Thus if zones of interest and ability are in the field of treatment, administration, research, or teaching, therapist-consultants will most likely seek out and be sought for selective projects in line with this expertise.

In some of these projects the consultants will become involved in organizing, administrating, and supervising a variety of other services, some of which they can do better than others. These include preventive care, home treatment, walk-in clinics, admission procedures, partial hospitalization, work programs, social rehabilitation, planning development of the locus of care, rural program development, metropolitan mental health center development, legal issues in establishment and operation, record keeping and research, and so on (Grunebaum H, 1970).

The Training of Mental Health Personnel

Mental disorders constitute a major public health problem resulting not only in syndromes that totally incapacitate a large section of the population, but also, in their early stages and incipient forms, directly or indirectly influencing the happiness and efficiency of every individual alive. Because of the ubiquity of the problem, psychotherapists are being increasingly drawn into programs of training on federal, state, and local levels. The broadening of vistas of mental health to penetrate into every nook and cranny of the community and diffusion of psychological knowledge into programs of education, correction, health, and welfare have resulted in an enlistment of psychotherapists toward planning programs and participating in their development in

accordance with the needs, readiness, and practical limitations existing in a specific area of the country. Psychotherapists are also playing a vital role in the recruitment of mental health personnel.

In view of the great shortage of mental-health workers, training programs are being sponsored with federal and state support, which include not only professional groups such as general practitioners, nurses, social scientists, health officers, health educators, ministers, teachers, social workers, occupational therapists, recreational therapists, speech therapists, and vocational counselors, but also subprofessional and technical personnel such as psychiatric aides and paraprofessionals. While it is difficult to estimate the precise personnel requirements, it is safe to assume that at least twice the number of mental health professionals will be needed to cope even minimally with the existing demand for services. In recognition of these needs, the Surgeon General's Ad Hoc Committee on Mental Health Activities (NIMH, 1962) encouraged the in-service training in mental health of professional personnel in organizations that deal with problems confronting human beings on every level of functioning, the introduction of mental health courses in schools of public health, more intensive exposure of psychiatric residents to social science and public health methods, and support for the training of greater numbers of high-level professional mental health personnel, particularly for work in community mental health programs.

In designing a training program for an agency or organization, the therapist-consultant will need to use some of the processes of consultation. This may be illustrated by a problem presented to the Postgraduate Center by the casework staff of the case study unit of one of the bureaus of a school system (Wolberg A, 1964). The staff was concerned with the need to learn new techniques to approach the hard-to-reach children expressing their emotional problems in poor school attendance. Home visits, referrals to community agencies, supervision of the children, consultation with community agencies, and appearances in court constituted the work done by the social work staff. After a series of conferences of the consultees with the casework staff, it was agreed that some of the children might benefit from group approaches. It was decided to organize a training

program to teach the social workers the group-counseling method within casework process.

Four broad phases in this program were planned: (1) Six to eight exploratory sessions with the case study supervisors of the bureau and the consulting supervisory staff of the Postgraduate Center to discuss typical cases handled by the bureau, with the hope (a) of developing a set of criteria for the choice of clients who would participate in the groups and (b) of developing group techniques appropriate to this situation. (2) A regular 15-session seminar in group process for the case-study supervisory staff of the bureau and for the three caseworkers who were to handle the first three trial groups. (3) Three consultants assigned to the first trial groups were to teach the caseworkers how to use group dynamic methods in handling their groups of children, and to teach the supervisors how to supervise this group process. Other supervisors and social workers were to observe the supervision of the worker. This phase was to continue for 2 or 3 years in a progressively diminishing manner as the bureau staff acquired greater skills. (4) In 4 or 5 years the project was to be expanded to train social workers in the bureau to assume responsibility for a citywide group program in the schools. After this the Postgraduate Center was to withdraw and the consultation program was to be terminated. According to the plan, each caseworker (attendance teacher) carried 2 groups of 8 children each, weekly, over a period of 1 semester (15 weeks), in addition to the caseworker's regular work. The objective was not to make group therapists out of the social workers, but to adapt group methods to casework procedure to enhance the mental health of the children.

The value of this program was proven by the marked improvement by the participant children in actual school attendance (complete cessation of absenteeism in 53 percent, marked reduction in 20 percent), in scholastic achievement, in attitudes toward school, and in general attitudes toward their classmates and adults. The school personnel expressed enthusiasm regarding the results of the program. A total of 25 attendance teachers was trained to manage groups, most of whom became supervisors and in turn began to train others.

Training programs must be tailor-made, designed for the specific needs of the professionals who are seeking further tutelage, taking into consideration their present education and the functions that they intend to fulfill. Generally, a consultation process will be required to assess what the training requirements are and the best means of executing the proposed goals. It is essential that the training equip the individuals to work more effectively within their particular profession and not be geared to making the "trainees" psychotherapists. Didactic lectures are secondary to case discussions and supervised work with clients. A group process is often helpful for the the professionals themselves, enabling them to become aware of some of their personal problems and resistances.

Public Education in Mental Health

The great need for public education in mental health was pointed out by Braceland (1955): "public information on what constitutes illness and health is a hodgepodge of folklore, information, and misinformation." He appropriately warned, moreover, that the techniques and particularly the use of mass propaganda methods may present a distorted picture of any public health problem. Data about mental and emotional disease may easily arouse fears and anxieties. The ineffectiveness of intensive educational programs using a wide variety of materials is, unfortunately, not too uncommon an experience, established attitudes rarely being changed. Braceland affirmed the need to avoid calling attention to the ravages of mental illness; rather it is essential, he noted, to stress hope and the promise of recovery with early diagnosis and treatment "to reassure rather than to threaten or frighten" and "the audience . . . spared technical language and abstruse, complex material that they are not prepared to handle." What requires emphasis is normal behavior, the fluctuations in emotional well-being, the universality of anxiety and some of its common manifestations, the determining (but not necessarily irreversible) influences of past experiences, the impact of social and cultural factors on personality development and functioning, the psychological needs at various developmental phases, the stress situations that create emotional insecurity at different age periods, and a description of how emotions influence humans toward unrealistic goals and immature behavior.

Mass approaches to public education in mental health must await the development of television and radio programs as well as the kinds of press reporting and magazine writing that does not emphasize the destructive, dramatic, and violent aspects of mental illness and emotional disturbance. If the sponsors of programs and the controlling forces in the publication field were to apply the organizational and creative skills they use to sell advertised products, they undoubtedly would be able to adapt mental health materials that would change attitudes. This would necessitate a shift in the content of mass media away from preoccupations with violence and disturbed relationships among people.

In the meantime, mental health workers may have to confine themselves to the influencing of small, motivated groups who need and ask for special kinds of information. Materials pertinent to the topics of interest may be procured, and leads regarding appropriate films, pamphlets, plays, and other audiovisual and graphic aids may be obtained, from such educational organizations as the Mental Health Materials Center, 30 E. 29th St., New York, NY 10016. There is a useful Public Health Service Publication (No. 218, Washington, D. C., 1960) titled *Mental Health Motion Pictures: A selective Guide.* A film guide, *Index to 16 mm Educational Films,* is published by NI-CEM, University of Southern California, National Information Center for Educational Media, University Park, Los Angeles, CA 90024. The Library of Congress publishes a catalogue of motion pictures and filmstrips on many educational topics. Films may also be obtained from Psychological Cinema Register, Audiovisual Service, Pennsylvania State University, University Park, PA 16802; and New York University Film Library, Washington Square North, New York, NY 10003. If audio materials alone would be sufficient, a catalogue with a full listing may be obtained from The Center for Casette Studios, 8110 Webb Avenue, North Hollywood, CA 91605; and from Xerox University Microfilms, 300 North Zeeb Road, Ann Arbor, MI 48106.

In the section on Bibliotherapy, books and pamphlets on different subjects written for the general public will give educators ideas of content and methods of presentation.

A brief outline of suggested methods of working with films and conducting discussion groups follows.

SUGGESTIONS ON METHODS OF INTRODUCING AND DISCUSSING MENTAL HEALTH FILMS (OR VIDEOTAPES)

1. *General.* Mental health films presented to lay groups are mainly informational in objective. This means that the discussion leaders function as "experts." They must make the largest contributions elaborating on the theme of the film and clarifying the questions brought up by the audience. Nevertheless, audience participation must be encouraged. This can be done by stimulating discussion on several points illustrated by the film.

   Many members of the audience will identify with characters in the film. Consequently, the tone of the discussion must always be sympathetic and reassuring. *Never* belittle or ridicule any character; *never* say a condition is hopeless or incurable.

2. *Previewing the film.* If possible, preview the film, preferably at least an hour before the actual showing. Make a notation in writing of the following: (a) What is the theme of the film? (b) What three or four points does it illustrate? The discussion that follows the film may be organized around these points.

   If a preview of the film is not possible, study the *leader's guide* issued with the film, if there is such a guide, at least an hour before the showing. Make notations in writing of the film theme and of several psychiatric points that are illustrated.

   If a preview of the film is not possible and if there is no leader's guide, make a mental note of the theme and points raised while watching the film at the actual showing.

3. *Starting the class or meeting.* The class or meeting must be started sharply on time. Latecomers will probably come on time at the next meeting if this is done.

4. *Introducing the film.* There are two methods of introducing the film: Method 1—Give a brief lecture (10 to 15 minutes) on the general topic illustrated by the film, indicating which points the audience is to observe. Method 2—Describe the film briefly (1 to 5 minutes), indicating the general theme and the points the audience is to watch for especially.

5. *Film showing.* Arrangements will probably have been made with a projector operator so that the film is ready for showing on a signal from you. Since

breakdowns in equipment are common, you should determine in advance if the projector is in good working order. Do this also with the videotape recorder if a tape is to be shown.

6. *Discussing the film.* After reviewing the film, you may proceed along several lines:

   a. *Lecture.* If there is to be a lecture, this should last no more than 15 minutes. The points in the film are introduced in the context as illustrative material. Following this, the meeting is opened to discussion.

   b. *Presentation of the salient points of the film.* The chief points illustrated by the film are mentioned, following which there is discussion.

   c. *Asking pertinent questions about the film.* The points illustrated by the film are presented as questions. This is a very good way to get audience participation.

7. *Handling group situations.*

   a. *Group failing to participate.* When the group fails to enter into the discussion, ask one or two provocative questions. If no one responds, call on one member of the group.

   b. *A member arguing too much.* Simply say, "I understand your reaction; perhaps other people here would like to comment on it." The group usually has a way of subduing the the disturbed member. If this does not work, invite the person to discuss matters with you after the meeting.

   c. *One member talking too much.* At a pause in his talk, cut the person off with a summarizing statement and direct a question at someone else.

   d. *A member persisting on talking off the subject.* Cut the person off with the statement, "That is interesting, and we may come back to that later." Direct a question at someone else.

8. *Terminating meeting.* The meeting should be terminated after about one hour of discussion, or lecture and discussion. A brief summary is sometimes helpful, as is assignment of reading material.

SUGGESTIONS ON CONDUCTING A DISCUSSION GROUP

1. *General.* A discussion group provides the participants with perhaps the best opportunity for learning. Sharing ideas and experiences promotes an exchange of information. Verbalizing attitudes and doubts helps to resolve resistances and learning blocks. Furthermore, the discussion group may serve a therapeutic function, enabling individuals to gain a measure of assuredness in expressing their ideas and opinions and in working through fears, hostilities, and other disabling attitudes in relation to a group.

2. *Physical arrangements.*

    a. *Size of group.* The ideal size of the group ranges from 6 to 10 people. This number makes it possible for all members to contribute actively. In exceptional or unavoidable instances, a larger group may be handled, though this will involve some sacrifice in individual activity.

    b. *Position of chairs.* Seating arrangement is important to avoid your being placed in too prominent a position, which is apt to stifle discussion. Members may be seated facing you and one another around a table, or, if this is impractical, in chairs placed in a circle or semicircle. It goes without saying that proper ventilation, comfortable lighting and where smoking is permitted ash trays add to the relaxed atmosphere that is most conducive to good discussion.

    c. *Length of discussion sessions.* This will vary depending on the circumstances, but a good average is *H* hours.

    d. *Starting the session on time.* The session should begin on time. Latecomers will probably come on time at the next session if this is done.

3. *The first session.*

    a. Once members are seated, a good way to start is to ask members to introduce themselves to the group by stating their names, disciplines, (if they have one, and the organization, if any, with which they are associated. This serves to "break the ice" and to introduce an air of informality into the atmosphere.

b. Next introduce the general subject to be discussed and relate it to the interests of the group members. A distributed outline designating material to be considered is a very helpful adjunct.

c. If essential information needs to be conveyed to the members before discussion begins, a short talk is in order. If desired, introduce an auxiliary lecturer, or a movie, filmstrip, or other audiovisual aid. Make this preliminary presentation as brief as possible.

d. Following this, begin the discussion. If there is any doubt in the minds of the members about procedure, inform them that no one will be called on formally, that anyone may speak up whenever desired, and that members should limit their comments to 2 or 3 minutes at most.

e. Encourage the group to participate by any of the following methods:

(1) Ask a provocative question relating to the outline or to the material under discussion.

(2) If there are two points of view on a topic germane to the discussion, call for a show of hands of those who share the different viewpoints. Then ask a question as to why one or the other point of view is taken.

(3) Select a topic related to the general subject and ask if there is anyone in the group who has had experience with this topic.

(4) Using a blackboard, list the different opinions or ideas of the members about a topic, or possible approaches to the topic. Group these into specific categories, and then ask questions about the various listings.

4. *Subsequent sessions.* At the start of each subsequent session, you may summarize the salient points about the previous session and then bring up the topic for the present session. If new information is to be introduced, this may be done by, for example, assigned readings, written reports from the members, an informative talk by an expert, or films.

5. *Activity of the leader.* Your function as leader in a discussion group is to help the members verbalize their ideas and integrate their thinking about a specific subject. Your role is to participate in the discussion only when the members stop talking, when they deviate from the topic under

consideration, or when they are not able to think things through for themselves. Such participation does not mean delivering a lecture, giving advice, or showing off knowledge.

To fulfill this function, there must be respect for all the members in the group and for their opinions, resistances, and resentments. The fact must be accepted that the learning process requires time and that people must resolve their doubts and suspicions before they can accept ideas, no matter how logical these may seem. This will necessitate great tolerance and the ability to handle aggression that is projected by some members toward the group and toward you. Required is an informal manner and a sense of humor. Essential also is an ability to talk the same down-to-earth language as the group, eschewing complicated formulations and avoiding impressing the members with abstruse talk.

From time to time, clarify the material presented, particularly conflicting issues, and summarize the contributions that have been made by the members. If certain points are not covered, ask questions about these. Never argue, belittle, or disagree with anyone. If you have a contribution to make yourself, make it briefly, saying, "This is what I have come to believe," or "This is what is generally believed."

Handling special situations. This is, on the whole, handled as done in this category under the section on discussing films.

a. *Group fails to participate.* When the group fails to enter into discussion, ask one or two provocative questions. If no one responds, call on one member of the group. If, after this person comments, nobody else volunteers, say, "Perhaps someone has a different slant on this."

b. *A member arguing too much.* Simply say, "I can understand your reaction; perhaps other people here would like to comment on it." The group usually has a way of subduing the disturbed member. If this does not work, invite the person to discuss matters with you after the meeting.

c. *One member talking too much.* At a pause in this talk, cut the person off with a summarizing statement and direct a question at the group.

d. *A member persisting on talking off the subject.* Cut the person off with the statement, "That is interesting, and we may come back to that later." Direct a question at the group.

e. *A side argument developing between two or more members.* Rap on the table or chair and say, "May I interrupt please. Perhaps others here would like to comment on this question that is causing controversy." If this does not stop the argument, or if the argument spreads, say, "Obviously there are several points of view; perhaps I can help integrate them." Attempt then to explain why the differences exist and how they can be resolved. If no resolution is possible, say, "Let us think about this matter further, and we may have a chance to come back to it later." Following this, ask another question, directing the discussion into another channel.

f. *One member constantly interrupting the comments of others.* Firmly say to the person at each interruption, "X [the person interrupted] has not finished talking, let us permit X to continue." If this does not stop the person from interrupting, say, "There is something that is bothering you, and it may be helpful for you to see me after the session." Arrange then to have a talk or talks with the person, and if the disruptive activity does not halt, suggest that the person drop out from the group.

g. *Side conversations.* Rap on the table or chair and say, "Please let us all concentrate on what is being said."

h. *The discussion straying too far afield from the subject.* Say, "This is interesting, but how does it apply to the subject we are discussing?"

i. *A member refusing to budge from an opinionated and obviously erroneous point of view.* Do not take issue directly. Merely say, "Perhaps Y would like to bring in source material next time to back up that point of view." Then pass on to another person.

j. *A member refusing to participate.* Respect the person's silence. After a number of sessions, if the person asks to speak, respond positively immediately. Rarely you may say, "Perhaps Z may want to comment on this subject." If the person indicates no or remains silent, gloss this over with, "Not at this time; well, perhaps later."

k. *Lags in the discussion.* Point out the differences in ideas or opinions that have been presented, and ask how these differences may be reconciled.

l. *Unnecessary repetition.* Summarize what has been said, point out

important aspects and highlights; then introduce a different question.

7. *The recorder and observer.* In some discussion groups it is helpful to appoint a volunteer who will record the salient features of the discussion for purposes of transcription or for summarization at the end of the present or at the beginning of the next session. Another volunteer, an observer, may be appointed to record the activity or passivity of the various members and leaders, the interpersonal reactions, and perhaps the dynamics of the group process, if trained in dynamics, which may also be prepared at the end of the session or at the beginning of the next session.

8. *Summarizing the discussion.* Before the session ends, it may be helpful to summarize the discussion, mentioning the salient points that have been covered, relating the material to what has gone on in previous sessions, restating differences of opinion, tying together topics that have not been coordinated, and adding suggestions about procedure and areas of future exploration. It is essential that the summary contain the conclusions of the group rather than your own conclusions. If the group conclusions are in your opinion inadequate or erroneous, a statement may be made to the effect that further discussion on the subject will open up areas that may yield important data.

9. *Reading assignments and reports.* Assigned readings, and verbal or written presentations by the members, are helpful as teaching aids. They serve also to introduce new material for group consideration. Suggestions regarding readings may be obtained in the Bibliotherapy section in Chapter 56.

VI
Addenda

Selected Texts for Special Situations and Problems

The literature in the field of psychotherapy flourishes with ever increasing contributions from all divisions of the behavioral sciences. Accordingly, the selection of recommended reading becomes progressively more difficult as new books and periodicals accumulate. The present section contains a representative sampling of the most popular texts among students and reviewers. A more complete bibliography explicating specific topics will be found in the various chapters of this book. Obviously it will be difficult or impossible for any therapist to read or even to acquire all the recommended texts, which will undoubtedly be found on the shelves of any good psychiatric library. Readers, nevertheless, will be able discriminately to cull from the suggested lists items that suit their interests and needs. New books, as well as revisions, will undoubtedly appear as time goes by. Nevertheless, many of the present texts will in all probability continue to survive as classics.

The lists of books that follows has been divided into 50 main categories.

Appendix A

Statistical Data[14]

PATIENT'S NAME   Date:

ADDRESS   Interviewer:

HOME TELEPHONE   Referred by:

BUSINESS PHONE

            Informant (*if any*): Name and Address

            With whom is patient now living? (*list people*):

Age of Patient	Sex	Religion
Education	Occupation	Salary
If unemployed, sources of income		
Marital Status	How long married?	Any previous marriages? when?
Age of mate	Occupation of mate	Salary of mate
Military Record		
Miscellaneous		

---

[14]Short form: To be filled out by therapist, initial interviewer, or intake worker in a clinic set up.

Appendix B

Statistical Data

Patient's Name:
Case No.:

1.GENERAL DATA:

a.	Age	Date of Birth:

b. Sex (M, F)

c. Race

d. Religion

e. Birthplace

f. If foreign-born, date of arrival in U.S.

g. Naturalization dates: 1st Papers   2nd Papers

h. Education

i. Occupation

j. Employed (yes, no)

k. Salary

l. Yearly income, all sources

m. If unemployed, on what sources of income, or on what person is patient dependent, giving occupation and relationship to patient of this person.

n. Military Service (yes, no) dates:

o. Name and address of nearest relative or friend

p. With whom is patient living at present?

2. RESIDENTIAL DATA:

a. Address

b. Character of Residence   ( )house ( )apartment ( )room
                                        ( )self-owned ( )rented, rental cost:

c. Place of legal settlement

d. Length of residence in this town or city

e. Length of residence in state

f.   Home phone   Other phone

g.   Previous addresses (*include dates*)

3. MARITAL STATUS:

a.   M, S, W, Div, Sep

b.   Date of marriage

c.   Date termination of marriage

d.   Name of mate, if any

e.   Dates of previous marriages, if any

f.   Dates of termination of previous marriages and reasons

g.   Names and ages of children

4. FAMILY IDENTIFICATION DATA:

a.   Father's name   Living or dead?

Age at present or, if dead, age at death and year of death

Birthplace

If foreign-born, date arrival U.S.   Citizenship

b.   Mother's maiden name   Living or dead?

Age at present or, if dead, age at death and year of death

Birthplace

If foreign-born, date arrival U.S.   Citizenship

c.   Siblings (list names, ages, and sex)

5. SOCIAL SERVICE EXCHANGE (for clinic patients):

(Long form: Complete statistical data outline to be filled out by therapist or social worker)

Appendix C

Initial Interview
(to be filled out by initial interviewer)

PATIENT'S NAME   Date:

RECOMMENDATIONS AND REMARKS

Personal Data Sheet

Please fill out the following blank as completely as possible. This will save time and make it unnecessary to ask you routine questions. All material is confidential and will not be released except on your written request.

Name

Address

(Will it be all right to write to you at the above address for billing, changes of appointment, etc.?)

Home phone_____ Other phone_____

Can we call you at either of these?

In the event of a change in appointment, at what time can we reach you at these numbers?

Age _____ Birthday _____ Sex (M, F)_____

Birthplace _____

If foreign-born, date of arrival in U.S.? _____

If foreign-born, are you a citizen? _____

Approximately how long have you lived in this city? _____

Marital status (Single, Married, Separated, Divorced) _____

If married, how long ago? _____ If separated or divorced, when?_____

If married more than once, list dates of marriage, length of time married, whether marriage terminated by divorce, annulment, death
_____

List number and ages of children, if any _____

Occupation _____ Approximate gross yearly salary _____

How long have you been doing your present kind of work? _____

If unemployed, source of income at present _____

How far through school did you go? _____

Name and address of nearest relative or friend _____

Any military service? _____

Whom are you living with at present? _____

Who referred you here? _____

How strongly do you want treatment for your problem (check)
( )very much ( )much ( )moderately ( )could do without it, if necessary ( )do not want treatment

What days and times can you come here for treatments?_____

If your answer to above is after 5 p.m., can you, if necessary, get away for an hour once weekly during the day? _____

If psychologic or other tests are necessary to help your condition, would you object to them for any reasons? _____

Do you know what psychotherapy is? _____

APPENDIX E

Family Data Sheet
(to be filled out by patient)

NAME:

Please fill out the following blank as complete as possible. This will save time and make it unnecessary to ask you routine questions. All material is confidential and will not be released except on your written request.

1. List the first names of your father, mother, brother, and sisters, in chronologic order, and supply the following information about each:

List first names	Age	Live in what city?	If dead, year and cause	Marital status —M, Div, Sep, Wid	Do you see them often or write often to them (yes, no)	Personality adjustment (good, fair, poor)	How do (or did) you get along with them (good, fair, poor)?
Father:							
Mother:							
Sisters:							
Brothers:							

2. If married, age of mate:_____ Are you living with spouse now? _____

Occupation of spouse:_____

How are you getting along with spouse (good, fair, poor)? _____

3. List all of your children both present and previous marriages, by first names in chronologic order, giving the following information on each:

Name	Living or dead	Ages	Living with whom at present?	Check if by previous marriage	Personality adjustment (good, fair, poor)	How do you get along with child (good, fair, poor)?

Examiner	Daily Progress Note15	Date

PATIENT'S NAME

At each visit enter (1) present state of symptoms or complaints (absent, improved, the same, worse), (2) how patient feels (anxious, placid, depressed, happy), (3) important life situations and developments since last visit and how they were handled, (4) generate content of session, (5) significant transference and resistance reactions, (6) dreams.

15 On the standard form, this Daily Progress Note is given two full sides of an 8½ by 11 inch sheet, to allow for as complete a report as is required.

Monthly Progress Summary

This form will be found helpful in clinics where there is routine supervision of the entire case load. It is turned over monthly to supervisor.

Month covered in this report:

(Fill out this side and on back of sheet elaborate on any checked items as well as other items of importance, using additional sheets if necessary.)

NAME OF PATIENT   NAME OF THERAPIST

NUMBER OF SESSIONS THIS MONTH   TOTAL NUMBER OF SESSIONS TO DATE

PATIENT'S RESPONSE TO THERAPY:

---

1. General progress to date:

    ( )excellent ( )satisfactory ( )poor

    Symptoms are ( )better ( )the same ( )worse

2. Appointments:

    ( )comes on time ( )comes early ( )comes late

3. Communicativeness:

    ( )satisfactory ( )overproductive ( )incoherent ( )underproductive ( )responds on to questions ( )long periods of silence ( )other, describe:_____

4. Relationship with therapist/Working relationship:

    ( )good ( )fair ( )poor ( )intense dependency ( )sexual feelings ( )fear ( )detachment ( )negativism ( )hostility ( )other, describe: _____

5. Resistance:

    ( )low ( )moderate ( )strong ( )interferes with progress ( )"acting-out" tendencies

6. Insight:

    ( )achieving insight ( )curiosity about dynamics ( )intellectual, but not emotional, insight ( )resists insight

7. Translation of insight into action:

    ( )excellent ( )satisfactory ( )poor

8. Present symptoms: (Describe any checked items on back.)

( )new physical symptoms or complaints	( )sexual disturbance	( )intense anxiety
( )exaggerated old	( )intense	( )hallucinations

physical symptoms	depression	
( )work disability	( )suicidal threats	( )delusions
( )marked insomnia	( )suicidal attempts	( )excess alcohol
( )overactivity	( )destructive tendencies	( )excess sedatives/drugs
( )other, describe:		

9. Severe environmental problems

( )finances ( )work ( )family ( )other

REMARKS

1.   ( ) Supervisory Conference Needed:

      ( )emergency foreseen ( )dynamics not clear ( )treatment going poorly ( )patient wants to discontinue ( )may need medication ( )therapist considering closing ( )other, describe:_____

2.   ( ) Consultation Needed:

      ( )with caseworker ( )with psychologist ( )with medical consultant ( )with psychiatric consultant ( )other, describe:_____

3.   Other (describe briefly on back of sheet what has been going on in treatment during the last month):

Termination Note

---

1. NAME OF PATIENT

2. DATE OF INITIAL INTERVIEW

3. DATE OF TERMINAL INTERVIEW

4. TOTAL NUMBER OF SESSIONS

5. REASON FOR TERMINATION

    ( )planned termination   ( )withdrawal by patient (explain)

6. CONDITION AT DISCHARGE

    a.   ( )Recovered: Asymptomatic with good insight

    b.   ( )Markedly improved

           ( )Asymptomatic with some insight

           ( )Asymptomatic with no insight

    c.   ( )Moderately improved

           ( )Partial reduction of symptoms with good insight

           ( )Partial reduction of symptoms with some insight

    d.   ( )Slightly improved: Partial reduction of symptoms with little or no insight

    e.   ( )Unimproved

    f.   ( )Worse (describe)

7. AREAS OF IMPROVEMENT (use back of sheet, if necessary):

    a.   Symptoms

    b.   Adjustment to environment: (work, community, etc.)

    c.   Physical functions: (appetite, sleep, sex, etc.)

    d.   Relations with people

8. PATIENT'S ATTITUDE TOWARD THERAPIST AT DISCHARGE (use back of sheet, if necessary)

    ( )friendly ( )indifferent ( )unfriendly

9. WOULD PATIENT OBJECT TO A FOLLOW-UP LETTER INQUIRING ABOUT PROGRESS?

    ( )Yes ( )No

10. RECOMMENDATIONS TO PATIENT AT DISCHARGE (if any, Use back of sheet if necessary)

11. DIAGNOSIS AT DISCHARGE

10. ADDITIONAL COMMENTS (use back of sheet)

Summary[16]

PATIENT'S NAME		
Date of Summary:		Therapist:
Prepared by:	Total Treatment Sessions:	Initial Interview Date:

I. CHIEF COMPLAINT

II. HISTORY AND DEVELOPMENT OF COMPLAINT

III. OTHER COMPLAINTS AND SYMPTOMS

Outline for Case Presentation

---

1. Sex

3. Marital status

4. How long married?

5. Number and ages of children

6. Age and occupation of mate

7. Any previous marriages? When?

8. Relgion

9. Education

10. Occupation

11. Employed? Salary

12. If unemployed, source of income

13. Chief Complaint
(in patient's own words)

14. History and Development of Complaint
(date of onset, circumstances under which complaint developed, progression
rom the onset to the time of the initial interview)

15. Other Complaints and Symptoms
(physical, emotional, psychic, and behavioral symptoms other than those of the
complaint factor.)

16. Medical, Surgical, (and in Women Gynecologic History)

17. Environmental Disturbances at onset of Therapy
(economic, work, housing, neighborhood, and family difficulties)

18. Relationship Difficulties at onset of Therapy
(disturbances in relationships with people, attitudes toward the world, toward
authority, and toward the self)

19. Hereditary, Constitutional, and Early Developmental Influences
(significant physical and psychiatric disorders in patient's family, socioeconomic
status of family, important early traumatic experiences and relationships,
neurotic traits in childhood and adolescence)

20. Family Data
(mother, father, siblings, spouse, children—ages, states of health, personality
adjustment, and patient's attitudes toward each)

21. Previous Attacks of Emotional Illness
(as a child and later. When did patient feel himself to be completely free from
emotional illness?)

22. Initial Interview

(brief description of condition of patient at initial interview, including clinical findings)

23. Level of Insight and Motivation at onset of Therapy
(How long ago did the patient feel that he needed treatment? For what? Awareness of emotional nature of problem, willingness to accept psychotherapy)

24. Previous Treatments
(When did the patient first seek treatment? What treatment did he get? Any hospitalization?)

25. Clinical Examination
(significant findings in physical, neurologic, psychiatric, and psychologic examinations)

26. Differential Diagnosis
(at time of initial interview)

27. Estimate of Prognosis
(at time of initial interview)

28. Psychodynamics and Psychopathology

29. Course of Treatment
(up to time of presentation)

   a. Type of therapy employed, frequency, total number of sessions, response to therapist

   b. Significant events during therapy, dynamics that were revealed, verbatim report of important dreams, nature of transference and resistance

   c. Progress in therapy, insight acquired, translation of insight into action, change in symptoms, attitudes, and relationships with people

   d. Verbatim account of all or part of a typical session, if desired

CLINICAL EXPERIENCE (indicate names of therapeutic centers, clinics, institutions, or agencies; date of affiliation; capacity in which you have functioned)

CASE EXPERIENCE

When did you begin practicing psychotherapy?

Can you estimate the total number of patients treated?

Can you estimate the total number of patient sessions to date?

Underline the kinds of problems you have handled:
character disorder, psychopathic personality, anxiety neurosis, anxiety hysteria, conversion hysteria, obsessive compulsive neurosis, psychosomatic problem, alcoholism, drug addiction, borderline case, schizophrenia, psychoneurotic depression, manic-depressive psychosis, involutional melancholia, paranoid condition, marital problem, childhood behavior problem, childhood psychoneurosis, childhood psychosis, convulsive disorder

SUPERVISED CLINICAL EXPERIENCE
give names of supervisors, place of supervision, dates, total number of sessions with each supervisor

SUPERVISORY EXPERIENCE

Have you ever supervised therapists in psychotherapy?

If yes, how many therapists?

Total number of supervisory sessions

Have you ever had a course of instruction in psychotherapeutic supervision?

GROUP THERAPY

Have you ever done group therapy?

If so, underline types:
inspirational and supportive groups, educational groups, discussion groups, analytic groups, social and activity groups, psychodrama, other:_____

Total number of group therapy sessions

PSYCHOTHERAPEUTIC TEACHING EXPERIENCE
(courses taught, dates, places)

HAVE YOU EVER PUBLISHED ANY MATERIAL ON PSYCHOTHERAPY *(papers, pamphlets)*
If so, list:

Questions You May Have about Psychotherapy[17]

DO I NEED PSYCHOTHERAPY?

If you have nervous symptoms such as tension, depression, fears, fatigue, and certain physical complaints for which your doctor finds no physical basis; if you find it difficult to get along in your work or in your relations with people, if you have a school, sex, or marital problem; of if you merely feel irritable, unhappy, and believe you are not getting the most out of life, psychotherapy will be of help to you

HOW DOES PSYCHOTHERAPY WORK?

Nervous symptoms and unwarranted unhappiness are the product of inner emotional troubles. In psychotherapy you are helped to understand your problems. In this way it is possible for you to do something constructive about solving them.

CAN PHYSICAL SYMPTOMS BE CAUSED BY EMOTION?

Many physical symptoms are psychosomatic in nature, which means that they have an emotional or nervous basis. When you come to think of it, it is not really so strange that emotional strain or worry should produce physical symptoms. After all, every organ in your body is connected with your brain by nerve channels; and so it is logical that when your nervous system is upset by some crisis or conflict, you may feel the effects in various organs of the body.

IF I CANNOT SOLVE MY PERSONAL PROBLEMS WITHOUT HELP, DOES THAT MEAN THAT I HAVE A WEAK WILL OR AM ON THE WAY TO A MENTAL BREAKDOWN?

No. Even if you have no serious symptoms, it is difficult to work out emotional problems by yourself because you are too close to them and cannot see them clearly. More and more people, even those with a great deal of psychologic knowledge, are seeking help these days because they realize this. The fact that you desire aid is a compliment to your judgment and is no indication that you are approaching a mental breakdown. Psychotherapy has helped countless numbers of people to overcome serious emotional symptoms and has enabled many others to increase their working capacities and to better their relationships with people.

WHAT KIND OF TREATMENT WILL I NEED?

The kind of treatment best suited for you can be determined only by a careful evaluation of your problem by a professional therapist.

In scientific work records are necessary, since they permit a more thorough dealing with one's problems. It is understandable that you might be concerned about what happens to the information about you, because much or all of this information is highly personal. Case records are confidential. No outsider, not even your closest relative or family physician, is permitted to see your case record without your written permission.

HOW CAN I HELP TO COOPERATE WITH THE TREATMENT PLAN?

The general practitioner has medications; the surgeon works with instruments; the heart specialist has x-rays and delicate recording apparatus. But for the most part, the psychotherapist has only one aid besides knowledge—YOU. Your cooperation and trust in the therapist are essential. You must feel free to take up with your therapist anything about the treatment process that disturbs you or puzzles you in any way. By doing this you have the best chance of shortening your treatment and insuring its fullest success.

17 This form is useful in determining the didactic and experimental equipment of an applicant for a clinic position.

Personal History Sheet[18]

Last Name:
First Name:
Date:

This material is necessary for the completion of your records. In answering the questions use extra sheets if required, noting the number of the question that is being answered. This, as all other information, will be kept confidential. If you are particularly troubled by any question and do not desire to answer it, merely write in "Do not care to answer."

1. How would you describe your health (excellent, good, fair, poor)?

   a. Physical

   b. Emotional

2. What physical illnesses have you had? When?

3. When was your last examination by a physician?

   a. For what condition?

4. Have you in the last 2 years had:

   a. Chest x-ray

   b. Urine examination

   c. Blood tests

5. Have you ever been turned down for life insurance?

   a. If yes, why?

6. Have you ever been in a hospital? _____ If yes:

   a. Name of hospital

   b. Nature of illness

   c. Date and length of hospitalization

7. When was the last time you felt well both physically and emotionally for a sustained period?

8. Have you received treatment for "nervous" or emotional difficulties? If so:

   a. Date

   b. Frequency of visits

   c. Nature of treatment

d.   Whom treated by

9.   Does your present job satisfy you?
     If not, in what ways are you dissatisfied?

10. Do you think you could handle a job more difficult than those you have held?
     If yes, describe.

11. What is your ambition?

12. Do you make friends easily?   Do you keep them?

13. Are most of your friends of one gender?   Which?

14. Can you confide in your friends?

15. How is most of your free time occupied?

16. What medications (and dosages) are you taking at the present time?

17. Check any of the following that apply to you

( )	headaches	( )	depressed
( )	dizziness	( )	suicidal ideas
( )	fainting spells	( )	always worried about something
( )	palpitations	( )	unable to relax
( )	stomach trouble	( )	unable to have a good time
( )	no appetite	( )	don't like weekends and vacations
( )	bowel disturbances	( )	over-ambitious
( )	fatigue	( )	sexual problems
( )	insomnia	( )	shy with people
( )	nightmares	( )	can't make friends
( )	take sedatives	( )	can't make decisions
( )	alcoholism	( )	can't keep a job
( )	feel tense	( )	inferiority feelings
( )	feel panicky	( )	home conditions bad
( )	tremors	( )	financial problems

Physical, Neurologic, and Laboratory Examinations

(Check items in which abnormality exists and explain below.)

I. Physical Examination

( )	Stature	( )	Tongue	( )	Abdomen
( )	Nutrition	( )	Gums and teeth	( )	Hernia
( )	Weight	( )	Pharynx	( )	Genitals
( )	Skin	( )	Tonsils	( )	Muscles
( )	Hair	( )	Neck	( )	Bones
( )	Scalp	( )	Thyroid gland	( )	Joints
( )	Eyes	( )	Chest	( )	Spine
( )	Nose	( )	Breasts	( )	Extremities
( )	Sinuses	( )	Lungs	( )	Nails
( )	Ears	( )	Heart	( )	Lymphatic glands
( )	Lips	( )	Blood vessels	( )	Other (explain below)
( )	Mouth	( )	Blood pressure		

II. Neurologic Examination

( )	Station	( )	Oculomotor, trochlear, and abducens nerves
( )	Gait	( )	Trigeminal nerve
( )	Tactile sense	( )	Facial nerve
( )	Pressure sense	( )	Auditory nerves
( )	Temperature	( )	Glossopharyngeal nerve
( )	Pain	( )	Vagus nerve
( )	Muscular sense	( )	Spiral accessory nerve
( )	Stereognostic nerve	( )	Hypoglossal nerve
( )	Olfactory nerve	( )	Knee jerk
( )	Optic nerve	( )	Abdominal and epigastric reflexes
( )	Achilles reflex	( )	Sphincteric reflexes

( )	Wrists, biceps, triceps reflexes	( )	Motor disturbances
( )	Babinski reflex	( )	Paresis
( )	Oppenheim's reflex	( )	Hypotonia
( )	Gordon reflex	( )	Tremors, tics, spasms
( )	Cremasteric reflex	( )	Other (explain below)

III. Miscellaneous Examinations

( )	Urinalysis	( )	X-ray examiniation
( )	Blood analysis	( )	Electrocardiogram
( )	Endocrine analysis	( )	Electroencephalogram
( )	Other (specify)		

IV. Summary of Physical, Neurologic, and Laboratory Examiniations

If examinations are essentially negative, check below. Explain items that have been checked above.

( )   Physical examination negative

( )   Neurologic examination negative

( )   Miscellaneous examinations negative

APPENDIX Q

Mental Examination

NAME OF PATIENT

(Check the following and elaborate below.)

I. Attitude and General Behavior

a. Physical appearance ( )disheveled ( )untidy ( )unkempt

b. Degree of cooperativeness ( )fair ( )poor

c. General manner ( )mistrustful ( )suspicious ( )antagonistic
( )negativistic ( )defiant ( )preoccupied

d. General activity ( )motor retardation ( )hyperactivity
( )stereotype ( )mannerisms
( )tics ( )echolalia
( )echopraxia ( )preservation
( )compulsion

II. Stream of Mental Activity

a. Accessibility ( )indifferent ( )self-absorbed ( )inaccessible

b. Productivity ( )voluble ( )circumstantial ( )flight of ideas
( )under-productive ( )retarded ( )mute

c. Progression of thought ( )illogical ( )suspicious ( )irrelevant
( )incoherent ( )verbigeration ( )blocking

d. Neologisms

III. Emotional Reactions

a. Quality of affect ( )elation ( )exhilaration ( )exaltation
( )euphora ( )mild depression
( )moderate depression ( )severe depression
( )apprehension ( )fear ( )anxiety
( )irritability ( )morbid anger
( )apathy ( )emotional instability

b. Appropriateness ( )incongruity with thought content ( )ambivalence
of affect ( )emotional deterioration

IV. Mental Trend—Content of Thought

a. Thinking ( )phobias ( )obsessive ideas
disorders ( )psychosomatic complaints ( )persecutory trend
( )ideas of reference ( )grandiose ideas
( )depressive delusions ( )nihilistic delusions
( )hypochondriac ideas ( )ideas of unreality

( )deprivation of thought ( )delusions of influence
( )autistic thinking

b. Perceptive   ( )auditory hallucinations ( )visual hallucinations
    disorders

c.   ( )olfactory hallucinations ( )tactile hallucinations
                             ( )reflex, microptic, hypnagogic, or psychomotor
                             hallucinations ( )illusions

V. Sensorium, Mental Grasp, and Capacity

a. Disorders of consciousness   ( )confusion ( )clouding ( )dream state
                             ( )delirium ( )stupor

b. Disorders of apperception   ( )mild ( )severe

c. Disorders of orientation   ( )time ( )place ( )person

d. Disorders of personal   ( )general amnesia ( )circumscribed amnesia
    identification and memory   ( )confabulation ( )retrospective
                             ( )falsification hypermnesia

e. Disorders of retention and   ( )mild ( )severe
    immediate recall

f. Disorders of counting and   ( )mild ( )severe
    calculation

g. Disorders of reading   ( )mild ( )severe

h. Disorders of writing   ( )mild ( )severe

i. Disorders in school and general ( )mild ( )severe
    knowledge

j. Disorders in attention,   ( )mild ( )severe
    concentration, and thinking
    capacity

k. Disorders in intelligence   ( )inconsistent with education
                             ( )mild ( )severe

l. Disorders in judgment   ( )mild ( )severe

m. Disorders in insight   ( )mild ( )severe

VI. Summary of Mental Examination

(check and describe abnormality, if any):

( )   Mental examination essentially negative

( )   Disturbance in attitude and general behavior

( )   Disturbance in stream of mental activity

( )   Disturbance in emotional reaction

( )   Disturbance in mental trend—content of thought

( )   Disturbance in sensorium, mental grasp and capacity

APPENDIX R

Authorization for Release of Medical Records

TO:_____

ADDRESS:_____

I would appreciate your releasing to _____ all records
or abstracts pertaining to my case. I herewith grant permission for this release.

SIGNED:_____

Witness:_____

Date:_____

Progress Report[19]

NAME:

DATE:

At the beginning of each month, it would be helpful if you would write a brief report on how you feel and what you believe has been accomplished in the past month.

Check the following:

The symptoms or complaints for which I sought treatment originally are:

( ) the same

( ) better

( ) worse

My understanding of my condition is:

( ) excellent

( ) good

( ) fair

( ) poor

I believe my relationship with my therapist to be:

( ) good

( ) fair

( ) in need of improvement

I would consider my progress to be:

( ) excellent

( ) good

( ) fair

( ) poor

Additional Comments:

19 This sheet may be given monthly to selected patients for a progress report.

Antidepressant Medications: Special Instructions for Patients[20]

TYPE OF MEDICINE

These medications properly taken can relieve depression *immediately or take up to 4 weeks of continuous medication.* The percentage of success with these medications is very high, and if the patient cooperates by not skipping medication and not under or overdosing hospitalization is rarely (less than 5%) necessary. The average time for signs of recovery to appear is 1 to 4 weeks.

DOSAGE

It cannot be overstressed that the medication should be taken as prescribed and not skipped. It is common for depressed persons to be their own worst enemies and thus, on one pretext or another, not take the medication as prescribed or most frequently to skip doses or days.

SIDE EFFECTS

Almost all good modern medicines have some mildly undesirable or minor reactions which are usually unimportant. Do not become alarmed. Usually it is best to tell the doctor if you do get them.

1. Dryness of the mouth is probably the most frequent. Ignore it, or chew gum, keep hard candy in the mouth, or take liquids often.

2. Blurring of vision—is usually due to a temporary enlargement of the pupil. If it bothers you a great deal or interferes with your work, tell the doctor.

3. Lowered blood pressure—*Do not stand suddenly*. If you should forget and stand suddenly after having been on the medicine for some time, you get nauseous or dizzy. If you are afraid of fainting, lie flat. Get an elastic bandage to wrap tightly around the abdomen (belly). The wrapping should be at least 8 inches wide. A tight girdle or similar support may be enough. An abdominal support purchased in a surgical supply house or drugstore is best. Put the support on before getting out of bed in the morning and continue to wear it daily until the doctor says you may stop. It is rarely necessary to wear elastic stockings or wrap elastic bandages around the legs to the hip. The belly support tightly and properly applied is usually adequate. If it is not, tell the doctor and have him check your blood pressure *in the standing position*. The doctor can also use additional medicines to raise your

pressure.

4. Constipation—Your body can adjust to bowel movements occurring every 2-3 days, and, thus, if medication or depression does this, laxatives are not required. Do not take any laxative but mineral oil or milk of magnesia except with the doctor's advice.

5. Minor and rare inconveniences—never reason for stopping medication.

a. Sweating—excessive perspiration may occur in some persons. This is usually a sign that an adequate dosage is being used. Excessive sweating may also be caused by nervousness, so do not stop medication under these circumstances; discuss it with your doctor.

b. Sleepiness—most fatigue and sleepiness is due to emotional problems. Rarely, temporary sleepiness of a week's duration is caused by medication. Under no circumstances stop the medication entirely because of this. Dose may be taken more toward bedtime, decreased with doctor's consent, or sleepiness will stop after a week on the medication.

c. Shakiness—most shakiness is due to the emotional problem. Rarely is it due to medication. Discuss this with your doctor.

**IMPORTANT! Most antidepressants will mix well with foods or other medicines. However, if you are treated by another doctor for anything, even a cold, you should remind him that you are taking an antidepressant or have been in the last two weeks

d. DO NOT USE ALCOHOL IN ANY FORM

e. Do not take any medication without the doctor's knowledge, especially over-the-counter medicines with the exception of aspirin, mineral oil, or milk of magnesia. In particular, avoid cold and cough medicines, antihistamines, and reducing or sleeping medicine. It is also well to avoid coffee and "colas" as they increase nervousness.

**MOST IMPORTANT—For those on MAO antidepressants only. If the doctor tells you that you are on an especially strong antidepressant, such as an MAO (monoamine oxidase inhibitor) for depression, then:

f. Do not use alcohol in any form, especially Chianti wine.

g. Do not eat cheese, except cottage cheese

h. Do not eat prepared herring or similar products, no wax beans, or other foods that the doctor may prohibit.

Almost all people get the "blues" or are depressed for some period of time. You have a longer period of depression than is healthy. You may usually feel that there is no hope for you …that you're not worth taking the time and money to cure …that you're too tired to make any effort …or that you're the one person who can't be cured. Usually your concentration and memory have temporarily declined. You may have little feeling for those you have loved before, even in your own family, and you may have little interest in sex. These and some other things are characteristic of depression. *They respond easily to treatment—do not give up hope.*

APPENDIX U

Questions You May Have about Hypnosis

Exactly What is Hypnosis?

Hypnosis is a state of altered consciousness that occurs normally in every person just before one enters into the sleep state. In therapeutic hypnosis we prolong this brief interlude so that we can work within its bounds.

Can Everybody be Hypnotized?

Yes, because it is a normal state that everybody passes through before going to sleep. However, it is possible to resist hypnosis like it is possible to resist going to sleep. But even if one resists hypnosis, with practice the resistance can be overcome.

What is the Value of Hypnosis?

There is no magic in hypnosis. There are some conditions in which it is useful and others in which no great benefit is derived. It is employed in medicine to reduce tension and pain that accompany various physical problems and to aid certain rehabilitative procedures. In psychiatric practice it is helpful in short-term therapy and also, in some cases, in long-term treatment where obstinate resistances have been encountered.

Who Can Do Hypnosis?

Only a qualified professional person should decide whether one needs hypnosis or could benefit from it. In addition to other experience, the professional person requires further training in the techniques and uses of hypnosis before being considered qualified.

Why Do Some Doctors Have Doubts About Hypnosis?

Hypnosis is a much misunderstood phenomenon. For centuries it has been affiliated with spiritualism, witchcraft, and various kinds of mumbo jumbo. It is a common tool of quacks who have used it to "cure" every imaginable illness, from baldness to cancer. The exaggerated claims made for it by undisciplined persons have turned some doctors against it. Some psychiatrists too doubt the value of hypnosis because Freud gave it up 60 years ago and because they themselves have not had too much experience with its modern uses.

If Hypnosis is Valuable, Shouldn't it be Employed in all Psychological or Psychiatric

Most psychological and psychiatric problems respond to treatment by skilled therapists without requiring hypnosis. Where blocks in treatment develop, a therapist skilled in hypnosis may be able to utilize it effectively. But only a qualified professional person can decide whether this is necessary or desirable.

Is the Use of Hypnosis Endorsed by the Proper Authorities?

Both the American Medical Association and the American Psychiatric Association have qualified hypnosis as a useful form of treatment in the hands of skilled doctors who have had adequate training and who employ it in the context of a balanced treatment program.

Can Hypnosis be Dangerous?

The hypnotic state is no more dangerous than is the sleep state. But unskilled operators may give subjects foolish suggestions, such as one often witnesses in stage hypnosis, where the trance is exploited for entertainment purposes. A delicately balanced and sensitive person exposed to unwise and humiliating suggestions may respond with anxiety. On the whole, there are no dangers in hypnosis when practiced by ethical and qualified practitioners.

I Am Afraid I Can't be Hypnotized?

All people go through a state akin to hypnosis before falling asleep. There is no reason why you should not be able to enter a hypnotic state.

What Does it Feel Like to be Hypnotized?

The answer to this is extremely important because it may determine whether or not you can benefit from hypnosis. Most people give up hypnosis after a few sessions because they are disappointed in their reactions, believing that they are not suitable subjects. The average person has the idea that he will go through something different, new and spectacular in the hypnotic state. Often he equates being hypnotized with being anaesthetized, or being asleep, or being unconscious. When in hypnosis, he finds that his mind is active; that he can hear every sound in the room; that he can resist suggestions if he so desires; that his attention keeps wandering, his thoughts racing around; that he has not fallen asleep; and that he remembers everything that has happened when he opens his eyes, and thus he believes himself to have failed. He imagines then that he is a poor subject, and he is apt to abandon hypnotic treatments. *The experience of being hypnotized is no different from the experience of relaxing and of starting to go to sleep.* Because this experience is so familiar to you, and because you may expect something startlingly different in hypnosis, you may get discouraged when a trance is induced. Remember, you are not anaesthetized, you are not unconscious, you are not asleep. Your mind is active, your thoughts are under your control, you perceive all stimuli, and you are in complete

communication with the operator. The only unique thing you may experience is a feeling of heaviness in your arms and tingliness in your hands and fingers. If you are habitually a deep sleeper, you may doze momentarily; if you are a light sleeper, you may have a feeling you are completely awake.

How Deep Do I Have to Go to get Benefits from Hypnosis?

If you can conceive of hypnosis as a spectrum of awareness that stretches from waking to sleep, you will realize that some aspects are close to the waking state, and share the phenomena of waking; and some aspects are close to sleep, and participate in the phenomena of light sleep. But over the entire spectrum, suggestibility is increased; and this is what makes hypnosis potentially beneficial, provided we put the suggestibility to a constructive use. The depth of hypnosis does not always correlate with the degree of suggestibility. In other words, even if you go no deeper than the lightest stages of hypnosis and are merely mildly relaxed, you will still be able to benefit from its therapeutic effects. It so happens that with practice you should be able to go in deeper, but this really is not too important in the great majority of cases.

How Does Hypnosis Work?

The human mind is extremely suggestible and is being bombarded constantly with suggestive stimuli from the outside, and suggestive thoughts and ideas from the inside. A good deal of suffering is the consequence of "negative" thoughts and impulses invading one's mind from subconscious recesses. Unfortunately, past experiences, guilt feelings, and repudiated impulses and desires are incessantly pushing themselves into awareness, directly or in disguised forms, sabotaging one's happiness, health, and efficiency. By the time one has reached adulthood, he has built up "negative" modes of thinking, feeling, and acting that persist like bad habits. And like any habits they are hard to break. In hypnosis we attempt to replace these "negative" attitudes with "positive" ones. But it takes time to disintegrate old habit patterns; so do not be discouraged if there is no immediate effect. If you continue to practice the principles taught you by your therapist, you will eventually notice change. Even though there may be no apparent alterations on the surface, a restructuring is going on underneath. An analogy may make this clear. If you hold a batch of white blotters above the level of your eyes so that you see the bottom blotter, and if you dribble drops of ink onto the top blotter, you will observe nothing different for a while until sufficient ink has been poured to soak through the entire thickness. Eventually the ink will come down. During this period while nothing seemingly was happening, penetrations were occurring. Had the process been stopped before enough ink had been poured, we would be tempted to consider the process a failure. Suggestions in hypnosis are like ink poured on layers of resistance; one must keep repeating them before they come through to influence old, destructive patterns.

How Can I Help in the Treatment Process?

It is important to mention to your therapist your reactions to treatment and to him

or her, no matter how unfounded, unfair, or ridiculous these reactions may seem. Your dreams may also be important. If for any reason you believe you should interrupt therapy, mention your desire to do so to your doctor. Important clues may be derived from your reactions, dreams, and resistances that will provide an understanding of your inner problems and help in your treatment.

Wouldn't Hypnotic Drugs be Valuable and Force Me to Go Deeper?

Experience shows that drugs are usually not necessary. Often they complicate matters. If you should require medications, these will be employed.

What about Self-Hypnosis?

"Relaxing exercises," "self-hypnosis," and "auto-hypnosis" are interchangeable terms for a reinforcing process that may be valuable in helping your therapist help you. If this adjunct is necessary, it will be employed. The technique is simple and safe.

Relaxing Exercise

These exercises may be performed the first thing in the morning before getting out of bed. They may be repeated during the day if desired. They should always be done at night prior to retiring; relaxing suggestion will eventually merge into sleep. The total time for each session should be at least 20 minutes.

After shutting your eyes, proceed with the following steps:

1. Deep slow breathing for about 10 breaths.

2. Progressive muscle relaxation from forehead, face, neck to fingertips; from chest to toes, visualizing and purposefully loosening each muscle group.

3. Visualizing a wonderfully relaxed scene or simply a blank white wall.

4. low counting to self from 1 to 20 while visualizing the relaxed scene (or white wall).

5. Relaxing or sleeping from 1 to 2 minutes during which visualization of the relaxed scene continues.

6. Make the following suggestions to yourself (using the word "you").

a. *Symptom relief* (disturbing symptoms, like tension, etc., will get less and less upsetting).

b. *Self-confidence* (self-assuredness will grow).

c. *Situational control* (visualize impending difficult situations and successful mastery of them).

d. *Self-understanding* (make connections if possible between flare-ups of symptoms and precipitating events and inner conflicts).

7. Relax or sleep for several more minutes.

8. During daytime arouse yourself by counting from one to five. At night do not arouse yourself; continue relaxing until sleep supervenes.

If sleep begins developing during the 4th step before the count comes to an end,

interrupt counting and proceed immediately to suggestions (6th step above). Then continue with count and go as deeply as you wish. A racing of the mind and a tendency to distraction are normal. When this occurs force your attention back to the exercises.

Remember, you will not really be asleep during these exercises. You will be aware of your thoughts and of stimuli on the outside. If, for any reason, before you finish you want to bring yourself out of the relaxed state, tell yourself that at the count of 5 you will be out of it. Count from 1 to 5 and say to yourself: "Be wide awake now, open your eyes." If negative thoughts crop up, bypass them, and continue with the steps outlined above. *Results are rarely immediate.* It takes a while to neutralize negative suggestions you have been giving yourself all your life. So be patient. Persistence is the keynote to success.

Tables & Figures

Table 2-1 Varieties of Psychotherapy

Type of Treatment	Objectives	Illustrative Therapies
Supportive Therapy	Strengthening of existing defenses. Elaboration of new and better mechanisms of maintaining control. Restoration to an adaptive equilibrium.	Guidance, Environmental Manipulation, Externalization of Interests, Reassurance, Pressure and Coercion, Persuasion, Emotional Catharsis and Desensitization, Prestige Suggestion, Suggestive Hypnosis, Inspirational Group Therapy, Supportive Adjuncts (Somatic Therapy, Muscular Relaxation, Hydrotherapy)
Reeducative Therapy	Deliberate efforts at readjustment, goal modification, and the living up to existing creative potentialities, with or without insight into conscious conflicts.	Behavior and Conditioning Therapy, "Relationship Therapy," "Attitude Therapy," "Interview Psychotherapy," Client-centered Therapy, Directive Therapy, Distributive Analysis and Synthesis (Psychobiologic Therapy), Therapeutic Counseling, Casework Therapy, "Rational Therapy," Reeducative Group Therapy, Marital Therapy, Family Therapy, Psychodrama, Semantic Therapy, Philosophic Approaches (Existential, Zen Buddhist), Strategic Therapy, Cognitive Therapy
Reconstructive Therapy	Insight into unconscious conflicts, with efforts to achieve extensive alterations of character structure. Expansion of personality growth with development	Freudian Psychoanalysis, Ego Analysis, Kleinian Analysis, Object Relations Therapy, Neo-Freudian Psychoanalysis (Adler, Jung, Stekel, Rank, Ferenczi, Reich, Fromm, Sullivan, Horney, Rado), Psychoanalytically Oriented Psychotherapy, Transactional Approaches, Existential Analysis, Analytic Group Therapy, Adjunctive Therapies (Hypnoanalysis, Narcotherapy, Play Therapy, Art Therapy)

of new
adaptive
potentialities.

Table 2-2 Approaches to Mental Illness

Approach	Principal Fields Involved	Affiliated Professionals and Workers	Illustrative Treatment Methods
Biological	Neuroanatomy, Neurophysiology, Neurology, Biochemistry, Ethology, Genetics, Behavioral Genetics	Neuroanatomists, Neurophysiologists, Neurologists, Geneticists, Physiologists, Biologists, Biochemists, Ethologists, Physicans, Nurses	Somatic Therapies (Drug Therapy, Sleep Therapy, Electroconvulsive Therapy, Insulin Coma, Psychosurgery)
Psychological	Conditioning and Learning Theory, Developmental Theory, Personality Theory, Psychoanalytic Theory	Psychiatrists, Psychologists (experimental, educational, developmental, clinical), Educators, Psychiatric Social Workers, Psychiatric Nurses	Psychotherapy (Psychoanalysis, Behavioral Therapy, Therapeutic Counseling, Gestalt Therapy, Hypnotherapy, etc.)
Sociological	Social Theory, Role Theory, Field Theory, Ecology, Cultural Anthropology, Group Dynamics	Sociologists, Social Workers, Social Psychologists, Anthropologists, Mental Health Aids, Paraprofessionals	Casework, Environmental (Milieu) Therapy, Rehabilitation, Group Therapy, Psychodrama, Sociodrama, Family Therapy, Social Therapy, Transactional Therapy
Philosophic	Religion, Philosophy	Clergymen, Philosophers, Psychotherapists	Religious Therapy, Transcendental Meditation, Existentialism, Zen Buddhism, Yoga, Cognitive Therapy

Table 7-1 Helping, Counseling, and Psychotherapeutic Relationships

	Helping Situation	Counseling Supportive Psychotherapy	Psychotherapy (Reeducative and Reconstructive Goals)
Objectives	Symptom relief	Correction of situational problem, rectification of deviant behavior, expansion of personal abilities and skills, restoration of defenses, prevention of emotional breakdown	Alteration of defenses, facilitation of interpersonal and social adjustment, personality growth and development
Interview focus	Manifest complaints and interpersonal problems	Symptoms, situational problems, conflicts, attitudes	Underlying roots of complaints and conflicts, defenses, coping mechanisms, fantasies, symbolisms
Psychic arena	Conscious processes	Conscious processes	Conscious, preconscious, and in psychoanalysis, unconscious processes
Temporal focus	Immediate present	Immediate present	Immediate present and historical past
Technical processes	Support, reassurance, emotional catharsis, placebo influence, group dynamics	Guidance, clarification, suggestion, environmental manipulation, use of community resources	Inculcation of insight, pattern reinforcement and extinction, and in psychoanalysis, dreams and free association
Transference	Positive transference encouraged and utilized	Positive transference encouraged and utilized, negative transference discouraged	Transference interpreted when it acts as resistance
Transference neurosis	Avoided	Avoided	In psychoanalysis purposefully promoted to release repressions and to detect sources of inner conflict, otherwise circumvented if possible
Countertransference	Positive feelings utilized to promote supportive process	Positive feelings utilized, negative feelings controlled	Constantly examined, analyzed, and resolved

Table 8-1 Course of Psychotherapy

(in relation to symptom relief, behavior change, and reconstructive personality change)

	Early Phases			Middle Phases	Late Phases
Negative Factors	Defective motivation↓	Continuing Conflict ↓	Secondary gains ↓	Resistance, Transference, ↓ Transference Neurosis	Dependency ↓
1. Symptom relief					
2. Behavior Change					
3. Reconstructive personality change					
Positive Factors	Placebo influence Emotional catharsis Idealized relationship Suggestion	Insight Interpretation	Working-through Process	Corrective relearning experience	Resolution of Dependency
	Group dynamics	Supportive	Educative and Adjunctive		Techniques

During early phases of therapy there is often an immediate and dramatic relief of symptoms brought about by such positive factors as the placebo influence, emotional catharsis, idealized relationships, suggestion, and group dynamics. There is some attitude and behavior change, but little or no reconstructive personality change. Therapy interrupted at this point – as it is in short-term therapy – will show a considerable degree of symptomatic improvement. However, if therapy continues, and particularly where habitual behavior patterns are challenged, resistance and transference will erupt and will reduce or temporarily eliminate symptomatic and behavioral improvement. Treatment stopped in the middle phases will then tend to show a poorer response than if it had been discontinued before. However, as working-through of transference and resistance goes on, and, as corrective relearning takes place, symptomatic and behavioral improvement will rise accompanied by reconstructive changes. A propitious experience during short-term therapy may initiate reconstructive changes that will still require protracted time span outside of the therapeutic situation before they become manifest. This eventuality is not as consistent as it might be in properly motivated patients, who are able to endure the rigors of long-term depth therapy conducted by "effective" therapists.

Table 8-2 Estimated Results in Psychotherapy

Estimates of symptom improvement, behavioral and reconstructive personality change with various kinds of approaches

Area of change	"Spontaneous" Improvement	Helping Situation with a Non-trained Helper*		Counseling Situation (trained counselor)		Therapeutic Situation (trained therapist)	
Symptom relief or cure		"Effective" Helper	"Ineffective" Helper	"Effective" Counselor	"Ineffective" Counselor	"Effective" Therapist	"Ineffective" Therapist
	60%	70%	30%	80%	30%	80-90%	30%
Behavior change	40	50	20	60-70	20	70-80	20
Reconstructive personality change	10	15	5	20	5	40**	5

* The same results will be obtained with untrained and unskilled counselors and therapists.

** Where therapist is not trained in depth techniques the figure will approximate 20%

The average person with an emotional problem will spontaneously seek out solutions for one's problems that will result in a certain degree of symptomatic and behavioral improvement, as well as of personality change. Opportunity for the *greatest improvement* above that of the "spontaneous" rate in all three areas will be afforded one with an "effective" psychotherapist, for *considerable improvement* with an "effective" trained counselor, and for *some improvement* with an "effective" helping agency. In the hands of an "ineffective" helping agency, counselor, or psychotherapist, changes for improvement will be approximately half that of the spontaneous rate.

Table 9-1
Brain Functioning and Psychoactive Drugs

Brain Area	Function	Chemical Effect	Drug
Neocortex	Thinking; reasoning	Stimulation	Caffeine, Amphetamine (1), Methylphenidate (10)
		Depression	Barbiturates (3), Nonbarbiturate Hypnotics (11)
Thalamus	Integrating sensation; transmitting and modulating alerting impulses	Stimulation	Barbiturates (3), Phenothiazines (13)
		Depression	Meprobamate (9)
Reticular formation	Alerting; integrating emotional responses to stimuli	Stimulation	Rauwolfia derivatives (14) (small doses)
		Depression	Phenothiazines (13), Barbiturates (3), Rauwolfia derivatives (14) (large doses). Amitriptyline (2), Imipramine (7), Methylphenidate (10), Nonbarbiturate Hypnotics (11), Thioxanthenes (16), Butyrophenones (17)
Limbic System	Regulating emotions	Stimulation	Phenothiazines (13), Rauwolfia derivatives (14), Thioxanthenes (16), Butyrophenones (17)
		Depression	Meprobamate (9), Barbiturates (3), Chlordiazepoxide (4), Diazepam (5), Oxazepam (12), Tybamate (15), Hydroxyzine (6)
Hypothalamus	Controlling autonomic and endocrine functions	Stimulation	*MAO inhibitors (hydrazines)(8). Amphetamine (1)
		Depression	Phenothiazines (13), Rauwolfia derivatives (14), Barbiturates (3), Thioxanthenes (16), Butyrophenones (17)
Synapses	Transmitting nerve impulses	Stimulation	Rauwolfia derivatives (14), Acetylcholine
		Depression	Epinephrine, Amphetamine (1), Mescaline, LSD, Imipramine (7), Amitriptyline (2), Gamma Aminobutyric Acid
Interneuronal circuits	Coordinating neuronal masses	Depression	Meprobamate (9)
Neurohormonal depots (serotonin, norepinephrine.	Regulating brain metabolism	Stimulation	MAO inhibitors (8), Imipramine (7)
		Depression	Phenothiazines (13), Rauwolfia derivatives (14) Benzoquinolizenes,

etc.)	Thioxanthenes (16), Butyrophenones (17)

* Electroconvulsive Therapy is said to stimulate the posterior hypothalamus (Gellhorn et al. 1963).

(1) Amphetamine (Benzedrine. Dexedrine, etc.); (2) Amitriptyline (Elavil); (3) Barbiturates (Phenobarbital. Pentothal. Seconal, etc.); (4) Chlordiazepoxide (Librium); (5) Diazepam (Valium); (6) Hydroxyzine (Vistaril); (7) Imipramine (Tofranil), Desipramine (Norpramin, Pertofrane); (8) MAO inhibitors (Nardil, Marplan), Niacin, etc.; (9) Meprobamate (Equinal. Miltown); (10) Methylphenidate (Ritalin); (II) Nonbarbiturate Hypnotics (Doriden. Noludar, etc.); (12) Oxazepam (Serax); (13) Phenothiazines (Thorazine. Stelazine. Mellaril, Trilafon, Permitil. etc.); (14) Rauwolfia derivatives (Reserpine etc.); (15) Tybamate (Solacen); (16) Thioxanthenes (Taractan. Navane); (17) Butyrophenones (Haldol).

From Wolberg LR: Psychotherapy and the Behavioral Sciences. Orlando, FL, Grune & Stratton, 1966.

Table 9-2
Symptomatic Uses of Psychoactive Drugs

Desired Drug Effect	Drug
Enhancing cortical activity (facilitating alertness and thinking)	Amphetamine (Benzedrine, Dexedrine, Dexamyl), Methylphenidate (Ritalin), Caffeine
Diminishing excessive cortical activity (producing calming and sedation)	Barbiturates (Phenobarbital), Nonbarbiturate hypnotics (Doriden), Bromides (Triple Bromides)
Controlling anxiety and tension	Diazepoxides (Valium, Librium)
Elevating mood (overcoming depression)	Amphetamine (Benzedrine, Dexedrine, Dexamyl), Methylphenidate (Ritalin), Mono-aminooxidase inhibitors (Nardil, Parnate, Marplan), Amitriptyline (Elavil), Imipramine (Tofranil), Desipramine (Pertofrane, Norpramin)
Eliminating apathy (especially in borderline or schizophrenic states)	Phenothiazines with a piperidine or piperazine ring on side chain (Mellaril, Stelazine, Trilafon)
Inhibiting excitement, confusion, tension, and anxiety (especially in schizophrenic and manic states)	Phenothiazines (Thorazine, Mellaril), Thioxanthenes (Taractan, Navane), Butyrophenones (Haldol)
Restoring mental integration (controlling hallucinations and delusions)	Phenothiazines (Thorazine, Mellaril, Stelazine, Permitil, Trilafon, etc.). Rauwolfia derivatives (Reserpine), Butyrophenones (Haldol)
Producing "model psychoses" (for abreactions and hypermnesia)	LSD, Mescaline, Psilocybin

From Wolberg LR: Psychotherapy and the Behavioral Sciences. Orlando, FL. Grune & Stratton. 1966.

Table 13-1
Technical Psychotherapeutic Similarities and Differences

	Supportive Therapy	Reeducative Therapy	Classical Psychoanalysis	Non-Freudian Psychoanalysis	Psychoanalytically Oriented Psychotherapy
Duration of therapy	One to several hundred sessions	Several sessions to several hundred sessions	2-5 years or longer	1-5 years or longer	Several sessions to several hundred sessions
Frequency of visits	1-3 times weekly	1-2 times weekly	4-5 times weekly	2-4 times weekly	1-3 times weekly
Detailed history taking	Usually	Often	Rarely	Occasionally	Often
Psychologic examinations	Intelligence testing, Vocational battery	Intelligence testing, Vocational battery, Projective testing	Projective testing may be employed	Projective testing may be employed	Projective testing often employed
Patient's communications	Interviews focused on symptoms and environmental disturbances	Interviews focused on daily events and interpersonal relationships	Unguided free associations	Interviews focused on current situations, interpersonal relationships, and other conflictual sources Free associations sometimes used	Interviews focused on current situations, interpersonal relationships, and other conflictual sources Free associations sometimes used
General activity of therapist	Toward strengthening of existing defenses	Challenging of existing defenses Activity - directiveness to nondirectiveness	Challenging of existing defenses Passivity, anonymity, nondirectiveness Constant analysis of transference and resistance	Challenging of existing defenses Activity - moderate directiveness to nondirectiveness Constant analysis of transference and resistance	Challenging of existing defenses Greater activity - directiveness to relative nondirectiveness Constant analysis of transference and resistance
Advice giving to patient	Often	Occasionally	Never	Rarely	Rarely
Transference	Positive transference encouraged and utilized to promote improvement	Positive transference controlled, and if possible utilized to promote improvement Negative transference analyzed as it develops in terms of the reality situation	Transference encouraged to point of development of transference neurosis Transference analyzed in terms of genetic origins	Transference encouraged to point of awareness of repressed attitudes and feelings Transference neurosis avoided by some analysts Transference analyzed in terms of	Transference encouraged to point of awareness of repressed attitudes and feelings Transference neurosis avoided as a rule Transference analyzed in terms of character

				character structure or genetic origins	structure and occasionally genetic origins
General relationship of patient to therapist	Positive relationship fostered and utilized	Positive relationship fostered and utilized	Relationship permitted to develop spontaneously	Relationship permitted to develop spontaneously	Relationship permitted to develop spontaneously Positive relationship occasionally fostered and utilized
Physical position of patient during therapy	Sitting up, face to face	Sitting up, face to face	Recumbent on couch	Sitting up, face to face or Recumbent on couch	Sitting up, face to face or Occasionally recumbent on couch
Dream material	Not utilized	Not utilized	Constantly utilized	Constantly utilized	Constantly utilized
Adjuncts utilized during therapy	Bibliotherapy Art therapy Group therapy Physical therapy Somatic therapy Hypnotherapy Occupational therapy etc.	Group therapy Bibliotherapy Other adjuncts occasionally used	None	Few or none	Analytic group therapy Hypnoanalysis Narcotherapy Play therapy occasionally Art therapy occasionally Drug therapy occasionally

Table 16-1
Traditional Specialized Functions of Various Team Members in a Community Psychiatric Clinic

Psychiatrist	Caseworker	Psychologist
1. Establishing a psychiatric diagnosis 2. Physical examination where needed 3. Neurologic examination where the psychiatrist is qualified 4. Administration of somatic therapy (drugs, ECT, etc.) 5. Arranging for commitment and hospitalization where necessary 6. Handling routine physical and neurologic check-ups on patients with physical and psychosomatic problems 7. Handling of psychiatric emergencies, such as severe depression, suicidal tendencies, excitement, psychotic manifestations etc. 8. Supervision of non-medical therapists in the management of emergencies	1. Intake interviewing (clarification of services to prospective patients and determining if services are consonant with the needs of the patient) 2. Preparation of patients for psychotherapy, dealing with resistances to treatment and establishing the proper motivation for treatment 3. Exclusive handling of, or acting as a consultant for, problems in patients relating to finance, health, employment, recreation, housing, exercise, companionship, and special training. Acquainting patients with, and aiding them to utilize most effectively, available community resources 4. Acting as a casework consultant to other team members where environmental manipulation in their patients is essential in addition to psychotherapy 5. Acting as liaison between the patient and the family, employer, teacher, etc. when it is essential to interpret the patient's illness to them, to give them reassurance or to enlist their interest and cooperation. 6. Handling of parents, mate, or children of patients who are being treated by team members and who require counseling or psychotherapy as an aid to the treatment of the patient 7. Handling of children with primary behavior disorders 8. Organizing and handling administrative details of educational projects of team. Interpreting the work of the clinic to the community, securing cooperation of the community in the work of the clinic, acting as liaison between the clinic and community organizations that are implementing community programs related to health, welfare, and social security	1. Diagnostic testing: intelligence, educational, achievement, vocational, projective personality traits 2. Exclusive handling of, or acting as consultant for: a. Problems of school adjustment, maladjustment and placement b. Corrective work in educational field: therapy of reading or other educational disabilities c. Career planning, vocational guidance d. Rehabilitative work for physical and sensory defects particularly in educational and vocational areas e. Speech disturbances 3. Organizing and handling administrative details of research projects of team 4. Behavioral techniques and biofeedback

Table 19-1
Activities of the Therapist

I. Opening the Interview

II. Maintaining the Flow of Verbalizations

      A. Managing pauses

      B. Managing silence

III. Directing the Flow of Verbalizations: The Principle of Selective Focusing

      A. Identifying an important theme

      B. Reading between the lines

      C. Guiding the theme into a goal-directed channel

      D. Guiding the theme into a goal-directed channel

IV. Inculcating Insight

      A. Accenting

      B. Summarizing

      C. Restating

      D. Reflecting

      E. Establishing connections

      F. Maintaining tension in the interview

      G. Extending measured support

      H. Confrontation

      I. Making interpretations

V. Terminating the Interview

Table 21-1
An Outline of Psychotherapy

	Beginning Phase	Middle Phase		End Phase
Phases	I	II	III	IV
Objectives	Establishing a working relationship with patient	Exploring the causes and consequences of the patient's disorder	Translating understanding into action. Instituting corrective measures	Terminating Therapy
Therapeutic tasks	1. Motivating patient to accept therapy. 2. Clarifying misconceptions about therapy. 3. Convincing patient that therapist understands his or her suffering and is capable of helping. 4. Tentative defining of goals in therapy and of the therapeutic situation.	1. Delineating and exploring environmental frustrations and maladaptive interpersonal drives through interviewing. 2. In cognitive therapy, searching for false self-statements. 3. In dynamic psychotherapy, probing for unconscious conflicts that mobilize anxiety and vitiate basic needs through psychoanalytic techniques of free association, dream interpretation, analysis of the transference, and the exploration of genetic material. 4. In behavior therapy, appraising factors that need reinforcement and symptoms that require extinction.	1. Creating incentives for change. 2. Dealing with forces that block action. 3. Helping patient to master anxieties surrounding normal life goals. 4. Correction of remediable environmental distortions. 5. Helping patient to adjust to irremediable conditions. 6. Symptom removal if desirable when immediate correction is urgent. 7. Adjustment to those symptoms and abnormal character patterns that for one reason or another cannot be removed during present therapeutic effort.	1. Analyzing the dependency elements of the therapist-patient relationship. 2. Redefining the treatment situation with the aim of encouraging patient to make independent decisions and to establish individual values and goals. 3. Helping patient to achieve as much independence and assertiveness as possible.
Resistances in patient	1. No motivation for therapy or inability to accept the fact	1. Guilt in acknowledging environmental disturbance or interpersonal	1.Resistance to abandoning primary and secondary neurotic gains.	1. Refusal to yield dependency. 2. Fear of assertiveness.

	that he or she can be helped. 2. Refusal to accept therapist's definition of the treatment situation 3. Hostility, aggression, detachment, intense dependency, sexual demands, and other resistances to a warm working relationship.	difficulties. 2. Unwillingness and, in the instance of a weak ego, an inability to face and to master anxieties related to unconscious conflicts, strivings, and fears.	2. Resistance to normality. 3. Resistance to activity through own resources.	
Counter-transference problems in therapist (manifestations)	1. Inability to sympathize with patient and to communicate in understandable terms with him or her. 2. Irritability with resistances of patient to accepting therapy and therapist 3. Inability to extend warmth toward patient and to show acceptance of the problems.	1. Avoidance by therapist of those problems in patient that inspire anxiety in therapist. 2. Desire to probe too deeply and rapidly at the start. 3. Irritation with resistance of patient toward gaining understanding of the problems.	1. Frustration, hostility, and discouragement in therapist to patient's refusal to use insight in the direction of change 2. Tendency to push patient too hard and too rapidly toward normal objectives. 3. Fear of being too directive, with resultant excessive passivity. 4. Resentment at patient's inability or refusal to cooperate with corrective procedures.	1. Tendency to overprotect or to domineer patient. 2. Inability to assume a nondirective therapeutic role.

Table 24-1 Personal Data Necessary from Patient

Statistical Data

       Name

       Address

       Telephone number

       Age

       Sex

       Marital status

       Education

       Occupation

       Employment status and income

Complaint Factor

1.   Chief complaint (in patient's words)

2.   History and development of the complaint

   a.   When did the complaint begin?

   b.   Under what circumstances?

   c.   What does the patient believe produced the complaint?

   d.   What treatment has been given?

3.   Other complaints or symptoms

   a.   Physical

   b.   Emotional

   c.   Psychic

   d.   Behavioral

4.   Previous attacks of emotional illness

   a.   As a child

   b.   Later attacks

   c.   Any hospitalization?

   d.   At what period does the patient believe him or herself to have been completely free from emotional illness?

5.   Effect of emotional illness on present functioning

   a.   Effect on physical health, appetite, sleep, and sexual functions

   b.   Effect on work

    c.   Effect on family and other interpersonal relationships

    d.   Effect on interests and recreations

    e.   Effect on community relations

6.   Evaluation of complaint factor

    a.   What evidence is there of adaptational breakdown, such as anxiety, depression, psychosomatic symptoms?

    b.   Are the defensive elaborations adaptive or maladaptive?

    c.   What are the patient's ideas and attitude about the problem?

Etiological Factors

1.   History of hereditary family illness

2.   Family data: relationships with parents and siblings

3.   Significant events in the past history

4.   Precipitating factors in present environment: assay of present environment to determine extent of stress on patient

5.   Other factors, including inner conflicts as revealed by dreams and symptoms

Assay of Personality Strengths and Weaknesses

1.   Level of maturation: physical growth, educational achievement and school progress, resolution of dependence, sexual maturity, marriage, parenthood, social relationships, and community participation

2.   Neurotic disturbances in childhood

3.   Interests, hobbies, ambitions

4.   Character structure: security feelings, attitudes toward authority, interpersonal relationships, attitudes toward self, and methods of handling conflict

5.   Motivational factors and level of insight

Table 27-1
Summary of Positive and Negative Prognostic Signs in the Patient

	Positive	Negative
1.	The age of the patient is not too advanced	Patient has advanced to an age when learning is not so easy, patterns are set, and considerable rigidity exists.
2.	Problems are of recent duration.	Problems date back to childhood or are of a long-standing nature.
3.	Patient's symptoms or behavior patterns are incapacitating or inconvenient or arouse resentments in the patient.	Patient's symptoms or behavior patterns cause no inconvenience and are not incapacitating. Symptoms are strongly protective in nature and yield positive dividends, such as support, attention, and monetary compensation. Symptoms satisfy a masochistic need in the patient.
4.	The patient is suffering from a stress, anxiety, phobic, conversion, or mild somatoform disorder.	The patient is suffering from an organic brain disorder, schizophrenia, manic-depressive reaction, involutional psychotic reaction, chronic anxiety reaction, chronic obsessive-compulsive reaction, drug addiction, sexual perversion, or severe personality disorder.
5.	The patient has a normal or high intelligence.	The patient has a borderline or low intelligence.
6.	The patient has a strong motivation for therapy. The patient applies for therapy and sees the need for it.	The patient has little or no motivation for therapy. The patient is brought into therapy by another person and does not see a need for it.
7.	The patient has insight into the emotional nature of the problem.	The patient has no idea that the problem is emotionally inspired.
8.	Elements of secondary gain are relatively lacking.	Secondary gain elements are present.
9.	There is no hereditary history of mental illness.	There is a hereditary history of mental illness.
10.	The patient has no constitutional abnormal stature or physique or endocrine disorder.	A constitutional disturbance is present.
11.	The patient was not subject to severely traumatizing influences in childhood.	Severe traumatic influences existed in the patient's childhood.
12.	Few or no distortions existed in the relationship of the parents with the patient.	There was severe disharmony in the home, severe difficulties between patient's mother and father, or severe distortions in the patient-parent relationship.
13.	The developmental history shows no serious defects in physical development, habits, school adjustment, emotional maturation, or sexual	The developmental history shows a serious maladjustment during infancy and childhood.

development.

14.	Adjustment failures in childhood were minimal: childhood neurotic disturbances were absent.	There was failure of adjustment in childhood; patient had childhood neurotic disturbances.
15.	Patient's relationships with people in general are good. There is plasticity in personality traits and defenses. The patient is able to establish a good relationship with the therapist.	The patient has severe disturbances in interpersonal relations. There is rigidity in personality traits and defenses. Transference elements are disturbing and interfere with a good relationship with the therapist.
16.	Assertiveness is present, and self-esteem is good.	Assertiveness is lacking, and self-esteem is diminutive.
17.	The patient's conscience is not too severe or too diminutive	The patient's conscience is excessively severe, is diminutive, or exerts an uneven pressure.
18.	The patient is capable of handling reasonable stress or of enduring reasonable anxiety without repressive or regressive reactions.	The patient tends to handle stress or anxiety by reactions of physical withdrawal, emotional detachment, fantasy, acting-out, aggression, sadism, alcoholic overindulgence, excess sedation, intense dependency, self-punishment, self-aggrandizement, intellectual confusion, emotional shattering, physical sickness, compulsions, depression, and feelings of unreality.
19.	The patient is capable of gratifying vital biologic and social needs in conformity with the mores of the group.	Patient is unable to gratify personal needs or does so in opposition to accepted mores.
20.	The patient's symptoms consist of anxiety, tension, mild depression, or mild psychophysiologic reactions or phobias.	Symptoms consist of stammering, sexual perversions, deep depression, violent rages, euphoria, apathy, various obsessions and compulsions, ideas of reference, delusions, hallucinations, impaired reality sense, depersonalization, alcoholism, drug addiction, and criminality.
21.	Immediate environmental precipitating factors are strong.	Immediate environmental precipitating factors are not intense.
22.	The patient's adjustment prior to illness was good.	Maladjustment was present since early childhood.
23.	The patient has achieved social maturity. There are no defects in physical growth, educational achievement and school progress, resolution of dependence, sexual maturity, marriage, parenthood, social relationships, and community participation.	The patient has been delayed in achieving social maturity. There are defects present in the patient's physical growth, educational achievement and school progress, resolution of dependence, sexual maturity, marriage, parenthood, social relationships, and community participation.
24.	The patient has adequate interests, hobbies, and recreational pursuits.	Patient has few or no interests, hobbies, or recreational activities.
25.	The patient's life situation will compensate for the	The abandonment of symptoms or the development of new patterns of behavior bring

	abandonment of symptoms and reward the development of new patterns.	negative results or expose the patient to dangers of a strongly threatening nature.
26.	Habitual environmental pressures on and responsibilities of the patient are average.	Habitual environmental pressures on and responsibilities of the patient that must be adjusted to are severe and irremediable. The patient will have to live in a disturbed or depriving environment (neurotic parents or mate, poor economic circumstances, harsh culture, and so on).
27.	Ambitions are in line with aptitudes and the reality situation.	Ambitions are out of line with aptitudes or reality.
28.	The patient has had no previous attacks of emotional illness.	The patient has had previous attacks of emotional illness.
29.	The patient has received no psychotherapy in the past.	The patient has received psychotherapy in the past that was unsuccessful.
30.	Therapy and the therapeutic situation do not impose too great hardships on the patient in terms of expense, time, travel, and so on.	Therapy and the therapeutic situation impose great hardships on the patient.
31.	Patient has no problems in communication.	Patient has problems in communication.

Table 27-2
Summary of Prognostic Signs Relating to the Therapist

	Positive	Negative
1.	The therapist is capable of understanding the dynamics of the patient's illness. The therapist is well trained and skilled.	The therapist is confused about the existing dynamics. The therapist is not well trained and lacks skills.
2.	The therapist is sufficiently sensitive to perceive what is happening in the treatment process.	The therapist is insensitive to what is going on within the patient and within himself or herself.
3.	The therapist is aware of his or her own feelings and is capable of remaining objective irrespective of the attitudes and behavior manifested by the patient.	The therapist is incapable of maintaining satisfactory objectivity.
4.	The therapist is flexible in the approach used.	The therapist is rigid in the approach used.
5.	The therapist has a capacity for empathy with the patient.	The therapist lacks empathy with the patient.
6.	The therapist tends to treat the patient in a respectful and cooperative manner.	The therapist is domineering, pompous, and authoritarian.
7.	The therapist is capable of being firm on occasion.	The therapist is too passive and submissive.
8.	The therapist is capable of establishing a working relationship with the patient.	The therapist is detached.
9.	The therapist is well adjusted and is satisfying basic needs.	The therapist tends to use the patient for the vicarious gratification of repressed or suppressed impulses, such as sexuality, the expression of hostility, and the gaining of prestige.
10.	The therapist is capable of tolerating the expression of varied impulses in the patient.	The therapist is incapable of tolerating such impulses in the patient as sexuality, hostility, or assertiveness.
11.	The therapist has no neurotic attitudes toward money.	The therapist's insecurity reflects itself in anxiety about fees and payments.
12.	The therapist is able to tolerate the vicissitudes	The therapist is unable to tolerate blows to personal self-esteem by the patient's acting-out tendencies, by

	inevitable in therapy.	manifestations of resistance and transference, and by the inevitable failures and frustrations in treatment.
13.	The therapist feels personally secure.	The therapist has a neurotic need to be liked, a compulsive tendency toward perfectionism, inordinate hostility, lack of creativity, no sense of humor, an inability to take criticism, low personal integrity, a diminished respect for people, a failure to acknowledge self-limitations, a low energy level, or poor physical health.
14.	The therapist is capable of giving the patient support in accordance with the patient's needs without overprotecting or dominating the patient.	The therapist rejects the patient or refuses to or is unable to extend to the patient measured support.

Figure 37-1 Outline of Personality Operations

Fig. 37-1. Outline of Personality Operations

Figure 44-1 Personality Mechanisms

Fig. 44-1. Personality Mechanisms. From Wolberg LR, Kildahl J: The Dynamics of Personality. Orlando, FL, Grune & Stratton, 1970. p. 215, with permission.

THE FIVE MOTORS

MOTOR ONE

HIGH DEPENDENCE

"I want you to be perfect, like a God; to be accepting and loving; to be wise and strong."

MOTOR TWO

RESENTMENT HOSTILITY

"I resent my need to be dependent on you. When you show any weakness, I am furious. I feel guilty and upset about my feelings. I feel like killing anybody who controls me."

MOTOR THREE

LOW INDEPENDENCE

"I know I must face responsibility, but I feel too weak, and unmasculine," (in females: "If I were a man, I would be strong and independent.")

MOTOR FOUR

DEVALUED SELF-IMAGE

"I feel like a shit and hate myself. I am a nothing and I'd like to be a somebody, but I can't."

MOTOR FIVE

DETACHMENT

"I am constantly running away. I get so angry at people. I don't want to see anybody. I'm so upset about myself. I try not to feel."

Table 56-1 Self-help Relaxation Methods

I. *Letting Go:* For most, it is a mistake to "try to relax." Just tense the muscle group and then visualize and verbalize to the muscle group "let go and keep on letting go."

II. *Breathing:* A Yogic style of deep slow breathing (6000 years old). Fill up with air from the lower belly (abdomen and diaphragm) toward the chest, like filling a glass of water, and *exhale slowly* thru the nostrils. You can first tense, or suck in the belly and feel tension in these muscles, and then say, "I will allow these muscles to let go," visualizing letting go on exhalation. Place hand below "belly button" and feel area move up on inhalation and down on exhalation. Relaxed breathing should continue throughout remaining exercises of tensing and relaxing.

III. *Forearm:* Many people can most quickly be aware of tensing the forearm and relaxing it on exhalation. Making a fist is one way of tensing and visualizing.

IV. *Face and Forehead:* Wrinkle forehead as tightly as possible, and then say to muscles, "Let go and keep on letting go." Practice this often. Furrow between the brows often and say, "Let go and continue to let go." Clench teeth, feel jaw muscles tighten, and let go with lips and teeth slightly parted. Show teeth and relax these muscles. *Push* tongue against upper palate (top of mouth) and let it relax between lower teeth (just almost touching bottom teeth). Close eyelids tightly and let go slowly. *IMPORTANT:* Look as far to left as possible with eyes closed, lids relaxed, and then let go and let eyes go and drift. Same to right and up and down. (Rolling eyeballs up with Yogic breathing and keeping them up is one way to be helpful for inducing self-hypnotism and later sleep in insomniacs.) Visualize and let the entire face smooth out as though you are smoothing it with both hands and let it stay smooth. (*Relaxation of eyes and tongue often controls unwanted thoughts and helps with insomnia.)*

V. If mind wanders, get it back to thinking of breathing and muscle group pictures as best you can. Tighten on inhalation and let go on exhalation.

VI. *Repetition:* Do not become discouraged since tension patterns have existed all of your life. Practice whenever possible. Soon shortcuts such as deep

breathing and words "calm," or "let go," or "relax" or words or pictures of your choosing may help form relaxing a habit. You may find for yourself certain muscle groups, such as face, shoulders, or breathing muscles, that allow you to relax most adequately.

VII. *Neck Practice:* The same procedures of breathing and tensing muscle groups apply to all part of body. You can, especially in the beginning, bend head back, relax. Head to the left and right.

VIII. *Shoulders:* Hunch up as far as possible and let go. Backward and forward also.

IX. *Lower Extremities:* Pinch buttocks together; feel tension and let go. Tighten and let go toes.

General: Practice at every available moment to do things in a relaxed fashion: then let yourself consciously breath deeply and relax in situations ordinarily causing tension. If possible, condition or habituate the relaxation of the entire musculature or letting go to deep breathing and the same key words or words that seem to suit you.

Time: Persistence and review are worthwhile since everyone agrees on the desirability and harmlessness of relaxation.

Table 56-2 Relaxation Training Procedure

Part 1

Sit quietly in a comfortable position.

Take a deep, slow breath.

Hold the breath for several seconds.

Slowly exhale.

Take another deep, slow breath.

Hold the breath and pull your toes toward your head, tightening your leg and calf muscles. Feel the tension.

Breathe out and let go completely.

Take another deep, slow breath.

Hold the breath and make a fist with both hands, tightening your arm and shoulder muscles.

Feel the tension.

Breathe out and let go completely.

Take another deep, slow breath.

Hold the breath and bit down as hard as you can, tightening your jaw muscles.

Feel the tension.

Breathe out and let go completely.

Take another deep, slow breath.

Hold the breath while tightening your stomach and neck muscles.

Feel the tension.

Breathe out and let your muscles go limp.

Take another deep, slow breath.

Hold the breath and tighten every muscle in your body until you feel your whole body start to tremble with tension.

Now breathe out and let go completely.

Take another deep, slow breath.

Hold the breath and tighten every muscle in your body.

Hold on to the tension.

Now breathe out and let go completely.

Take another deep, slow breath.

Hold the breath and tighten every muscle in your body.

Hold the tension.

Now breathe out and let go, relaxing completely.

Part II

Concentrate on slow, deep breathing throughout this entire section.

Slowly repeat each of these phrases to yourself as you hear them.

I feel very calm and quiet.

I feel very comfortable and quiet.

I am beginning to feel quite relaxed.

I am beginning to feel quite relaxed.

My feet feel heavy and relaxed.

My feet feel heavy and relaxed.

My ankles feel heavy and relaxed.

My ankles feel heavy and relaxed.

My knees feel heavy and relaxed.

My knees feel heavy and relaxed.

My hips feel heavy and relaxed.

My hips feel heavy and relaxed.

My feet, my ankles, my knees and my hips all feel heavy and relaxed.

My feet, my ankles, my knees and my hips all feel heavy and relaxed.

My neck, my jaws and my forehead all feel heavy and relaxed.

My whole body feels heavy and relaxed.

My stomach and the whole center portion of my body feel heavy and relaxed.

My stomach and the whole center portion of my body feel heavy and relaxed.

My hands feel heavy and relaxed.

My hands feel heavy and relaxed.

My arms feel heavy and relaxed.

My arms feel heavy and relaxed.

My shoulders feel heavy and relaxed.

My shoulders feel heavy and relaxed.

My hands, my arms and my shoulders all feel heavy and relaxed.

My hands, my arms and my shoulders all feel heavy and relaxed.

My neck feels heavy and relaxed.

My neck feels heavy and relaxed.

My jaws feel heavy and relaxed.

My jaws feel heavy and relaxed.

My forehead feels heavy and relaxed.

My forehead feels heavy and relaxed.

My neck, my jaws and my forehead all feel heavy and relaxed.

My left elbow, my left shoulder feel warm and heavy.

My whole body feels heavy and relaxed.

My breathing is getting deeper and deeper.

My breathing is getting deeper and deeper.

I can feel the sun shining down on me warming the top of my head.

The top of my head feels warm and heavy.

The top of my head feels warm and heavy.

The relaxing warmth flows into my right shoulder.

My right shoulder feels warm and heavy.

My right shoulder feels warm and heavy.

My breathing is getting deeper and deeper.

The relaxing warmth flows down to my right hand.

My right hand feels warm and heavy.

My right hand feels warm and heavy.

The relaxing warmth flows back up to my right arm.

My right arm feels warm and heavy.

My right arm feels warm and heavy.

The relaxing warmth spreads up through my right elbow into my right shoulder.

My right elbow, my right shoulder feel warm and heavy.

My right elbow, my right shoulder feel warm and heavy.

The relaxing warmth flows slowly throughout my whole back.

I feel the warmth relaxing my back.

My back feels warm and heavy.

My back feels warm and heavy.

The relaxing warmth flows up my back and into my neck.

My neck feels warm and heavy.

My neck feels warm and heavy.

The relaxing warmth flows into my left shoulder.

My left shoulder feels warm and heavy.

My left shoulder feels warm and heavy.

My breathing is getting deeper and deeper.

The relaxing warmth flows down to my left hand.

My left hand feels warm and heavy.

My left hand feels warm and heavy.

The relaxing warmth flows back up to my left arm.

My left arm feels warm and heavy.

My left arm feels warm and heavy.

The relaxing warmth spreads up through my left elbow into my left shoulder.

My whole body is heavy, warm, relaxed.

My left elbow, my left shoulder feel warm and heavy.

The relaxing warmth flows to my heart.

My heart feels warm and easy.

My heart feels warm and easy.

My heartbeat is slow and regular.

My heartbeat is slow and regular.

The relaxing warmth flows down into my stomach.

My stomach feels warm and quiet.

My stomach feels warm and quiet.

My breathing is deeper and deeper.

My breathing is deeper and deeper.

The relaxing warmth flows down into my right thigh.

My right thigh feels warm and heavy.

My right thigh feels warm and heavy.

The relaxing warmth flows down into my right foot.

My right foot feels warm and heavy.

My right foot feels warm and heavy.

The relaxing warmth flows slowly up through my right calf, to my right knee, to my right thigh.

My right leg feels warm and heavy.

My right leg feels warm and heavy.

My breathing is deeper and deeper.

My breathing is deeper and deeper.

The relaxing warmth flows down into my left thigh.

My left thigh feels warm and heavy.

My left thigh feels warm and heavy.

The relaxing warmth flows down into my left foot.

My left foot feels warm and heavy.

My left foot feels warm and heavy.

The relaxing warmth flows slowly up through my left calf, to my left knee, to my left thigh. My left leg feels warm and heavy.

My left leg feels warm and heavy.

My breathing is deeper and deeper.

My breathing is deeper and deeper.

The relaxing warmth flows up through my abdomen, through my stomach and into my heart.

My heart feels warm and easy.

My heart feels warm and easy.

My heart pumps relaxing warmth throughout my entire body.

My whole body is heavy, warm, relaxed.

My whole body is heavy, warm, relaxed.

(*continued*)

I am breathing deeper and deeper.

I am breathing deeper and deeper.

My whole body feels very quiet and very serene.

My whole body feels very comfortable and very relaxed.

My mind is still.

My mind is quiet.

My mind is easy.

I withdraw my thoughts from my surroundings.

Nothing exists around me.

I feel serene, secure, still.

My thoughts are all turned inward.

I am at ease, completely at ease.

Deep within my mind I can visualize and experience myself as relaxed.

I am comfortable and still.

My mind is calm and quiet.

I feel an inward peace.

I feel a new sense of well being.

I am breathing more and more deeply.

Part III

Now lift your arms slowly, high over your head.

Take a deep, deep breath.

Hold the breath and slowly lower your arms and hands.

When your arms and hands touch your chair breathe out and go completely limp.

Hold your hands in front of you as if you were praying.

Take a deep, deep breath.

Press your hands together until you feel your arm muscles tremble.

Breathe out and go completely limp.

Take a deep, deep breath.

Hold the breath and slowly draw your hands toward your face.

When your hands touch your face, breathe out and let go.

Go completely limp.

You are breathing deeper and deeper.

You are breathing deeper and deeper.

Slowly say the following phrases to yourself.

My whole body feels quiet, comfortable and relaxed.

My hands and arms feel heavy, warm and relaxed.

My legs feel heavy, warm and relaxed.

My mind is quiet.

I withdraw my thoughts from my surroundings.

I feel serene and still.

My thoughts are turned inward.

I am at ease.

Deep within my mind I can visualize and experience myself as comfortable and still. My mind is calm and quiet.

I feel an inward peace and quiet.

I am now relaxed and alert. *[If biofeedback training is to be utilized, simply say:* I am now ready to begin my training session.]

Table 56-3 Uses, Characteristics, and Doses of Psychotropic Drugs

d=daily; bid = 2 times daily; tid= 3 times daily; qid = 4 times daily.

T=tablets; P=parenteral; S=spansules; caps=capsules; IM=intramuscularly; IV=intravenously; SR=sustained release;

max=maximum; av=average; gr=grain; mg=milligrams; cc=cubic centemeters

Psychostimulants

Drug (How Dispensed)	Uses	Dosage	Misc.
1. Sympathetic amines a. dextroamphetamine (Dexedrine; S 5, 10, 15 mg; T 5) b. methamphetamine (Desoxyn: T5 mg, Gradumet T 5, 10, 15 mg)	1. Very mild depression; appetite control; oversedation and fatigue; enuresis; attention deficit disorder with hyperactivity in children, narcolepsy	a. 5-15 mg at 9 am & 2 pm; (S) 10-15 mg at 9 am. b. 5 mg at start, raise 5 mg weekly. Usual dose 20-25 mg d	1. Rapid action. Do not use in schizophrenia, agitation and hypertension. Can cause irritability and insomnia. Habituation danger serious; user for no more than 3 months. Monitor blood pressure, especially in hypertension.
2. Methylphenidate (Ritalin: T 5, 10, 20 mg; SR 20 mg)	2. As in (1) but effects are weaker.	2. 10-20-30 mg(T) at 9 am & 2 pm. In children start with 5 mg(bid) gradually raised.	2. As in (1). Do not use in anxiety, Tourette's syndrome, drug dependent patients.
3. Pemoline (Cylert: T 18.75, 37.5, 75 mg; chewable T 37.5 mg)	3. Attention deficit disorders	3. Single morning dose – start with 37.5 mg/day, increase by 18.75 mg at 1 wk intervals until desired effect.	3. Clinical improvement is gradual. May require 3-4 weeks for good effects. Do not use in psychotic children or in kidney disease.

Anitdepressants

Drug (How Dispensed)	Uses	Dosage	Misc.
1. Tricyclics			

a. imipramine (Tofranil: T 10, 25, 50, 50 mg; P 25 mg in 2 cc; Tofranil PM, 75, 100, 125, 150 mg sustained action	a. For retarded endogenous depression	a. 25 mg qid increased to 50 mg qid. Max. 250 mg d. Use the 10 mg size in older patients. P-IM-to 100 mg in divided doses	a. Action in 7-21 days. Do not give with MAO inhibitors. Do not use in schizophrenia, epilepsy, glaucoma, urinary retention. Use cautiously in cardiovascular illness. Avoid cimetidine. Dryness of mouth and perspiration are side effects. Insomnia and hypotension seen occasionally. Desipramine not recommended for children.
desipramine (Norpramine: T 10, 25, 50, 75, 100, 150 mg. Pertofrane: caps 25, 50 mg)		100-200 mg daily. In elderly 25-100 mg.	
b. amitriptyline (Elavin: T 10, 25, 50, 75, 100, 150 mg: P 10 mg per cc	b. A sedating antianxiety antidepressant; for agitated depression	b. 25 mg tid increased to 50 mg tid; max. 250 Use the 10 mg size older patients. Maintenance 50-100 mg.	b. As in (a) but with more sedative features. Action in 10-30 days. Potentiates alcohol and barbiturates.
nortriptyline (Aventyl: T 10, 25 mg; liquid 10 mg per 5 cc)		10 mg bid increased to 10 mg qid; in 1 week 25 mg bid increased to 25 mg qid.	Avoid in cardiovascular disease. Not recommended for children.
c. doxepin (Sinequan: caps 10, 25, 50, 75, 100, 150 mg; oral concentrate 10 mg per cc) (Adapin: caps 10, 25, 50, 75, 100 mg)	c. For neurotic, alcoholic, and psychotic depression especially when accompanied by anxiety.	c. 25 mg tid increased to 50 mg tid (for mild or moderate depression) 50 mg tid increased to 100 mg tid (for severe depression)	c. Side effects less than other tricyclics. A preferred drug for cardiac patients. Action in 10-21 days.
d. protriptyline (Vivactil: T 5, 10 mg)	d. Slight stimulant qualities.	d. 5 to 40 mg daily divided into 3 or 4 doses. Max 60 mg. Lower dose in adolescence and elderly.	d. Potentiates response to alcohol and barbiturates.
e. amoxapine (Asendin: T 25, 50, 100, 150 mg)	e. Slight sedative qualities	e. 50 mg bid or tid raised to 200 to 300 mg daily; max. 400 mg. In	e. Somewhat more rapid action than imipramine or amitriptyline. Has neuroleptic advantages and dangers. Use cautiously in cardiac and convulsive disorders.

		elderly ½ this dosage.	
f. trimipramine (Surmontil: caps. 25, 50, 100 mg)	f. Antianxiety sedative antidepressant.	f. 25mg tid gradually increased to 150 mg. daily. Max. 300 mg d. Maintenance 50 to 150 mg daily.	f. Not recommended for children. Avoid in cardiovascular disease. Anticholinergic side effects.
2. MAO Inhibitors	2. For neurotic and atypical depression		2. Action in 1-4 weeks.
a. phenelzine (Nardil: T 15 mg)		a. 15 mg tid (max d 90 mg) reduce slowly; maintenance d 15 mg.	a. Potentiates amphetamines, alcohol and barbiturates. May intensify schizophrenia. Produces hypotension, dry mouth, blurred vision, dizziness. Do not use in liver, kidney, or heart diseases. Sexual dysfunction may occur. Avoid tyramine foods and over-the-counter medicaments. Avoid in hypertension, cardiovascular disease.
b. tranyleypromine (Parnate: T 10 mg)		b. 10 mg at 9am & 2pm; in 2 weeks , 20 mg at 9 am & 10 mg at 2 pm.	b. Action in 2-21 days. As in (a).
3. Trazodone (Desyrel: T 50, 100, 150 mg)	3. Serotonin uptake inhibitor. Sedative qualities. No anticholinergic side effects, which is of advantage in glaucoma, urinary retention, constipation, or for elderly.	3. 50 mg tid increase by 50 mg/day every 3 days to max. of 400 mg d.	3. Side effects occasionally of priapism and cardiac arrhythmia may require cessation of drug. Generally less cardiotoxic than tricyclics.
4. Maprotiline (Ludiomil: T 25, 50, 75 mg)	4. A tetracyclic drug that helps depressions with anxiety, dysthymic disorders (neurotic depression), and major depressive disorders.	4. Start with 25 tid, after 2 weeks, gradually increase to 150 mg (max. 225) In elderly start with 25 mg increased to 75 mg if necessary.	4. Avoid in seizure disorders. Anticholinergic side effects. Caution in patients with cardiac disease, urinary retention, glaucoma. Long half-life. Avoid in patients on thyroid medication.
5. Wellbutrin	5.	5. 75 mg tid,	5. Low incidence of daytime

		increase by 75 mg every 3 days to 450 mg max d.	drowsiness, anticholinergic effects, or sedation. Little effect on weight, heart rate, and blood pressure. Avoid in seizure disorders, psychotic depression, history of psychosis.
(Buprion T 75 mg)	antidepressant with little cardiovascular effect.		
6. Combination drugs perphanzine + amitriptyline (Triavil: 2-10, 2-25, 4-10, 4-25, 4-50 mg. Etrafon 2-10, 2-25, 4-10, 4-25mg.)	6. For anxious and agitated depression as well as depression in schizophrenia.	6. One T tid or qid., (max d. 2 T tid); maintenance 1 T bid, tid or qid.	6. Contraindicated in glaucoma, urinary retention. Action in a few days or a few weeks. See amitriptyline and perphenazine. Some authorities feel combination drugs are unnecessary and even contraindicated.

Neuroleptics

Drug (How Dispensed)	Uses	Dosage	Misc.
1. Phenothiazines			
a. chlorpromazine (Thorazine: T 10, 25, 50, 100, 200 mg; S 30, 75, 150, 200, 300 mg; P 25 mg in 1 cc, 50 mg in 2 cc, 250 mg in 10 cc; syrup, 10 mg in each tsp; suppositories 25, 100 mg; concentrate 30 mg in 1 cc and 100 mg in 1 cc.)	a. The sedative phenothiazine for paranoidal, agitated, confused, and hyperactive reactions in schizophrenia, manic-depressive reactions, agitated senile dementia. Safest for children and young adults.	a. 10-25 mg tid; after 1-2 days increase by 2-=25 mg semiweekly to 1000 mg if necessary. P 25 mg for excitement IM, repeat in 1 hr if necessary then oral 25-50 mg tid.	a. Action in a few days. Potentiates barbiturates. Drowsiness, dryness of mouth, stuffiness of nose, tachycardia, hypotension, photosensitivity, allergic skin reactions, jaundice may occur. Use cautiously in atherosclerosis, cardiovascular diseases. Rarely skin pigmentation, ocular changes, blood dyscrasias. Parkinsonism requires Cogentin, Artane, or Kemadrin (qv below).
b. thioridazine (Mellaril: T 10, 15, 25, 50, 100, 150, 200 mg; concentrate 30 mg per cc and 100 mg per cc)	b. Excellent sedative phenothiazine for ambulatory out-patient treatment of hyperkinetic and agitated psychoses. Helps some depressive reactions and hyperactive disturbed children.	b. Nonpsychotic patients: 10-25 mg tid or qid. Psychotics: 100 mg tid or qid (Max. 800 mg d)	b. Minimum of side extra pyramidal reactions. Action is rapid. High doses may cause pigmentary retinopathy. Use in neurological problems and in elderly. Avoid in severe cardiac illness.
c. trifluoperazine (Stelazine: T 1, 2, 5, 10 mg; P 2 mg per cc; concentrate 10 mg per cc)	c. For apathetic, depressed, withdrawn schizophrenics. Low dosage relieves tension and agitation. High dose for manic states, agitated depression, active schizophrenia.	c. Office patients: 1-2 mg bid or tid. Hospital patients: 5 mg tid or qid (max. 40-50 mg d) P 1-2 mg IM repeated 4-6 hours. In	c. Side effects in high dosage are common, namely extrapyramidal reactions – dystonia and parkinsonism require Cogentin, Artane, or Kemadrin (qv below). Lower anticholinergic effects.

		nonpsychotic anxiety up to 5 mg d. max. 12 weeks.	
d. perphenazine (Trilafon: T 2, 4, 8, 16 mg; repetabs 8 mg; concentrate 16 mg per 5 cc; P 5 mg in 1 cc)	d. For psychotic disorders with apathy, and control of severe nausea and vomiting in adults	d. 2-4 mg tid; increased to 4 mg qid, max. 8 mg tid. 1-2 repetabs bid.	d. As above (c). Tolerated by elderly.
e. fluphenazine (Permitil: T 0.25, 2.5, 5, 10 mg; oral concentrate 5 mg per cc)	e. For psychotic agitation, hostility, aggression, behavior problems in children, and senile agitation.	e. Office patients: 0.5 mg d to 10 mg. Hospital patients 2-5 mg bid (max. 20 mg d). (Children and elderly: 0.25-0.5 mg d; max. 1 mg)	e. As above (c)
(ProlixinL T 1, 2.5, 5, 10 mg; elixir: 0.5 mg per cc; P 2.5 mg per 5 cc IM only)		Same as above. Divided doses at 6-8 hour intervals. Maintenance 1-5 mg. d; P 1.25 mg increased 6-8 hr intervals to total of 10 mg.	As above. After IM injections for emergencies, continue on 2-3 times P does with oral T.
f. fluphenazine enanthate (Prolixin Enanthate: P 25 mg in 1 cc preassembled syringes; vials of 5cc)	f. Potent long-acting injectable phenothiazine derivative for psychotic disorders	f. 25 mg (1cc.) IM or subcutaneous every 2 weeks. Adjust dose according to response from 12.5-100 mg every 2 weeks	f. Action in 24-48 hours, lasting about 2 weeks. Useful where oral medication cannot be depended on. Extrapyramidal reactions frequent, which can be controlled with antiparkinsonian drugs. Contraindicated in subcortical brain damage.
g. fluphenazine decanoate (Prolixin Decanoate: P 25 mg in 1 cc preassembled syringes; vials of 5 cc)	g. Potent long-lasting injectable phenothiazine derivative for schizophrenia	g. 12.5 -25 mg IM or subcutaneous every 4 weeks. Adjust does in small increments to 50 or 100 mg.	g. Action in 24-72 hours, lasting about 4 weeks. Useful where oral medication cannot be depended on. Extrapyramidal reaction frequent and will require antiparkinsonian drugs.

2. Dibenzoxaxepines

a. loxapine succinate (Loxitane: C 5, 10, 25, 50 mg; concentrate 25 mg per cc; P 50 mg per cc, IM)	a. Tranquilizes and suppresses aggressive activities in schizophrenia.	a 10-25 mg bid, usual maintenance dose 60-100 mg d.	a. Action in ½ to 2 hours for 12 hours. Contraindicated in drug-induced depressive states (alcohol, barbiturates). Lowers convulsive threshold. Fewer anticholinergic and

			hypotensive effect but use cautiously in cardiovascular disease. Extrapyramidal reactions frequent.
3. Butyrophenones			
a. Haloperidol (Haldol: T ½, 1, 2, 5, 10 mg; concentrate 2 mg per cc; P 5 mg per cc)	a. For psychotic disorders and severe tics. Use where sedation is undesirable. Good for paranoidal patients, manic excitement, assaultive behavior, alcoholic delirium, neurological disorders, torticollis, intractable hiccups and vomiting, and confused negativistic geriatric patients.	a. Moderate symptoms and older patients ½ to 2 mg bid or tid. Severe symptoms: 3-5 mg bid or tid (max. 100 mg); P 2-5 mg repeated if necessary.	a. May be tolerated in some patients better than phenothiazines. Extrapyramidal reactions common. Low anticholinergic and cardiac complications.
b. (Haldol Decanoate P 50 mg per cc)	b. Sustained protection against schizophrenic relapses	b. Start with 10-15 times previous oral dosage of Haldol (max 100 mg) adjust dose required as needed. Give by deep intramuscular injection into gluteal region. In exacerbation of symptoms, supplement with oral Haldol.	b. Peak level in 6 days; half-life 3 weeks. Before starting convert to and stabilize pt on oral Haldol from any other neuroleptic being taken.
4. Thioxanthenes			
a. thiothixene (Navane: C 1, 2, 5, 10, 20 mg; concentrate 5 mg per cc; P 2 mg per cc)	a. For psychotic disorders; esp. with depressive and anxiety symptoms.	a. Mild symptoms: 2 mg tid (max d 15 mg). More severe symptoms: 5 mg bid to 30 mg (max d 60 mg).	a. May be tolerated in some cases better than phenothiazines. Less sensitivity to sunlight. Lower extrapyramidal and myocardial effects.
b. chlorprothixene (Taractan: T 10, 25, 50, 100 mg; concentrate100 mg per tsp; P 25 mg in 2cc)	b. Agitated, anxious, depressed schizophrenics.	b. 25-50 mg tid or qid. Max. 600 mg d. P 25-50 mg up to tid or qid.	b. Avoid in cardiac and respiratory disease.

5. Dihydroindolones

a. molindone (Moban: T 5, 10, 25, 50 , 100 mg; concentrate 20 mg per cc)	a. For psychotic disorders.	a. 50-75 mg/d increased to 100 mg/d in 3-4 days. Mild symptoms 5-15 mg tid or qid; moderate 10-25 mg tid or qid. Severe symptoms: up to 225 mg total.	a. Side reactions less than phenothiazines.

6. Dihydroindolones

a. Lithium carbonate (T 300 mg) (See also Haldol, Thorazine, and Mellaril above).	a.–d. For control and prophylaxis of manic episodes in manic-depressive psychosis (Bipolar disorder – manic)	a. Usual dose, 300-600 mg tid. Adjust dosage to maintain serum levels between 1-1.5 mEq/l.	a-d. Action in 1-3 weeks. Contraindicated in colitis and severe renal and cardiovascular disease, or where diuretics are taken. Test serum levels twice weekly acute phase; in maintenance therapy at least every 2 months. Some skin eruptions and renal impairment possible in long term therapy.
b. Lithane T 300 mg.		b. As above	
c. Lithobid: slow release T 300 mg.		c. 1800 mg/d; maintenance 900-1200 mg/d	
d. Cibalith- S: Syrup 300 mg per tsp.		d. 2 tsp tid; maintenance 1 tsp tid or qid.	

7. Anti-Parkinson Drugs

a. Cogentin (T 0.5, 1.2 mg; P 1 mg in 1 cc)	a-d. For dystonia, akithisia, parkinsonism. Do not use prophylactically.	a. Usual dose 1-2 mg d. or P 1-2 mg	a-d. After symptoms disappear for 1-2 weeks, withdraw to determine need for drug. For temporary use only; withdraw within 4-12 weeks.
b. Artane (T 2.5 mg; elixir 2 mg each tsp; sustained release C 5 mg)		b. 1 mg 1st day; 2 mg 2nd day; increased if necessary to 5-15 mg d.	
c. Kemadrin (T 5 mg)		c. 2.5 mg tid increased to 5 mg tid or qid.	
d. Synmetral (C 100 mg; Syrup 50 mg per tsp)		d. 200 mg d.	

Axiolytics

Drug (How Dispensed)	Uses	Dosage	Misc.
a. diazepam	a. Anxiety, muscle	a. 5 mg d to	a. Avoid in glaucoma and

(Valium: T 2. 5. 10 mg; P 5 mg per cc)	spasms, drug and alcohol withdrawal, insomnia due to anxiety, status epilepticus.	tid. Severe anxiety 10 mg tid or qid; P: IM or IV 2-20 mg repeated if necessary in 3-4 hours.	epilepsy. Drowsiness possible. Reduce dose in elderly patients. Avoid alcohol. Long half-life.
b. cholordiazepoxide (Librium: caps 5, 10, 25 mg; P 100 mg in 5 cc)	b. Excellent tranquilizer with palliating qualities for anxiety, alcoholism, muscle spasms. IV in delirium tremens and as an anticonvulsive.	b. 10 mg tid or qid. Severe anxiety: 20-25 mg tid or qid; P 50-100 mg IM or IV repeated if necessary in 2-6 hours.	b. Ataxia, especially in older persons. Avoid alcohol
c. alprazolam (Xanax: T 0.25, 0.5, 1 mg)	c. Anti-anxiety agent with antidepressant qualities	c. 0.25 to 0.5 mg tid Max d. 4 mg. In elderly start with 0.25 mg bid or tid. Increase or reduce as necessary. Larger doses needed to prevent panic attacks.	c. Short half-life. Temporary drowsiness and lightheadedness may occur. Avoid alcohol.
d. oxazepam (Serax: caps 10, 15, 30 mg; T 15 mg)	d. Anxiety, alcoholic withdrawal, senile agitation	d. Mild anxiety: 15 mg qid. Severe anxiety: 30 mg tid or qid. Older patients: 10 mg tid.	d. Initial drowsiness usually passes.
e. lorazepam (Activan: T 0.5, 1.0, 2.0 mg; P 2 & 4 mg per cc)	e. Short-term relief of anxiety and neurotic depression. IV and IM used prior to surgical procedures.	e. 2-6 mg daily in divided doses; no more than 2 mg in elderly in divided doses. IV 2 mg; IM 4 mg.	e. Sedation in 16 percent of patients; dizziness less frequently. Avoid alcohol. Short half-life.
f. hydroxyzine (Vistaril: caps 25, 50, 100 mg; P 25-50 mg in 1 cc; oral suspension 25 mg per tsp)	f. Mild anxiety, psychophysiological reactions. IM or IV for extreme anxiety and alcoholic withdrawal.	f. 25-100 mg tid or qid. P & IM: 50-100 mg repeated as necessary, 4-6 hours.	f. Side effects mild. May be used with psychotherapy. Potentiates barbiturates and narcotics.
(Atarax: T 10, 25, 50 mg; syrup 10 mg per tsp)	Antihistamine antipruritic, antiemetic properties. For chronic urticaria and dermatitis.		

g. clorazepate dipotassium (Tranxene: 3.75, 7.5, 15 mg; Tranxene SD: 11.25 and 22.5 mg)	g. Anxiety	g. 15-60 mg d. Elderly or debilitated patients: 7.5-15 mg d.	g. Avoid in depression or psychosis.
h. meprobamate (Miltown, Equanil: T 200, 400, 600 mg)	h. Anxiety, tension headache, muscle spasms, insomnia. Use is diminishing in favor of benzodiazepines.	h. Adults: 400 mg d to tid (max. 2400 mg d) Children: 100-200 mg bid.	h. Potentiates alcohol and sedatives. Hypotension possible, esp. in older persons. Habituation with prolonged use. Avoid driving until drug dose is stabilized. Avoid rapid withdrawal of drug. Drowsiness, allergic reactions possible. Tolerated by older persons.
i. busiprone (BuSpar T 5, 10 mg)	i. a non-benzodiazepine anxiolytic useful in generalized anxiety reactions. Relatively non-sedating and non-additive with few side effects	i. 5 mg tid. Increase by 5 mg over 2-3 days up to 60 mg max. Optional 20-30 mg d.	i. Does not potentiate alcohol sedation or impair psychomotor skills.

Sedatives and Hypnotics

Drug (How Dispensed)	Uses	Dosage	Misc.
1. Barbiturates	1. Helpful in short-term allaying of tension, anxiety, and insomnia. P: Iv or IM for convulsions		1. Use with caution in liver disease. Habituation, tolerance, and addiction possibilities great; not for prolonged use.
a. phenobarbital sodium (T 15, 30, 60, 100 mg; P 30, 60, 130 mg; Elixir 20 mg in tsp)	a. Short-term sedative and hypnotic.	a. Sedation: 15-40 mg tid. Hypnotic: 100-200 mg.	a. Slow acting; long duration.
b. amobarbital sodium (Amytal: T 15, 30, 50, 100 mg; P 250, 500 mg)	b. (as in a) IV amytal solution useful in narcosynthesis	b. Sedation: 65-200 mg d. Hypnotic: 100-200 mg P (IV or IM) 60-500 mg (10% sol) 0.5 to 1.0 cc per minute.	b. Moderately rapid acting; medium duration.
c. butabarital (Sodim Butisol: T 15, 30, 50 , 100 mg. Elixir 30 mg per tsp.)		c. Sedation 15-30 mg tid or qid. Hypnotic: 50-200 mg.	c. Rapid acting, short duration.
d. pentobarbital		d. Hypnotic: 50-100	d. Moderately rapid

sodium (Nembutal: caps 50-100 mg. P 50 mg per cc. Suppositories 30, 60, 120, 200 mg.)		mg; P 150-200 mg IM, 100-500 mg IV. Suppositories: children 30-60 mg; Adults 120-200 mg.	acting; short duration.
e. secobarbital sodium (Seconal: pulvules 50-100 mg. P 50 mg in 1 cc)		e. Hypnotic: 100 mg; P (IV or IM) 50-100 mg.	e. Moderately rapid acting; short duration.
f. amobarbital and secobarbital sodim (Tuinal: caps 50, 100, 200 mg)		f. Sedation: 50 mg; Hypnotic: 50-200 mg.	f. Moderately rapid acting; medium duration
2. Nonbarbituates			
a. flurazepam hydrochloride (Dalmane: caps 15-30 mg)	a. Effective hypnotic for all types of insomnia.	a. 15-30 mg before retiring	a. Low incidence of dependence, but avoid too longed administration. Avoid in pregnancy.
b. temazepam (Restoril C 15, 30 mg)	b. A short acting benzodiazepine. Anti insomniac agent.	b. 15-30 mg; 15 mg in elderly.	b. Avoid in pregnancy
c. triazolam (Halcion T 0.25, 0.5 mg)	c. A very short acting anti-insomniac agent.	c. 0.25 to 0.50 mg; 0.125 to 0.25 in elderly.	c. Avoid in pregnancy
d. glutethimide (Doriden: T 250, 500 mg; caps 500 mg)	d. Useful in elderly and chronically ill patients. For 3-7 days only.	d. Sedation: 250 mg. Hypnotic: 500 mg.	d. Onset in 15-30 minutes; duration 6 hours. Occasional skin rash. Avoid in chronic insomnia.
e. methyprylon (Noludar: T 50, 200 mg; caps 300 mg)	e. Well tolerated and effective. For short-term use.	e. Sedation: 250 mg Hypnotic: 500-1000 mg	e. Onset in 15-45 minutes; duration 5-8 hours. Avoid in chronic insomnia.
f. chloral hydrate (Noctec: caps 250-500 mg; syrup 500 mg per tsp)	f. Low toxicity; well tolerated in chronic illness.	f. Sedation: 250 mg tid Hypnotic: 500-1000 mg	f. Onset in 20 minutes. Avoid in cardiac, kidney, and liver disease.
g. ethchlorvynol (Placidyl: caps 200, 500, 750 mg)	g. Insomnia due to anxiety or excitement. 3-7 days only.	g. Hypnotic: 500-1000 mg	g. Do not give to patients with suicidal tendency Avoid in chronic insomnia.
h. paradehyde	h. A safe hypnotic and anticonvulsant in psychotic patients.	h. ½ to 1 ½ tsp in iced fruit juice or milk; 2 tsp in agitation. P 1-2 cc IM (Sterile sol)	h. Onset in 20 minutes. Avoid in gastrointestinal and liver disease

Table 57-1 Therapeutic Focus, Goals and Selection of Modality

(A) COMPLAINT FACTOR (target symptoms)	(B) SYNDROMES	(C) AREAS OF PATHOLOGY	(D) GOALS	(E) THERAPEUTIC FOCUS (implicated links)	(F) APPLICABLE FIELDS	(G) EFFECTIVE THERAPEUTIC MODALITIES
Depression Hyperactivity Hallucinations Severe anxiety Panic attacks Impulsivity and inattention Binge eating Obsessions and compulsions Phobias	1. Major depression 2. Bipolar disorder a. depressed b. manic 3. Atypical depression 4. Schizophrenic disorder 5. Schizophreniform disorder 6. Generalized anxiety disorder 7. Panic disorder 8. Attention deficit disorder 9. tensions]						
Distorted values and standards Maladaptive belief systems	Multiform adaptational difficulties	Cognitive distortions	Reeducation Cognitive restructuring	Philosophical spiritual link	Philosophy Theology Meta-psychiatry	Cognitive therapy Education Existential therapy

Target symptoms (A) characteristic of different syndromes (B) may often be expediently resolved by dealing directly with specific responsible areas of pathology (C). Goals in therapy here (D) are directed at such distortions. Looking at behavior as a chain of interrelated systems (biochemical, neurophysiological, somatic, conditioned, intrapsychic, developmental-interpersonal, social-environmental, philosophic-spiritual) a suitable focus is on the implicated links of this chain (E). Distinctive fields of interest (F) and special theories related to each link inspire a number of therapeutic modalities (G) that may be preferred approaches in certain syndromes even though through feedback interventions bracketed to other links may also be effective.

Table 61-1 Outline of Evaluation for Certification

Technical Skill

1. Diagnostic skill

   a. Ability to establish diagnosis and tentative psychodynamics after one or two sessions with the patient

   b. After six weeks, the ability to describe the patient's character manifestations and how they will most likely work out in relation to the therapist.

   c. After six weeks, ability to write an organized case report including diagnosis, psychodynamics and estimate of rate of progress.

2. Treatment planning:

   a. Formulation of a plan of treatment consistent with some theoretical orientation.

   b. Estimation of areas of difficulty.

   c. Estimation of which stage of therapy a patient is in and formulation of what to do accordingly.

   d. Estimation of when the patient is ready to discuss transference.

   e. Judgment in management and timing of interpretations and communications.

3. Session-to-session handling of the patient.

   a. Perception and understanding of continuity and discontinuity of communications of the patient within a session and from session to session.

   b. Recognition of manifestations of resistance.

   c. Judgment about when to give ego support and ability to do so.

4. Skill in handling the middle phases of therapy

   a. Judgment in the use of dreams in the best interests of the patient's therapy.

   b. Judgment in the use of transference in the patient's best interest

   c. Awareness and use of countertransference

   d. Ability to recognize acting-out and to help the patient recognize this either in what patient does in the session or between sessions, including the desire to terminate therapy prematurely.

5. Skill in handling emergencies, including the recognition of the severity of a crisis.

6. Skill in handling problems of termination.

   a. Recognition of when termination should be planned for.

   b. Preparation of the patient for this.

Personality of the Therapist

1. Ways of relating to the patient.

   a. Genuine interest in and empathy for the patient.

   b. Readiness and capacity to relate emotionally to the patient in a healthy way, that is:

      i. To disengage from neurotic involvements

      ii. Be aware when it is productive to express feelings, positive and negative.

      iii. Be able to estimate the attitudes and role that are assumed in the therapeutic sessions(awareness of roles that may hurt the patient, such as putting up a front, being managerial, rigid, detached, overconcerned, not showing respect).

   c. Appraising factors in the previous experience of the patient.

      i. Sorting out real hardships from neurotic ones in the life of the patient.

      ii. Appraising what might have gone on in a previous therapy.

      iii. Being alert to grievance collecting.

   d. Speaking in terms natural to the patient; using technical language only when necessary.

   e. Ability to use values judiciously especially when therapist's value judgments differ from those of the patient.

   f. Ability to learn by mistakes.

2. Ways of relating to supervisor.

   a. Ability to communicate therapy sessions and problems meaningfully to the supervisor.

   b. Relative freedom from defensiveness in relation to what is going on in therapy with a patient.

   c. Respect for and honesty toward the supervisor.

   d. Use of supervisory sessions in order to learn.

   e. Tolerance for new point of view other than one's own.

   f. Ability to discuss one's own evaluation in a mature way.

3. Ways of relating to the administration.

   a. Reliable in relation to requirements (e.g.paperwork)

   b. Reliable in relation to class attendance.

   c. Reliable in making arrangements for supervision.

   d. Reliable in relation to patient load.

   e. Honesty in relation to administration.

   f. Reasonable consideration for clerical personnel.

4. Ways of relating to colleagues.

a. Respect for colleagues in different disciplines.

b. Ability to cooperate with colleagues on related cases (husband and wife, child and parent).

c. Mature attitudes in classroom and professional meetings, toward presenting of case material by colleagues.

Direction of Growth and Promise

1. Continuing ability to learn from patients

   a. Continuing improvement in recognition of similarities and dissimilarities in various patients.

   b. Awareness that one does not know everything about the psychodynamics of one's patients (accepts the fact that one does not know all the answers).

2. Recognition of areas in which one is competent as well as those in which one needs to learn more.

3. Ability to develop own individual style without needlessly imitating an idealized supervisor.

4. Progressive diminution of countertransference reactions.

5. Continuing interest in scientific problems of personality (diagnosis, prognosis, and psychodynamics) and psychotherapeutic techniques.

6. Estimate by supervisor(s) as to how the therapist with function when on his or her own and in a new status.

   a. Will the therapist continue in supervision or consult when there is a need?

   b. Will the therapist feel free to exchange problems with colleagues?

7. After certification will the therapist work in the community, such as teach, do research, work in some organization or clinical setting, or participate in professional activities?

Supervisor-Supervisee Relationship

1. Ease with which supervisor can work with supervisee (Add any statement you wish to make about your evaluation).

Table 67-1

A Multilevel, Multisystem, Method for the Study of Problems of Organizations and the Individual Functioning in these Organizations as They Attempt the Solution of Problems: A Mental Health Consultation Technique—Directives to the Consultant

Part 1. Definition of Problem

Succinctly formulate the chief problem for which the study is undertaken based on the subjective estimation of the problem by members from three levels of the organization, (administrative, supervisory, and line staff). The statement must include what the problem means to the organization and to the individuals functioning in the setting. Important administrative, supervisory, and staff members should be interviewed.

Part 2. Detection, Identification, and Description of the Problem

    A. Study of the individuals in the organization who have the particular problem or who are affected by it.

        1. Study formal records.

        2. Study anecdotal records.

        3. Study questionnaires that have been answered by the individuals requesting the study.

        4. Direct interviews with three or four individuals affected by this problem.

        5. Study the work records of individuals affected by this problem in relation to skill, absenteeism, illness.

    B. Study peer groups in three levels of the organization, (administrative, supervisory, and staff personnel) members of which are affected by the problem.

        1. Hold a series of four group discussions with peers from each

organizational level and answer these questions:

(a) How does each individual react in the group?

(b) Can the members communicate?

(c) Do subgroups form as the discussion proceeds?

(d) Are some members disruptive?

(e) Are any of these group members emotionally disturbed?

(f) Does this disturbance cause trouble in the group?

(g) Does the emotional difficulty affect work roles?

C. Study of the organization in relation to this particular problem.

1. What is the function of this organization?

2. Study the institutional records for the purpose of determining how the problem affects the operation of the organization.

3. What disposition has been made of the problem up to the present?

4. How seriously does the problem affect the organization?

5. Has the problem affected individuals in a destructive way?

6. What institutions or organizations or agencies in the community is this organization responsible to with respect to this problem?

7. Is this trend or problem a unique one that exists only in this organization? Or does it exist in all organizations? Or only in some? Specify.

8. What efforts have been made to reverse this trend? And what techniques have been used? By whom? Where?

9. Typical day in the organization with respect to this problem.

10. Group discussion with at least four or more individuals on the supervisory level with respect to the information collected to date.

11. Is there any discrepancy between the ideas of the supervisors and those of the staff with respect to the problem?

12. Are there subgroups within the organization that are competing or are antagonistic to one another?

13. Is the consultative process threatening to individuals within the organization, and do they build up resistance to it? Illustrate.

Part 3. Analysis of Data

A. What are the motivations of the individuals who requested the consultation?

B. Where are the main pressures in the organization?

C. What groups of individuals need additional skills?

D. Can the supervisory staff give the members of the group the appropriate training for the skills, or do they themselves need further education?

E. Can you determine the point at which information is acceptable and at which it can be integrated by the supervisors and by the staff?

F. Are other resources than skills of the consultant needed to assist in the retraining of the staff?

G. Is there conflict between workers and supervisors? Between supervisors and administrators?

H. Are there intra-agency clashes between departments? Among people due to lack of role boundary? Due to personality problems?

I. What are the main problems as you see them according to the analysis of the data? List.

J. Will the changes in role by training or retraining cause dislocation of a temporary nature in the organization?

Part 4. Planning and Decision Making

A. What plan do you suggest?

B. How will you explain this plan to the administration? To the supervisors? To others who may have to be informed?

    1. Illustrate the types of communication that you will use with the above categories in the social organization.

C. Where do you anticipate that resistance will occur and for what reasons?

    1. Can anything be done to counteract this?

D. What is the nature of your relationship with the members of the organization with whom you will have to work? Explain.

E. Steps in working out the plan.

    1. List the steps you will take to carry out the plan.

    2. How will this reverse the trend or help the problems that you have found?

        (a) Document this plan and the rationale for the steps you are taking with theoretical concepts from the literature.

        i) What are the specific techniques you will employ?

        ii) What do you anticipate as a result of the carrying out of this plan?

Table 67-2
Mental Health Consultation Guide for Multisystem Consultation Method

Within an Organization Tensions are Expressed on	Expressions of Problems Found upon Entry into an Organization	Psychological, Social, and Health Factors Contributing to Organizational Difficulties
Individual Level: by Executives Supervisors Staff	Lack of clarity in goals Inability to achieve objectives Lack of skills (inadequate training) Rigidity; confused hierarchy Inability to change practices Apathy, boredom, and lack of interest in work Procrastination, lack of initiative Sense of hopelessness Inability to undertake responsibility Self-excusing	Characterologic, neurotic, and psychotic difficulties Frequent illnesses Alcoholism Delinquency and crime Drug addiction Chronic disease Absenteeism Other
Internal Relationships Level by individuals who belong to subgroups involved with agency philosophy, policy making, and establishing rules and regulations. Management in relation to owners, stockholders, and boards of trustees Intramanagement relationships Administrative actions Staff-management relationships Staff interaction Staff-client relationships	Inadequate administration Cluttered and inoperative channels of communication: divisive techniques; unclear administrative channels; lack of coordination of activities Confusion in giving and taking orders Interdisciplinary and departmental conflicts (prestige, control, status, and authority problems) Unqualified staff Conflicts between policy makers and those who carry out policy Lack of participation in group process Fear of democratic process and need for authoritarian system Inadequate system of rewards and recognition for personal achievement Inadequate personnel practices, training programs, and counseling Vague and conflicting aims Inadequate programming for goal achievement Inadequate board of trustees, owners, or corporate personnel	Projection of difficulties onto others Hostility, aggression, or compulsive competitiveness Acting-out of sadomasochistic fantasies Withdrawal Obsessive doubting, indecisiveness Resistance to change Recurrent frustrations in work effort Conflicting interpersonal relations Unconscious sabotaging Paranoid feelings (griping, complaining, undermining) Laissez-faire attitudes
External Relationships Level by individuals who are working with Organized Professional Groups Labor Religious organizations Civic organizations Political groups Business groups Press Government	Difficulties in obtaining cooperation of community leaders Inadequate interagency cooperation on programs Failure in communication with groups Failure in obtaining acceptance from professional groups Difficulty in obtaining acceptance of community	Failure of staff and/or organization to satisfy standards acceptable to the community Failure of staff to meet standards of professionals in the community Inadequate service

groups
Inability to reduce conflicts with
groups in the community
Poor image of performance and
role of organization
Inadequate techniques to deal
with community criticism and
pressures

Failure to meet
community needs

Consequences to Organization	Consultation Activity Aimed at Problem Resolution; Consultant Assists Staff toward	Recommendations and Plans
Inadequate service Loss of work due to high rate of lateness and absenteeism	Presenting of problems through case method Discussing staff studies and staff understanding of problems presented by individuals Collecting of information on staff attitudes based on opinions expressed Observing of interaction of staff members (in framework of group dynamics) Making inferences as to problems presented and their analysis and evaluation	Programming for individual counseling, psychotherapy, and/ or referral sources Clarification of roles Clarification of duties Clarification of supervisory practices
Organizational goals not achieved due to inappropriate planning and programming Inadequate supervision and controls; unclear responses and practices Inability of staff to meet requirements of job High turnover of qualified people Duplication, errors, minimization of benefit from skills of expert staff Difficulty in rendering service Failure on collaboration efforts Low morale	Discussing of organizational chart to obtain clarification of lines of authority and channels through which decisions are made and implemented Identifying needs and problems of staff and making inferences as to kinds of and intensity of problems in the organization; establishing the expertness of staff and agency resources to cope with the problems Exchange of ideas Handling feedback from communication	Changes in staff orientation and role Education for new roles through training Adaptation of mental health information and techniques to the needs of the organization and its goals and practices
Low prestige Confused public image Lack of community	Interpreting goals and purposes to community Organizing services useful to the district in which the organization exists Public relations	Joint programs with agencies Community education Consultation services Work in professional

| acceptance Difficulty in raising funds or obtaining credit Difficulty in obtaining adequate staff | Fund raising (for non-profit organizations) Changes in board membership Programming in relation to other organizations | societies Explicit public relations programs that are educational as well as informative Reporting of work done |

1 *ego strength* is somewhat ambiguous, but in the sense it is employed here it connotes the positive personality assets that will enable the individual to overcome anxieties, to yield secondary gains of illness, and to acquire new, more adequate defenses.

2 The existence of a portion of mental activity at the periphery of awareness or permanently blockaded from awareness was known to scientists and philosophers before Freud. Freud's contribution was to demonstrate the dynamic operation of the unconscious in the daily life of the individual and its role in psychological illness. He devised ways of examining and exploring unconscious ideation, and he formulated a theory organized around the workings of this hidden portion of mental activity. Though some of his hypotheses have been altered and new terms for the unconscious have been elaborated (such as Rado's "nonreporting brain activity"), Freud's basic contentions about the unconscious and his methods of decoding it continue to be accepted as a most fundamental contribution.

3 Freud (1934) regarded the original libidinal charge or "cathexis" of the ego, as "primary narcissism." Part of the libidinal cathexis of the ego was later yielded to outside objects. This enabled the individual to participate in relationships with others. The original libidinal cathexis of the ego persisted and was related to the object cathexis, like the body of an amoeba is related to the pseudopods that it puts out. And like pseudopods that could be withdrawn into the body of the ego, so object libido might, in times of stress, be withdrawn with return of narcissism ("secondary narcissism"). Infantile conflicts and patterns were also revivified in this process. Sexual perversions constituted the positive expression of pregenital libidinal fixations, while neurotic symptoms were a negative or converted expression (Freud, 1938a).

4 For example, an investigation of the results of 241 private patients treated over a 15-year span revealed that psychoanalysis of whatever duration and intensity had only supportive value for seriously sick patients (Heilbrunn, 1963).

5 There are, of course, many agencies that are not typical in this sense but are "primary" casework agencies in the sense that caseworkers administer the agency and carry the main treatment load. Psychiatrists, psychologists, and other professionals are used as consultants in such agencies. They are also more purely treatment agencies in the sense that need for their services is defined primarily by emotional breakdown. Many child guidance clinics and family service agencies fall into this category. The typical caseworker does not work at such an agency, however. The practice of a caseworker in such a setting is akin to that of a psychotherapist.

6 Some parts of this section have been adapted from Wolberg LR, Kildahl JP: The Dynamics of Personality. Orlando, FL, Grune & Stratton, 1970.
