> I have seen Mr. _____ in consultation and agree with you that a strong emotional element is involved in his present somatic complaint. I believe psychotherapy definitely to be indicated; but I am not, at the present time, able to

prognosticate the outcome due to the incomplete motivation that exists for treatment. Mr. _____ responded satisfactorily to the interview and expressed a willingness to start therapy with me. I should like to thank you for the referral.

Sincerely yours,

Correspondence may also be required when it is necessary to get further information about the patient from former therapists, from clinical psychologists who have administered tests, from physicians who have rendered recent examinations, and from institutions in which the patient was hospitalized. A "release" form, such as in Appendix R, signed by the patient, will usually be required when requesting such information.

During the first interview, or later if needed, consultations with a number of professionals may be considered essential. When the therapist takes the time to explain the reasons for this, little or no difficulty will be encountered.

MEDICAL, NEUROLOGIC, AND PSYCHIATRIC CONSULTATIONS

It goes without saying that each patient under psychotherapy requires a thorough physical and neurologic examination to rule out organic somatic illness. If the patient has been referred to the therapist by a physician, the therapist may check with the former as to whether or not physical and neurologic examinations have recently been administered. If not, arrangements for these should be made with, or through, the patient's physician. A blank such as that in Appendix O should be filled out by the physician and filed in the patient's case record. For patients on whom a complete neurologic examination is done, a form such as in Appendix P may be found helpful.

Disorders of the cognitive, affective, and behavioral functions are usually psychologically caused but may be due to physiological disturbances whose existence, if suspected, should be ruled out. (See also the chapter on diagnosis.) Thus anxiety may be due to a certain tumor in the adrenal medulla (pheochromocytoma) or overactive thyroid (hyperthyroidism, Graves' disease). Conversion disorders (hysterical neuroses, dissociative disorders) may be mistaken sometimes for neurologic disease or gross brain disease; and somatization or somatoform disorders can be mistaken for actual physical disease. Depressions may be the product of (1) toxic substances (alcohol, sedatives, cocaine, antihypertensive drugs), (2) infections (viral hepatitis, infectious mononucleosis, tuberculosis, syphilis), (3) endocrine disorders (myxedema, Cushing's disease, Addison's disease), (4) neurologic illness (multiple sclerosis, Parkinson's disease, cerebral tumors, early dementia), or (5) nutritional problems (pellagra, vitamin B12 deficiency, collagen

disorders, or neoplasms). Schizophrenia may be simulated by some organic disorders such as drug toxicity (amphetamine), brain disease (neurosyphilis), and some types of hypothyroidism. Memory loss may be a product of early dementia (Alzheimer's disease, Pick's disease, multi-infarct dementia, infectious dementia, encephalopathy, sclerosing encephalitis, meningitis, or poisoning (lead or carbon monoxide). Amnesia may occur with cerebrovascular disease of the brain or lesions in the mamillary bodies and medial thalamus. Personality changes may develop with an expanding tumor of the brain or Huntington's chorea. Apathy, emotional lability, and various somatic symptoms (often considered a sign of hysteria) may be the result of multiple sclerosis. Impotence and inhibited sexual desire may be a manifestation of depression (expressed or masked), antihypertensive medication, psychotic drugs, diabetes, and some spinal cord diseases. Difficult or painful coitus (dyspareunia) may be a sign of suburethral diverticulum, retroflexion of the uterus, and pelvic inflammatory disease. When there are any signs of aphasia, apraxia, altered awareness of the body image (anosognosia), impairment of consciousness, syncope, or confusional states, there may exist lesions of the brain, epilepsy, diabetes, hypoglycemia, ingestion of exogenous toxic agents, or endogenous toxins and deficiencies (uremia, hyponatremia). A pain syndrome is sometimes psychogenic, but it may also be due to lesions in the thalamus. Vertigo may be a product of labyrinthine disease. Recurrent severe headaches necessitate a ruling out of expanding brain tumors, meningeal irritation (syphilis, tuberculosis), metastatic neoplasms, vascular disturbances, toxic states, hypertension, iritis, and glaucoma. Hiccups can be psychogenic but if prolonged may be due to irritation of the medullary centers controlling the diaphragm.

It may be seen from this that the list of maladies is long and discouraging because almost every symptom for which psychological treatment is sought may accompany certain physical conditions. When there are any doubts, consultation with a good internist or neurologist is important.

If organic illness is discovered on examination, the patient must be guided by the advice of the physician about required medical or surgical treatments. If no organic illness

is found, the physician should be used as a consultant whenever physical symptoms of any kind develop during the course of psychotherapy. Insistence that the patient see his or her own physician is not only good medicine but also makes for good public relations. Even when the therapist is a psychiatrist who has not lost the medical diagnostic skills, the rules outlined will be found helpful. To do physical examinations or to prescribe medications other than psychotropic drugs may not be prudent, except perhaps in supportive therapy and in the more superficial reeducative therapies.

The expediency of psychiatric surveillance of certain patients being treated by non-medical therapists has already been discussed. The results of the psychiatric examination should be filed in the case record, using an outline or a form such as in Appendix Q. The psychotherapist then may be advised how to handle any emergencies that develop during the course of treatment, such as severe depression, suicidal attempts, and psychotic outbreaks. The therapist can, when necessary, administer or refer the patient for narcotherapy, hypnosis, electroconvulsive therapy, or drug treatments, such as tranquilizers, energizers, antidepressants, endocrine products, or antagonists like Antabuse. The therapist may also arrange for hospital admission or commitment when required.

CASEWORK CONSULTATION

The therapist may desire a consultation with a caseworker from a local social agency when any of the following difficulties exist:

1. Severe financial problems requiring supplementary help

2. Need for job placement or relocation

3. Need for rehabilitative services

4. Need for special health services

5. Need for better housing or for neighborhood relocation

6. Need for recreational facilities

7. Need for special schooling and training

8. Social security problems

9. Need for referral to special clinics or hospitals for the management of physical illness when resources are unknown or financial difficulties prevail

10. Aid in placement of a child in a foster home or institution.

In supportive and some types of reeducative psychotherapy the patient may be referred for adjunctive therapy directly to the caseworker or a special social agency that deals with the particular problem. The caseworker helps the patient use the community resources best suited for the patient's needs. In reconstructive therapy this may also be done; however, the activity of a caseworker as an accessory helper may, in some patients, tend to disrupt the therapeutic relationship. Should such patients require casework services, the therapist may get the necessary information from the caseworker, such as the best available resources to meet the patient's needs. The therapist may then acquaint the patient with possible courses of action, encouraging the patient to make his or her own plans. The therapist handles therapeutically any delays or other resistances to effective use of the resources.

A caseworker may also be employed to deal with parents, mate, or children of a patient when such relatives require placement, hospitalization, counseling, or guidance as an aid in the treatment of the patient. Among the services rendered by the caseworker are the dispensing of information related to sexual problems, child-parent relationships, marital relationships, hereditary influences, budgeting, home management, housing difficulties, work problems, difficulties associated with alcoholism, and problems of old age. Premarital and marital counseling are other areas in which the help of the caseworker is often sought. Additionally, the caseworker may be used as a liaison between the patient and the patient's family, employer, teacher, and others when it is essential to interpret the patient's illness to them, to give them reassurance, or to enlist their active interest and cooperation.

In psychiatric clinics, caseworkers are often used for intake interviewing, to clarify

the service of the clinic to prospective patients or to the referral source, and to determine if the service offered by the clinic is consonant with the needs of the patient. In addition, they are employed to take case histories and to prepare patients for psychotherapy by dealing with resistances to and establishing the proper motivation for treatment. When indicated, they help, directly or indirectly, to manipulate the patient's environment. Lastly, they serve to interpret the work of the clinic to the community and to enlist the cooperation of the community with the clinic. Caseworkers act as a liaison between the clinic and community organizations that are implementing community programs related to health, welfare, and social security.

PSYCHOLOGIC AND RELATED CONSULTATIONS

A consultation with a clinical psychologist may occasionally be necessary if the patient requires intelligence tests, vocational tests, and tests for special aptitudes (Freeman, FS, 1962; Hoch & Zubin, 1951; Sundberg, 1962; Tallent, 1963; Cronbach, 1960; Schaefer, 1948; Anderson & Anderson, 1951; Abt & Beliak, 1959; Buros, 1953; Rapaport et al. 1946). These are used as an aid in planning a better environmental adjustment for the patient. Projective tests are also used as a rapid means of revealing important traits and tendencies. The test situation serves as a tiny segment of life, a kind of laboratory in which the individual divulges customary needs, hopes, impulses, and defensive drives. A trained, astute observer may analyze the strivings of the patient as they are projected into the test materials as well as the patient's defenses and may make remarkably accurate assumptions about the character structure and the unconscious conflicts of the person.

The most important tests employed by the psychologist are:

1. Measures of the ability to learn—Stanford-Binet Test (Terman & Merrill, 1960), Wechsler Intelligence Scale (Wechsler, 1955; Koppitz, 1963)

2. Personality questionnaires—Minnesota Multiphasic Personality Inventory (MMPI) (Hathaway & Meehl, 1952; Schofield et al., 1956)

3. Projective tests—Rorschach Ink Blot Test (Rorschach, 1942; Klopfer & Kelly, 1942; Beck, 1944, 1945, 1952; Ulett & Goodrich, 1956; Rickers-

Ovsiankina, 1960; Thorndike & Hagen, 1961), Thematic Apperception Test (Murray, 1938; Tompkins, 1947; Anderson & Anderson, 1951; Beliak, 1954), Szondi Test (Deri, 1949), House-Tree-Person Test (Buck 1950), Man-Woman Drawing Test (Machover, 1948, 1951)

Sometimes there is an examination of handwriting (Lewinson and Zubin, 1942; Sonneman, 1951), art creations (Lewis, 1925), manipulated play materials (Erikson, 1939), and word associations (Jung, 1919), cognitive functions (Folstein et al., 1975), psychiatric disorders (Wing et al., 1974), and alcohol screening (Selzer, 1971). Among the items of information revealed are clues to the intelligence, originality, creativity, and sensitivity of the person; the severity of anxiety; the defenses employed against anxiety, such as inhibition, repression, phobias, compulsive reactions, aggression, acting-out, somatic preoccupations, fantasy, and retreat from reality; the intensity of hostility and defenses against hostility; the nature of interpersonal relations and current disturbances of character, such as dependency, aggression, sadism, masochism, detachment, and paranoid tendencies; the quality of self-esteem and whether there are distortions in narcissism, grandiosity, and self-devaluation; sexual problems, inhibitions, fears, and perversions; masculine and feminine identifications; existing inner conflicts; schizoid and disintegrative tendencies; organic brain disease; and ego strengths and weaknesses. This helps in making a diagnosis and in differential diagnosis, in assessing personality, and measuring intellectual level.

The virtue of psychological tests is primarily in the diagnostic sphere. Attempts to evaluate ego strength and to predict the outcome of therapy by means of testing are usually speculative. If the clinical psychologist makes predictions about the quality of change that the patient will achieve in psychotherapy, estimates definite goals in treatment, and indicates the kinds of techniques to which the patient will best respond, he or she is straining the test materials, attempting to adapt them to areas for which they were never designed.

Prognostic estimates and predictions of what will happen in therapy on the basis of psychological tests are often fraught with disappointment. Although it is possible to

determine customary responses to authority, and the habitual interpersonal reactions that emerge in a relationship situation, it is not always possible to guarantee that these responses will develop with the therapist. Therapy involves a special kind of a relationship, the uniqueness of which may prompt latent or new responses. Much, of course, will depend on the therapist, on whether he or she falls in line with the role the patient expects him or her to play. Similarly, it is difficult to anticipate the interpersonal potential of the patient, since it is unknown how the therapist will manage the tentative thrusts of the patient toward a different kind of relationship. Finally, it is not easy to predict what the patient will do with insight, whether he or she can acquire insight or use it, once it is evolved, in the direction of change. For these developments, too, are largely contingent on the nature of the therapeutic relationship and the skill of the therapist.

All psychologic tests are brief samplings of the patient's reactions to a limited test situation, at a special time, with a specific test administrator. The patient may at another time, with a second test administrator and under changed conditions, respond differently. Test results must, consequently, always be correlated with clinical findings. The more experienced the therapist, the more the therapist will rely on clinical judgment and the less emphasis will be put on psychological test materials.

Beginning therapists usually feel more confident when they have in front of them a personality survey that describes some of the patient's defenses and conflicts. The contribution that the test makes to the therapists' feelings of security more than offsets the disadvantage of having a preformed opinion about the patient. As the therapists become more experienced, they find that psychological tests are not accurate in all instances. They then regard them as tentative blueprints of neuroses that will require more or less extensive alterations as they delve into the patient's problems. Finally, they may, if their experience is sufficiently extensive, rely much more on their clinical judgment than they do on psychological tests. They may heed certain warnings sounded by the tests, such as the presence of disintegrative tendencies, which will make them gauge carefully the interpretive pressures that they apply so as not to overtax the strength of the patient's ego. They will still grant priorities to clinical "intuition," however.

In the hands of an experienced clinical psychologist who is conservative in test interpretations, psychological tests are valuable aids to the therapist, provided the latter does not permit the tests to interfere with the spontaneous planning and execution of the therapeutic approach. Therapy is more influenced by the skill of the therapist and by the capacity to set up a good working relationship with the patient than it is by the existing clinical syndrome. Thus, psychological tests may reveal strong schizophrenic tendencies. This revelation may frighten the therapist, and, on the basis of warnings by the psychologist that the patient cannot stand a reconstructive approach, the therapist may smother the patient with supportive props. Were the therapist to gauge the depth of therapy by the strength and quality of the relationship with the patient, there would be a much more accurate measurement of the extent of stress that the patient's ego could tolerate. On the basis of a good relationship, reconstructive therapy might be possible, and the patient might be able to endure and to resolve considerable anxiety.

Some therapists, who have had training in the administration and interpretation of psychological tests, prefer to test the patient personally rather than to send the patient to a clinical psychologist. By doing this they are able to observe the behavior of the patient and the manner of the patient's approach to, and execution of, the tests, which may give them valuable clues in addition to those revealed by the test responses. Often therapists do not score the tests but rely mainly on a qualitative analysis of the responses. Some therapists use test administration therapeutically, accenting certain responses to encourage the patient's associations (Harrower, 1956).

Apart from these traditional uses of psychologic tests, there are some psychologists who advocate the employment of projective materials to provide for a more objective measure of therapeutic progress (Piotrowski & Schreiber, 1952). By taking a test at the start, during, and end of treatment, it is believed possible to validate clinical impressions of changes developing in psychotherapy.

If the initial interviewer decides in favor of psychological tests, it will be necessary to prepare the patient for referral to a clinical psychologist. An explanation may be given the

patient along lines indicated by the following excerpt:

> *Th.* I should like to get a psychologic examination. Would you have any objection to this?
>
> *Pt.* What is this examination?
>
> *Th.* Psychologic tests are like x-rays, they enable the therapist to see things about a person that would otherwise require many therapeutic sessions. In this way it helps to cut down the time of therapy.
>
> *Pt.* Are the tests expensive?
>
> *Th.* They cost more than a single treatment session, but they may save money in the long run.
>
> *Pt.* I want to do anything that is necessary, doctor.
>
> *Th.* All right, I'll make the arrangements for you.

Obviously the fee for testing must be within the financial means of the patient. Some patients may not be able to afford psychologic testing, and the therapist may then have to forego it.

The most common test employed in reconstructive therapy is the Rorschach. Sometimes the Thematic Apperception, the Szondi, and the Man-Woman Drawing tests are used. A complete battery of tests, which is the preferred routine, is prohibitive in cost for the average patient, although the therapist may be able to make special financial arrangements for this with the clinical psychologist. When only isolated tests can be afforded, the therapist should indicate to the clinical psychologist the special area of interest, such as diagnosis, dynamics, and so forth so that a proper selection can be made of the tests administered.

In recent years, divorce mediation has come into prominence and can be a productive alternative to adversarial proceedings in conventional divorce. The divorce mediator acts as a neutral party enabling couples to negotiate with each other on important issues of distribution of marital property, arrangement of family finances, child support, custody, and visitation. Clients are also helped to separate emotional from practical issues, such as to recognize tax consequences of options. Specially trained

counselors and lawyers may be found through local social agencies. Legal counseling in a variety of areas may be necessary and social agencies may also be of help here.

In addition to giving tests, psychologists are helpful when career planning and vocational and educational guidance are necessary as part of the treatment plan. Some psychologists are trained to do premarital, marital, adolescent, and old-age counseling. They also act as research supervisors in organizing and handling details of research projects.

Corrective work in the educational field, such as the treatment of reading and educational disabilities, may require the consultative services of special professionals such as remedial reading instructors. Rehabilitation workers may help in physical and sensory defects that interfere with the functioning of the patient. Speech disturbances may require the aid of a speech therapist.

The services rendered by such professionals as psychologists, remedial teachers, rehabilitation workers, and speech therapists are adjunctive to psychotherapy. Because prolonged contact may be required with adjunctive workers, it is essential that the workers be well-integrated individuals. It is important, too, that they recognize their limited role and not interfere with the therapist by giving the patient advice and interpretations that have nothing to do with their specific area of function. The therapist will always have to work out with the patient the matter of divided transference when consultants are employed. This need not constitute too difficult a hazard unless the consultants are themselves seriously disturbed emotionally.

The Initial Interview: Important "Don'ts" during the Initial Interview

1. **Do not argue with, minimize, or challenge the patient.** If the patient presents a point of view that is obviously prejudiced or distorted, one may be tempted to argue with or challenge it. These tactics are ill advised since the patient probably needs to maintain a distorted point of view to bolster defenses. Criticizing the viewpoint or theory may seem logical but, since there is no close relationship with the therapist, the patient may be unable to tolerate an attack on his or her defensive system. When the patient presents a fallacious idea and insists it is true, he or she may be told, "Understandably you may feel this way, but there *may* also be other ways of looking at this situation." Should the patient keep probing this point, the therapist may say, "I do not yet know enough about the problem to make positive statements."

2. **Do not praise the patient or give false reassurance.** Because the patient's self-esteem is so damaged, he or she will probably be unable to accept any praise even though it is sincerely offered and realistically justified. Actually, there is little reason for praising the patient for any virtues, such as appearance, poise, or accomplishments, since the patient is undoubtedly aware of these and has discounted them. Reassurance may also be a futile gesture, although some reassurance may be attempted when the patient shows symptoms of adaptive collapse and grossly minimizes chances for recovery with psychotherapy.

3. **Do not make false promises.** These will boomerang, and the patient will use them deftly in resistance. The interviewer has no way of knowing what the course of therapy will be, and to pledge results before observing how the patient works is folly. The same holds true for promises of special privilege. To make these hastily to lure the patient into therapy and then to withdraw them because they cannot possibly be fulfilled can be greatly damaging to the patient's trust in the therapist.

4. **Do not interpret or speculate on the dynamics of the patient's problem.** The patient is obviously unprepared for interpretations until a working relationship has been established with the therapist. To assault the

patient with explanations at the start is like attempting to plant a seed on untilled soil. Not only will interpretation not take, but its effectiveness will have been vitiated when an attempt is made to interpret later. Similarly, to speculate on the dynamics of the patient's problem is to bombard the patient with concepts that will do little except to mobilize resistance. If the patient asks for interpretations or wants an outline of the involved dynamics, the therapist may say, "It will be necessary to find out more about the problem before I can offer you a really valid opinion of it."

5. **Do not offer a diagnosis even if the patient insists on it.** This is because a diagnosis is often employed as a masochistic torture weapon. The therapist may provide an importunate patient with the explanation that an emotional problem is present that can be approached through psychotherapy. The type of problem is not important from a practical standpoint. Actually, it is impossible to make a complete diagnosis without studying the patient over a period of time.

6. **Do not question the patient on sensitive areas of life.** It is important not to interrogate the patient on sensitive points, particularly appearance, status, sexual difficulties, and failures in life. An opening may be given the patient to talk about these, but if blocking occurs, it should be respected until some later date when the relationship is sufficiently firm to countenance greater tension and anxiety. It is necessary in the initial interview, and indeed throughout the first phase of therapy, to avoid all comments that are offensive or humiliating to the patient. In fact, this should be the rule throughout therapy.

7. **Do not put the patient on a couch for the initial interview.** The establishing of rapport and the eliciting of important data are best accomplished in face-to-face interviewing. A great deal of anxiety is apt to be mobilized in a patient if the interviewer insists on the couch position.

8. **Do not try to "sell" the patient on accepting treatment.** Once the facts are presented to the patient, the choice of whether therapy is pursued must be the patient's. To force the patient into therapy may create insurmountable problems for both patient and therapist.

9. **Do not join in attacks the patient launches on parents, mate, friends, or associates.** Because the patient feels ambivalent about people he or she attacks, the therapist's criticism of these people may be resented. The

patient may consider the therapist impulsive, naive, or judgmental to join in an attack with as little information as has been revealed. The therapist's best response is sympathetic listening, not defending, condemning, or condoning the person attacked. If the patient complains about a remark that was made to him or her that was upsetting or about a bad situation, the therapist may say, "A remark like that would be disturbing to you," or "This situation must have upset you," or "Actions of this sort can be disturbing to a person." Examples of unsuitable and suitable responses follow:

Pt. My wife is impossible. She's always been this way—nagging, yelling, disagreeable. Nothing satisfies her.

Unsuitable responses:

Th. That's terrible. Doesn't she know what it does to you?

Th. That's bad. She's a destructive person.

Th. Maybe you're prejudiced against her.

Suitable responses:

Th. This must upset you.

Th. It must be difficult for you.

Th. A situation like this could be disturbing to any person. Do you think you get unduly upset by it?

10. **Do not participate in criticism of another therapist.** Even if the patient presents accounts of unprofessional behavior, it is bad practice to criticize another therapist. No matter how strong the evidence may be, one never knows how much of the patient's story is colored by misinterpretation or transference. In the event the patient complains that there was no progress with a former therapist, one must also not agree. Often, significant inner changes have occurred that are blocked by transference. A resolution of hostility toward the former therapist may bring out the fact that considerably more progress was made than the patient had estimated. It should be remembered that should the interviewer fail to help the patient, one may become the victim of accusations that are made to the next therapist whom the patient consults. An example of how criticism may be handled is given in the following excerpt:

Pt. When I say that for three years I wondered what the hell went on, it's true. I don't know what—I can't summarize what I learned or what happened for three years with Dr.____ I just didn't get anywhere, and I'm at a loss to say just what transpired all that time.

Th. You feel it was a waste of time?

Pt. Yes. I … I … I do feel that it was mishandled, and I do feel that it was time wasted, and in many ways.

Th. Perhaps certain problems came up in your relations with Dr.__

Pt. Yes, I know I'm as slippery as the next patient as far as being treated goes.

Th. Slippery?

Pt. Dr.____ always complained I just didn't catch on, didn't do the right kind of associating.

Th. Perhaps the situation just didn't progress for many reasons. At any rate we may be able to discuss your feelings about your past treatment in greater detail later on.

32
The Initial Interview: Dealing with Inadequate Motivation

Patients who come to the initial interview with inadequate, little, or no motivation for therapy require special handling because their mental set makes them refractory to the usual interview procedures. Among such patients are those with psychosomatic problems referred by physicians; delinquents, criminals, psychopathic personalities, sexual perverts, and other individuals involved in legal difficulties who are sent in by courts or correctional agencies; husbands and wives whose mates threaten divorce unless their partners get treatment; clients of social agencies who have been inadequately prepared for therapy; alcoholics or drug addicts who are shepherded into the therapist's office through cajolery, threats, or exhortations; children with behavior and emotional problems brought in by parents or referred by schools; and psychotic persons out of contact with reality.

An inadequately motivated patient may utterly refuse to start therapy in defiance of the therapist and the referring agency. Or the patient may apathetically accept his or her plight, reporting as if to a parole officer, with no intention of cooperating or of conceding that help is possible. Accordingly, it is impossible to establish the kind of working relationship that permits the achievement of meaningful therapeutic goals. With proper handling, however, it may be possible to deal with defective motivation and to create the incentives essential for effective treatment. A general outline for the management of the poorly motivated patient follows;

1. Recognition and reflection of the patient's negative feelings about therapy and the therapist.

2. Indication of an understanding and acceptance of these feelings.

3. Display of a neutral attitude toward the patient's needing or being able to benefit from psychotherapy, until more facts are known about the

patient's problem.

4. Expression of the opinion, when sufficient facts are known to the therapist, that the patient requires psychotherapy and may benefit greatly from it. Attempting to establish some incentive for therapy.

5. Sympathy with the patient's feeling, if negativism prevents revelation of facts but attempting to handle what is behind this feeling.

6. Dealing with the patient's misconceptions about psychotherapy, answering questions as directly as possible.

7. Refraining from "selling" the patient on therapy; respecting the verdict should the patient decide against therapy.

8. Accepting the individual as a patient even if the patient's decision has been made reluctantly.

RECOGNIZING AND REFLECTING NEGATIVE FEELINGS

Because the patient is defensive, evasive, inwardly outraged, and perhaps expressively hostile, little will be achieved until these untoward attitudes and feelings are resolved. Therefore, it is urgent to focus on them as soon as possible. This is relatively easy when the patient verbalizes readily or otherwise is self-revealing. Often, however, disturbed feelings are not openly apparent and must be perceived from how the patient talks rather than from what is said, or they may be recognized from random gestures, mannerisms, and facial expressions.

For instance, a delinquent girl referred for treatment sulks silently in her chair, fidgets around when asked a question, then answers in an evasive way with apparent disinterest in the proceedings. The therapist may make one of the following remarks:

"Perhaps you feel you ought not to have come here."

"Perhaps you're angry about being sent here."

"I can understand that you'd be annoyed about this situation."

These responses may immediately cut into the underlying mood and enable the girl to comprehend that her feelings are recognized. The result may be an outburst of hostile emotion toward the referring agency and an opening up to the therapist.

A woman, suspected of being emotionally disturbed, is sent to the therapist by her assigned social worker after she applies to a family welfare organization for help. The only reason that she accepts the referral is to please the social worker through whom she expects to secure supplementation of her income. Her lack of motivation causes her to withhold as many facts about herself as possible and to be as evasive as she can without offending. Under these circumstances, once conscious of her attitudes, the therapist might say, "I can very well see that you would feel resentful or uncomfortable about coming here. You probably do not believe that it is necessary and might feel that you could very easily do without it. I do not blame you for feeling that way inasmuch as you didn't really come to the agency to seek any emotional help." This may relax the patient considerably, for she senses in the therapist a sympathetic person. She may then begin to express her feelings about the agency and finally to verbalize her problems quite candidly.

A man with a character disorder expressed in petulant, querulous, and sadistic tendencies comes in for an interview on the insistence of his wife, who threatens to leave him unless he gets psychiatric treatment. After spending 10 minutes or so disarming the therapist with a genteel account of how well adjusted he is, the therapist interrupts:

> *Th.* But there must be some reason why you came to see me?
>
> *Pt.* I wish I knew why. My wife insists that I'm cracked.
>
> *Th.* Cracked?
>
> *Pt.* Yes. (*laughs*)
>
> *Th.* Why does she make such a claim? *(The patient then irately expostulates on certain incidents in which he was unfairly treated by relatives of his wife. His responses, though retaliatory, were, he claims, tempered out of respect for his spouse. Yet she accused him of being cruel and irrational—tendencies he claimed, that were not an integral part of his personality.)*
>
> *Th.* Do *you* think that you have personality problems?

Pt. Not any more than anyone else.

Th. Then it must make you angry to have to come here to see me.

Pt. (pause) Well… she thinks I should go to you. I'm mad at her, not at you.

Th. Well, I would think you'd be as mad as the blazes to come here when you really don't see the need for it.

Pt. (laughs) I guess I am mad, but I don't blame you. Maybe I have been acting unreasonable at times. I suppose I'm hard to get along with sometimes.

Th. Everybody gets upset and acts unreasonable sometimes.

Pt. I don't know that I do any worse than anyone else.

Th. So that you'd resent being sent to a psychiatrist for no real reason.

Pt. Do *you* think there is anything wrong with me?

Th. From what you've told me, you seem to have a problem with your wife.

Pt. It's that she keeps picking and nagging and wanting to make me over. *[From this point on the patient's relationship with his wife is discussed and the patient participates enthusiastically.]*

INDICATING ACCEPTANCE OF NEGATIVE FEELINGS

By reflecting negative feelings, the therapist conveys an acceptance of them. The therapist, furthermore, may elaborate on the patient's right to feel the way that he or she does, demonstrating an understanding of the patient's mode of thinking. This is illustrated in the following excerpt of an initial interview:

(The patient stomps into the office with a swagger. She is a young woman with a short, cropped haircut and a severely man-tailored tweed suit. She radiates an air of masculinity and is obviously disturbed and hostile.)

Th. Would you like to tell me about your problem?

Pt. (rapidly and angrily) The first thing I'm going to tell you is that I am against psychiatry completely.

Th. Why?

Pt. Because of past experience. I'm coming here against my will.

Th. I see.

Pt. Definitely against my will.

Th. Can you tell me about that?

Pt. In the year of 1970 I had two psychiatrists working with me. One was a society doctor who got me in and gave me 10-minute sessions, talking about nothing, and charging me 35 bucks; the other was a complete ass, who just sat on a chair, did nothing. He said he would try to work with me twice a week. He didn't help me one single bit and I am against it because of that.

Th. Well it does sound like you had some ungratifying experiences.

Pt. The first doctor wasn't really a psychiatrist, but he posed as one.

Th. How long did you go to him?

Pt. Just went a few times, maybe 10, I don't know offhand, but I felt it wasn't doing me any good.

Th. What was the reason for going to him in the first place?

Pt. I was kicked out of school.

Th. College?

Pt. Yes. They promised to let me come back if I had psychiatric treatment. I used to go to see the guidance woman, and she said that I had to see a psychiatrist. One of the teachers complained—a special narrow-minded, bigoted woman who had the same affliction I did and that they had condemned me for. This was homosexuality, I guess. I don't know till this day. They got me into such a state that I was willing to do anything and everything. I had no psychiatric treatment; then I went to two of them. They were working with me, trying to get me back to school, and then after this year was up, the president talked to these doctors and everybody else. They started messing around, and then said they wouldn't take me back anyway, so that finished me up at college. That was the only reason I went for psychiatric treatment. I went in with an open mind. I said, "OK, if you can cure me and get me back to school," but it didn't work. And every since then, I mean, I don't particularly care for college; but I want my degree. I know what I want in life as far as a career goes. I am working toward it now. So I got to go back to college.

Th. So if you're antipsychiatry, why did you come to see me?

Pt. Well, that's not the point. I don't want you to cure me, as far as that's concerned. I talked to the guidance woman about the whole thing. She is a wonderful person and I adore her, except I think she is psychiatry conscious. She has been insisting on this and I am always trying to please her. In fact, it's not the homosexualism that bothers her, it's the way I dress and walk and things. I was a little out of hand at school.

Th. Is that what *they* say?

Pt. Well, no—that's what *I* say.

Th. What sort of trouble did you have?

Pt. Well, I don't smile enough; I look queer, I suppose; my mind is always a mile away, although I did good in school. I have an excellent mind and my marks showed it. I don't dress; I wear men's shirts; and I am always in this kind of an outfit, which is a little different from what the typical girl wears at college.

Th. I see.

Pt. Well, it looks different and my walk is terrific.

Th. You mean you walk with a swagger?

Pt. I do, definitely.

Th. Is that affected, or is that you?

Pt. I tried to calm it down, but it just doesn't work. You see, I was in physical education, and I am very athletically inclined, and the swagger does come, but it's not to the degree that I have. My voice is very gruff; in fact, my speech teacher gave me an E because he didn't like the way I spoke. And that's the lowest mark I ever got, and maybe I will be able to fix that up. It's just these little things—the way I smoke a cigarette. My behavior patterns that I have just don't qualify with the normal. I try to keep away from women 'cause I might be tempted, and as yet I haven't been.

Th. What do you mean as yet you haven't been?

Pt. Well, I haven't gone after women, to go to bed with me I mean.

Th. You never have had any homosexual relations?

Pt. Oh yes, but not at college.

Th. What they object to is just the fact that you dress in a certain way and talk in a certain way?

Pt. As this guidance woman puts it, they feel that in the state that I am in now, whatever that is— they have given me no definition of it— they feel that I am not a responsible person and that I may possibly forget myself and commit an act. Therefore, they feel I am not a good risk, but they don't know that I work well with children 'cause I have done a lot of field work, and I have done an excellent job. I have a good reputation at home. These college students and the professors, of course, can recognize the fact that I am queer I guess.

Th. Well, the business of working with children—your course is what?

Pt. It's educational sociology in group work.

Th. What would you like to do?

Pt. I thought about going back to physical education. In fact, I may start my graduate work in September.

Th. You don't see anything wrong with the things you are doing, do you?

Pt. Certainly I do.

Th. Well what's wrong with them?

Pt. Anything that doesn't conform to society is wrong in their eyes.

Th. But in *your* eyes—I'm talking about yours.

Pt. I got a conflict. I apparently have two personalities—one is the homosexual, the other is heterosexual. I can't make up my mind which personality I want to be. I think it's the homosexual because my relationships with men have been "snafu." I don't know. The guidance person thinks I hate women really. She has analyzed this thing with me, every time I talked to her. I always give the right answers as far as myself is concerned. I like women. I like to be with them, but I'm a very obvious homosexual and that's what's wrong with me.

Th. Well, when you are with them, how do you act with them, with the girls?

Pt. I'm aggressive, naturally.

Th. Do you ever take a passive role with them?

Pt. No.

Th. And what about your relations with men?

Pt. I am very much in love with one now, and he is also a homosexual. My only associations which are very satisfying are with gay boys. (*laughs*) If I talk to you much longer, you'll get my lingo. Isn't it awful?

Th. You seem to be ashamed of it.

Pt. I'm not ashamed of the fact that I'm a homosexual, but I am ashamed of the fact that I'm obvious.

Th. Well, would you like to change your being obvious?

Pt. Yes, that's the point. I don't particularly care about being cured as far as that's concerned. because a lot of great people were homosexual. If *they* could be homosexual, well *I* certainly can. I'm completely indifferent to that.

Th. Would you like to change some of these mannerisms that you talk about?

Pt. That's the point, if I can get out into society and work. In fact, my ultimate goals are to teach in a

college.

Th. I see.

Pt. Now, I'm not going to do anything—inflicting my behavior upon my students—but it is obvious, and that's where the drawback is. And ever since I started in this work, it's not the students. The kids love me. In camping experiences, too, it was always the counselors or the teachers that jump on me because they see something.

Th. Maybe you feel that if you expose yourself to therapy. I'm likely to try to change your preference for homosexuality.

Pt. Well, are you?

Th. I naturally won't change anything you don't want changed. As a matter of fact, you're the one that determines how far you want to change. Actually, I don't blame you for being mad at psychiatry, if you feel psychiatry is trying to force you to be something you don't want to be. But getting treatment merely to get into college may do *you* absolutely no good.

Pt. They don't exactly demand it; they haven't gotten to that stage. I don't want you to misunderstand. It was the guidance woman's idea, and she has been at me ever since I've known her. She has taken a keen interest in my work, and she feels that I'm good at it and that my future shouldn't be wasted because I am in this conflict. I am unhappy you see.

Th. What conflict are you in?

Pt. Whether I should go this way or whether I should go that way in sex.

Th. Well, maybe you'd like to work out which direction you'd really like to go, either the one or the other, as long as you are clear in your mind and convinced in your heart.

Pt. I think that I would be homosexual, *(pause)* because my whole environment as a child, and ever since I can remember, has been one that was conducive to homosexuality.

Th. Let's accept that; at least for the time being. Are there any other conflicts you might want to handle? *[attempting to discover some incentive for therapy]*

Pt. I sort of isolate myself, I'm afraid, and, as soon as I finish a class, I want to run home. Or I run down to the Village to this friend of mine, and I stay with him. What bothers me most of all is the way I look and walk and act. It upsets me.

Th. In other words, you feel the mannerisms and the gestures are not approved of?

Pt. That's right.

Th. And that's what bothers you more than anything else?

Pt. Yes.

Th. Would you like me to let us help you with *that* problem?

Pt. If you can; if not, I might as well go to the Bowery. Do you think you can? This problem of what I should wear, what I shouldn't wear. My sister is ultra, ultra feminine, and I have the clothes to wear, but I would prefer to be in this attire. *[The patient defines an area on which she wishes to work.]*

Th. I'll do what I can to help you understand yourself better. If you have the desire to work things out, I believe I can help you.

Pt. That's the whole thing except that there is this tremendous fear that I'm not myself. But, I'd like to get started if you can, as soon as possible.

MANIFESTING AN OPEN MIND ABOUT THE PATIENT'S NEED FOR THERAPY

Should the patient want to know whether the therapist considers the problem presented severe enough for psychotherapy, the therapist may say that a positive answer will have to be postponed until more information is obtained. Such an attitude helps convince the patient that the therapist is not an arbitrary authority. The patient may also be told that the therapist is not sure that the patient needs or does not need treatment, but that as soon as enough facts are available, the therapist will be better able to provide advice. The following excerpt is an example of this:

Pt. Do you think I need to get these treatments?

Th. I am not sure yet. Suppose we talk more about your problem; then I will give you an idea of whether or not I think you need psychotherapy.

CREATING INCENTIVES FOR THERAPY

When satisfied, during the interview, that enough facts have been gathered to justify a positive statement to the patient, the therapist may remark, "Now I know enough about the problem to give you one definite statement. I do think you can benefit greatly from therapy. Whether you want therapy is another matter; but it could be of help to you."

Should the patient demand a reason for the therapist's conclusion, the latter may frankly state that the patient is not as happy, or well adjusted, or creative as possible, or that the patient is being victimized by certain symptoms that are signs of neurosis. The

therapist must respect the fact that only the patient can decide whether or not to pursue therapy, no matter how much it may be needed.

It is necessary sometimes to attempt the building of incentives for treatment. Illustrative is the following excerpt from the first session with a single, 24-year-old woman whose mother was insistent that she see a psychiatrist because of attacks of moodiness and spells of depression. The patient sat forlornly in the chair, replying to questions with monosyllabic answers and denying that her symptoms were bad enough to warrant treatment.

> *Th.* Are you completely satisfied with your present life and adjustment?
>
> *Pt.* Yes.
>
> *Th.* It's very gratifying to be well satisfied. Understandably you wouldn't want any treatment if there is nothing wrong.
>
> *Pt.* No.
>
> *Th.* Your mother thinks you ought to get treatment. I wonder why?
>
> *Pt.* I don't know.
>
> *Th.* Maybe you're angry that she sent you here, if you didn't need treatment.
>
> *Pt.* I'm not angry.
>
> *Th.* Mm hmm. *(pause)* But there must be some area in which you aren't completely happy.
>
> *Pt.* Well … *(pause)*
>
> *Th.* Are you satisfied with the way everything is going in every area of your life?
>
> *Pt. (pause)* No, not exactly.
>
> *Th.* Mm hmm. *(pause)*
>
> *Pt.* It's that I don't go out much, not much. I don't go out with boys.
>
> *Th.* I wonder why?
>
> *Pt.* I don't know. I don't have a desire to go out, I mean the energy. I get tired.
>
> *Th.* Would you like to want to go out more? *[attempting to create an incentive for therapy]*

Pt. Oh, yes. I often wonder what I could do to make me want to go out.

Th. Well, if you really would like to work with me on that, maybe I could help you with it.

Pt. But could you do anything to make me want to go out?

Th. I wouldn't make you do anything, but if you were interested, we could explore this area and find out what it was that held you back.

Pt. I think I would like that, if you could do it.

To help promote motivation for therapy the interviewer may want to be alert to any of the following manifestations on which the patient's attention may be focused:

1. Distressing symptoms of failure in adaptation, such as tension, anxiety, and psychosomatic symptoms.

2. Incapacitation and inhibition of function produced by anxiety and defenses against anxiety, like phobic, conversion, obsessive, and depressive reactions.

3. Recognition by the patient that personal capacities are not being lived up to and that basic needs are being sabotaged.

4. Fear of the consequences of neurotic aims, such as retaliation for acting-out or detection of homosexuality.

5. A desire to be like other people.

ATTEMPTING TO DEAL WITH CONTINUED OPPOSITION TO TREATMENT

When the patient shows continued negative attitudes toward therapy and toward the therapist, it may be helpful to point out that many persons can be benefited by psychotherapy even though they do not see the need for it at the start. If the therapist, from personal experience, is able to relate in detail a case he or she has treated with problems resembling those of the patient, it may create a spark of incentive. Reciting a detailed history, such as the one described in Chapter 36, may give the patient an idea of how psychotherapy works.

Sometimes assigned reading of informational books on psychotherapy (see

bibliotherapy) may aid in the working out of the patient's blocks to treatment. Another helpful adjunct, available to the therapist who is acquainted with psychological testing, is to give the patient a projective test and then to discuss carefully and tentatively the test findings. Many patients open up remarkably when their problems are approached in this indirect way. Finally, if the patient is willing to risk personal exposure in an educational group, and if there is one available, the ensuing psychoeducational discussions in the group may resolve the patient's resistance.

CLARIFYING MISCONCEPTIONS

Throughout the interview it is necessary to clarify any misconceptions that the patient has about psychotherapy and to answer, as factually as possible, whatever questions the patient may ask.(See Chapter 34).

If the patient accepts psychotherapy but has spurious goals in mind in regard to what he or she wants to achieve from treatment, special handling will be required. For instance, a man applies for therapy with the complaint of tension that prevents the development of his singing voice. His ambition is to become an opera singer. As he elaborates on his problem, it becomes apparent that he is really searching for success in terms of his father's conception of achievement. A music teacher himself, the father had trained his son to be a singer. The boy was driven to practice incessantly to discipline himself for a great vocal career. His coming to New York at the age of 20 had a twofold purpose: first, to study with a famous voice teacher and, second, to get an audition at the Metropolitan Opera Company. Upon leaving home, however, the patient's vocal ambitions began to ebb, and he found himself increasingly engaged in social and intellectual pursuits that diverted him from voice exercises. Whenever he sang before a group, or even practiced singing for any length of time, he became uneasy, tense, and anxious. He came to therapy at the advice of a friend who was also receiving psychotherapy.

One might speculate that the patient was evidencing a delayed adolescent rebellion against his father that took the form of a desire for a self-appointed career. A reasonable objective in therapy, thus, would be the promotion of independence, even though this

might mean an abandonment of singing as a profession.

Yet to tell the patient that his goal to be an opera singer was neurotic and that therapy would bring him to an independent course might drive him away from treatment. A preferable approach would be to accept the patient's motivation to acquire a better singing voice but to avoid any intimation that his voice might improve in caliber. He could be told that therapy may help him understand the source of his tension and the basis of any other interferences with his singing ability.

In the actual treatment of this patient it soon became apparent to him that his value system and self-esteem were dominated by the goals of his father. Attitudes of submissiveness and reverence masked deep resentment and desires for freedom. Breaking away from his father in coming to New York released his aggression. His refusal to practice singing was one sign of rebellion. Tension and anxiety were the emotions consequent to this conflict. The patient was able to make a conscious choice of a career when he determined, in consulting with prominent critics, that his voice was not of operatic quality. He was surprised to find that his father accepted his decision benevolently after he had asserted himself and had insisted on giving up music in favor of a business career.

There are many neurotic goals that patients imagine will be realized from therapy, such as demands for power and perfectionism, a desire to endure hardships without flinching, and a yearning to remain poised under all circumstances. These motivations will not, of themselves, block entry into therapy, but they must be handled with determination at some point.

Among the most stubborn of inadequately motivated patients are those suffering from psychosomatic problems. Clinging to an organic etiology may be due in part to ignorance of how emotional factors can produce physical illness. In addition to the fear of being classified as a "mental case," the patient may consider that agreeing with a psychologic diagnosis is a sign that his or her suffering is regarded as "imaginary." When the patient is afflicted with disabling symptoms like blinding migraine headaches, intense

gastric pains, or diarrhea, he or she may not be able to countenance any other but an organic cause. Applying to a psychiatrist for help is to the patient a sign of weakness, an indication of lack of will power, and an insignia of defeat. Deep fears of revealing repulsive personal secrets or of being unmasked as a contemptible, perverse creature reinforce the patient's antagonism. The possibility of embarking on a long and costly therapeutic adventure, the outcome of which is not guaranteed, is additionally unsettling. Because of these resistances, the referring physician has a formidable job in getting the patient to accept a psychiatric referral. As general practitioners have become more sophisticated in their understanding of mental health, they have been able to deal more adequately with many of patients' objections to receiving psychotherapeutic help. A few articles have appeared in medical journals that outline techniques of referring a patient to a psychotherapist, and these can benefit physicians effectiveness considerably.

In spite of good preparation, nevertheless, the patient may cling desperately to a conviction that the ailment is organic in nature and that a doctor will eventually be found who can locate the lesion and prescribe the proper medicaments. The patient may insist that the therapist become involved in this search, and, despite the patient's understanding that no medicines will be prescribed in psychotherapy, there is an almost frantic plea in the patient's manner, if not in verbalizations, for a remedy that will spell the renaissance of hope.

While the patient may intellectually be convinced of the fact that emotions can influence bodily processes, he or she may be unable to apply this information. The therapist may have to reiterate the thesis of how being upset can produce widespread disturbance in every part of the body, inducing even greater discomfort and pain than organic illness. The therapist must, however, always leave the door open to the possibility of at least a partial organic factor. To insist on its complete absence is an indication to the patient of the therapist's arbitrariness and prejudice. The fact is that the patient *may* have a concomitant organic condition; indeed, it is hardly conceivable that there is no physiologic correlate in every psychologic disorder. The physical disorder may be completely reversible once the patient's emotional difficulty is ironed out. Yet it may exist

in fact and perhaps be demonstrated by laboratory and clinical tests.

A prolonged physical ailment may undermine the person and bring out associated emotional elements. The resulting turmoil will then accentuate the physical distress. As a matter of fact, a condition that starts out as physical may, after a while, incite emotional elements that persist long after the physical cause has disappeared. In the event that the patient seeks to know how emotions can cause bodily pains, the therapist may explain that the brain is connected to every organ in the body by nerves. When mental suffering occurs, the effects may be transmitted through nerves to the bodily organs, affecting their function and producing, for example, painful spasms. When mental or emotional relief eventuates, the organ may be restored to normal activity.

The patient will probably repeatedly have to be told that a reciprocal relationship exists between mental and physical processes—that nerves influence organs and vice versa. Sometimes a physical ailment touches off worry and other disturbing feelings, and the emotional disturbance then exaggerates the ailment. It would surely be remarkable if suffering from pain and other uncomfortable symptoms did not promote worry. Once anxiety is mobilized, a chain reaction begins, and the physical condition becomes more and more aggravated. Treating the physical condition with medicines or surgery may not remove the nervous component. Treating the nervous component, on the other hand, helps the organ return to its normal condition. This is why the treatment of the emotional part of the patient's trouble may restore physical health.

Because the patient may require the preservation of psychic integrity through a psychosomatic symptom, one must always cautiously and tentatively advance the possibility of emotional causation, always respecting the patient's need for refuge in a physical cause.

If the patient accepts the sincerity and authority of the therapist, he or she may be willing to explore the emotional aspects of the problem. Sometimes the patient will listen in a polite manner and then will insist on further medical consultations and tests before submitting to psychotherapy. The therapist here should respect the patient's wishes and

refer the patient back to the physician, with the comment that the patient is unwilling at present to accept psychotherapy. Often this tolerant and open-minded attitude evidenced by the therapist will inspire the patient to return, motivated for treatment, when an additional excursion for diagnosis has proven futile.

These principles may be illustrated by considering the case of a man who, because of a disabling gastric complaint, consults his family physician. A series of laboratory tests, clinical examinations, and x-rays reveals no discernible organic lesion. Alkalis, antispasmodics, vitamins, and sedatives are to no avail. In desperation the patient consults a number of specialists, and finally he makes the rounds of medical clinics but with no abatement of his symptoms. His suffering eventually drives him back to his original family doctor, who had intimated, to the dismay of the patient, that there might be psychological factors responsible for the patient's trouble. This indicated to the patient that the doctor considered him insincere and somewhat of a faker. But, having exhausted every possible avenue of traditional medical help, he finally is willing to listen to his physician and to consult a psychotherapist.

His approach to the psychiatrist at the initial interview is one of mingled disdain, fear, frustration, and hostility. Secretly he hopes that the therapist will produce some kind of magic pill that will allay his suffering. He has been willing to try something new, but he comes to treatment with his "tongue in his cheek." He is willing to give this strange doctor a chance to do something that the other doctors have not been able to do, but naturally he has his doubts. The slightest intimation that there is a psychological aspect makes him fear that his pain may be considered imaginary.

The following is an excerpt of part of a session with a patient of this type who has no wish for therapy, but whose lack of motivation is dealt with successfully by the therapist. After the patient discourses on his doubts that he has a psychological problem that requires psychotherapy, the interview proceeds:

> *Pt.* But how can stomach trouble be caused by the mind?
>
> *Th.* The brain is connected to every organ in the body, and when a person is disturbed, it is

understandable that the disturbance or worry or conflict can get into every organ of the body through nerve channels. And then the organ gets upset.

Pt. But there's nothing wrong with my mind. I'm not worried about anything except this pain and how to get rid of it.

Th. Perhaps that's right. As a matter of fact, you *may* have something really wrong with your stomach. Have you satisfied yourself that there is nothing wrong? [*Since patients are suspicious that the therapist will bend backward to label a condition psychological, this remark is intended to show the patient that the therapist is not eager to come to this conclusion without good evidence.]*

Pt. Well, the doctors all say that there is nothing wrong. They've given me all the tests. But I feel there is something. *[This conviction of the patient against all of the evidence may be obdurate resistance to his accepting psychotherapy.]*

Th. You've had all of the tests?

Pt. Yes, and they all add up to nothing.

Th. Perhaps you wouldn't be satisfied until you find someone who tells you there is something wrong. It certainly seems reasonable to exhaust every possibility to your satisfaction, that is, get the best doctors to look you over, before you get psychiatric help, *(pause) [This lack of eagerness on my part to accept the patient until he is convinced he wants psychiatric help may spur him on to accept it.]*

Pt. Do *you* think there is nothing wrong with my stomach?

Th. There *must* be something wrong; otherwise you wouldn't have pain. The question is whether the cause of the pain is emotional, or organic, or both. Frankly I don't know which it is, since I'm not acquainted too much with your condition. But from your account, nothing organic has been found. And you've had good doctors. Dr. _ is a good doctor; he's conservative, and he sent you to see me, which shows he feels there is at least the possibility of an emotional factor.

Pt. But what could it be, if it isn't my stomach?

Th. You mean what would the emotional factors be if your stomach trouble was not organic?

Pt. Yes.

Th. That's why you were referred to me. Perhaps we might be able to find out. You know, emotional trouble can give you a bigger bellyache than physical trouble.

Pt. As bad as mine?

Th. I don't know how bad yours is, but it can be mighty bad, even worse than organic trouble, *{pause)* Apparently you can't accept this fact as applying to you. Maybe you think it's disgraceful to have emotional problems?

Pt. Well, if I were that much out of control … Well, maybe it's so, but I don't, can't see how. Wouldn't I know if there is something wrong, with my mind, I mean?

Th. With your emotions, you mean? Well, usually not. But I don't know that there is anything wrong either. We'd have to give ourselves a little time and begin exploring, (*pause*)

Pt. Doctor, do you think *you* can help me?

Th. If you have an emotional problem that is causing this trouble, yes, that is, if you really wanted to be helped.

Pt. But I do want to be helped. I've spent a fortune of money, and nothing has been done.

Th. Maybe you'd rather wait and keep trying other internists until you're convinced the organic factors are the most important ones.

Pt. But I've tried and tried.

Th. Yes, but you are still not convinced. Why don't you think things over, and, if you'd like to give this a try—with an open mind, I mean—call me and we'll get started. *[Throwing the choice squarely on the patient's shoulders.]*

Pt. I get the pain over here, *[points to his abdomen)*

Th. It must be very distressing [*showing sympathy]*

Pt. Yes, doctor, it drives me practically out of my mind.

Th. You know, a person with even a real organic problem involving his stomach can get very upset. And his emotional tension can in turn stir up trouble for him.

Pt. This pain does upset me and I think it does make my stomach worse.

Th. So you see, emotional trouble, worry, and tension can upset your stomach.

Pt. Well, I do know there are some things my wife does that upset me. *[This is the first indication of the patient's desire to work with his emotional problem. He talks about his difficulty at home and then makes arrangements to start therapy.]*

Because the patient with a psychosomatic problem is often unconvinced that a physical symptom is or can be emotionally determined, the best way of losing such a patient is to insist that the problem is psychological. Since the patient may, at least temporarily, need the symptom, the therapist is wise at the start of therapy to allow the patient to retain the idea of its organicity. The therapist may inform the patient that any symptom, even an organic symptom, creates tension because of discomfort or pain. The

tension delays healing. What needs to be done is to reduce tension, and this can stimulate the healing process. Teaching the patient simple relaxation methods and allowing the patient to verbalize freely should soon establish a therapeutic alliance, and through this the patient may be helped to come to grips with worries and conflicts.

It is sometimes expedient within the first few minutes of the interview to try to get the patient to convince the skeptical therapist that a psychological problem exists in his case. Thus a patient appears for an interview arranged by his physician. After the usual opening formalities he states:

> *Pt.* Dr._sent me to see you.
>
> *Th.* Yes.
>
> *Pt.* He thinks my trouble is in my head.
>
> *Th.* Mm hmm.
>
> *Pt.* This pain in my head. Migraine.
>
> *Th.* What makes you think it is psychological and not physical?
>
> *Pt.* I'm not sure. In fact I don't think its psychological because I'm pretty well adjusted.
>
> *Th.* Perhaps it is physical.
>
> *Pt.* I've tried a lot of doctors and the only thing that helps a little is ergotamine.
>
> *Th.* It still may be physical. Tell me who you have seen for this and what they said. *(The patient enthusiastically for the next 10 minutes details his futile adventures with doctors. After this he pauses and asks a question.)*
>
> *Pt.* Could this be psychological?
>
> *Th.* I am not sure. But I can tell you one thing. Even if it is organic, and it may be, the pain and tension you have suffered can spark off attacks and prevent healing.
>
> *Pt.* I do get tense sometimes.
>
> *Th.* Tell me about this. *(The patient then launches off into various troubles he is having in his work and with his wife.)*
>
> *Th.* I'd say you have enough trouble to spark off migraine. But the basis may still be organic, although you've seen quite a number of good doctors.

Pt. Do you believe I can be helped?

Th. The best way to find out is to get started.

Pt. I'd like to do this.

Patients receiving disability payments for an injury are particularly unmotivated to give up psychological pain and other symptoms that complicate their problems. Here the factor of secondary gain appears through avoiding hard work, supporting dependency needs, and getting attention and sympathy. Such patients cannot be forced to change. The primary task here, as in the case of the psychosomatic patient, is to first establish a therapeutic alliance. No hard-and-fast rules can be given since patients will require innovative stratagems designed for their special situations. Patients receiving disability checks are particularly difficult to convince that anything psychological keeps them from returning to work. One tactic is never to imply that the patient is in any way psychologically manufacturing the symptoms because this will obstruct the establishing of a working relationship. The approach at first may, as in the psychosomatic patient, be organized around tension reduction to help the patient assuage suffering. As tension is lessened, the patient will begin talking more about himself or herself and perhaps about some family adjustment problems. The therapist may soon be able to inquire about the hopes, ambitions, and goals of the patient. Questions may be asked such as, "What would you like to do?" "How would *you* like to feel?" "What do you enjoy most?" Very often when the patient realizes that the therapist does not expect conformity to standards that others set for the patient, a therapeutic alliance will begin. Reflecting the patient's anger without condemning it helps convince the patient that there is nothing wrong with feeling the way he or she does. How the patient can go about fulfilling personal own goals is then planned. An interesting article on techniques of dealing with such unmotivated patients has been written by Swanson and Woolson (1973).

The therapist's handling of the patient's denial tendencies is crucial. Blank unbelief often operates as a primary defense to insulate the patient from the implications of the illness (Lindemann, 1944). Such denial, interfering with the true assessment of the reality situation, constitutes a great danger for the individual. In coronary illness for example, the

patient may engage in dangerous overactivity, neglect of diet, and absentmindedness about taking essential medications. It is, therefore, important to review with the patient his or her ideas of the illness and attitudes toward it, especially hopelessness. By careful clarification coupled with reassurance existing misconceptions and cognitive distortions may be corrected. The relationship with the therapist can greatly help the patient to accept a factual assessment of the patient's situation. The therapist here serves "in a role similar to the protecting parent who makes painful and threatening reality less intolerable to the child, thus enabling the child to accept and face reality, with its hazards, rather than having to deny and 'shut out' " (Stein et al., 1969).

Sometimes lack of motivation for treatment is predicated on a need to retain the boons bestowed by a neurosis. Thus the cement that holds a marriage together may be agoraphobia in a wife whose symptom binds the husband to the wife out of guilt and sympathy. Fear that the marriage will break up should she get well will be a formidable obstacle to a proper response to treatment. Here couples therapy may be mandatory before a good response to behavior therapy, individual psychotherapy, or group psychotherapy can be expected. This type of motivational lack may result in acceptance or indifference to one's symptoms, a patient going through the motions of exposure to treatment, even demonstrating interest in the dynamics without any impact on his or her dysfunctional behavior patterns.

Treatment guidelines using psychoeducation, family intervention, psychodynamic interpretations, paradoxical intention, and assertiveness training for the behavioral treatment of resistant anxiety-disorder patients have been suggested by (Hanrahan et al., 1984) to help patients learn new skills, to understand resistances, face anxiety-provoking situations, and complete essential homework assignments. A program to acquaint students with modes of managing unmotivated patients has been developed by Swanson and Woolson (1973).

AVOIDING THE 'OVERSELLING' OF THE PATIENT

Lack of on the part of the patient motivation may persist no matter how expert the

therapist. The patient may cling to the notion of self-reliance, believing that it is threatening to have to depend on the therapist. The patient may harbor a deep masochistic need for suffering and refuse to relinquish the symptoms. In addition, the patient may possess a contempt for normal values in life that he or she anticipates will be the outcome of therapy. The patient may suspect the intention of the therapist. Common fears are that creativity, talent, and uniqueness will be exterminated in treatment, that therapy sometimes wrecks marriages leading to separation or divorce, that life may become bereft of pleasures that are now derived from neurotic indulgences. He or she may fancy that getting treatment constitutes a hostile act against the family, which actively or indirectly opposes the therapy. The patient may contemplate with dread the overcoming of any ostensibly symptomatic handicap since this has justified failure in adjustment. There may be many other reasons for the patient's refusal to cooperate that will nullify the therapist's efforts to guide the patient into therapy.

From a strategic point of view, it may be argued that irrespective of how resistive the patient may be at the start of therapy, the developing relationship will eventually undermine such resistance. This is probably correct, and many patients who are initially unmotivated do eventually accept therapy. The great problem is to convince the patient to continue in treatment in spite of doubts. This is easier said than done, and the therapist may, in the eagerness to help the patient, try to "oversell" psychotherapy. The best practice is to present the facts frankly to the patient and then leave the choice of therapy entirely up to the patient. Under these circumstances the patient may decide not to start treatment but later may return motivated, having spontaneously worked out the resistance in the interim period.

The following case illustrates this. It is part of an initial interview with a patient with physical symptoms who was referred by a physician. An unsuccessful attempt is made to bring him to an awareness of possible emotional sources of his illness. Also unsuccessful is an effort to convince him to accept therapy for a potential psychological problem. Throwing the choice back at the patient makes him decide to get a further physical checkup. He is encouraged to call the therapist when he is ready to accept treatment.

Pt. I'm here because I've been working very hard, sometimes till 11 o'clock at night. I was so tired that I thought something was physically wrong, but I was told that there was nothing wrong with me. No matter what reassurance I get, I am still depressed. When I was coming to your office, I felt sort of a fear. I can't explain it, but if I was with my wife, I know that I wouldn't feel that way. When I walk by myself, I get that feeling and I can't reassure myself, but, no, I do reassure myself. I say to myself that this is silly and I have no reason to feel this way. I don't tell this to anyone, just you now, doctor. *[The patient has symptoms of somatic disturbance, depression, and anxiety—manifestations of a collapse in adaptation.]*

Th. You feel fearful? *[focusing on his anxiety]*

Pt. Yes, fearful; that's it. *(pause)*

Th. How long has this fear been going on?

Pt. Well I guess … I get up at night, and, and that's why my wife came here to explain what goes on at night. *[Patient's wife is in the waiting room.]*

Th. What goes on at night?

Pt. Well, I get up at night. I don't know what food I eat the night before that gives me a full night's sleep, but certain days I do get a full night's sleep, and I get up in the morning, and I still feel that jittery fearful condition. But if I get up during the night, and open up my eyes any time during the night, and I feel the taste in my mouth; if I feel that I'm nauseous, I'm nauseous—if I feel that I want to take an Alka Seltzer, first thing I wake her up out of her sleep. First thing I wake her up. Really, I shouldn't, shouldn't do it, but I know I shouldn't do it, but, if I do, for some reason I feel reassured if she's up. I tell her I don't feel good, and she says, "All right just forget about it, and just lie down on your stomach and force yourself to go to sleep." *[Feelings of anxiety and helplessness make him apply to his wife for succor and reassurance.)*

Th. Do you feel physically sick?

Pt. See, Doctor, the trouble is I still feel that I'm physically sick, in spite of the fact that I had an x-ray taken about a year ago. Dr.____ in the Bronx told me at the time, and he showed me the pictures right in front of me too. He says the x-ray shows that there's nothing wrong physically. However, year, maybe less than a year, I believe you can find out exactly just when it was, I was told by the doctor there was nothing they could find out about my condition, there was nothing there. You could call Dr._ You see, he'd probably have pictures and he could explain it better. But that's the way he explained it to me.

Th. Now this has been going on for how long?

Pt. Well, it isn't so very long. I'd say 3 or 4 years—I mean on and off; but the conditions, well from medical doctors I got examinations. They never found anything wrong during all those years. I did feel during that time, and I still feel during the present day, that it isn't mental, that it is something physical that I feel. I don't know how. I get reassured and reassured and reassured, and the only thing is that people confide and talk to me in a certain sense, and it immediately disappears. And then it comes back again almost right away.

Th. Anything else wrong?

Pt. No, everything is very, very nice. When I'm at home, we got a television set 9 or 10 months ago and I feel reassurance—we, we— the recreation, I mean. I feel wonderful at home, too, but I can be looking at the television, and if I distract my attention from the television, I still feel that feeling. I would say that 3 years ago, 3J, 4 years ago my boss says, "Joe"—well, they call me Joe for short, he says instead of Joseph—"Take 2 weeks this spring, take 3 weeks." I mean. I felt kind of run down, and I always felt that when I'm run down, you know, from continuous work, I should rest up more.

Th. What do you think this is all about?

Pt. Well I don't know. That's why I don't know whether it's my physical condition or whether it's my mental condition. I still feel that it's my physical condition for the simple reason that no matter how I feel, I always snap out of my mental condition. Because if I feel too depressed to a certain degree, I don't try to fight deeply against it. I try to get the help of people whether it's in the business or anywhere else. Or else I just cry it out and get the tension off my chest. I mean I don't try to fight it to the extent that it should get the best of me. You see, I got—to get it down to brass tacks, doctor, I have everything to live for. I have a wonderful, I've got a wonderful family, a wonderful family from my side, I mean my brother and my sisters, and my wife on her side, her brother, her father. My father-in-law lives with us, my daughter and her husband live with us. We have a pleasant environment. I enjoy coming home. I got everything to fight in the direction of health. And so it, that's really the root of it, it gives me the power to fight because I know that everybody is with me.

Th. You feel that there is a physical condition that's undermining you, that makes it hard for you to do things, particularly to work?

Pt. Yes, but when I get that mental condition, I do feel that it comes from something, something physically wrong. I don't know what it is. It might be, it might be the smallest thing, but still the smallest thing might be … *(pause)*

Th. Do you think there is anything seriously physically wrong with you?

Pt. I never feel that pain as I—I never feel any pain. The only pain is the usual condition.

Th. A physical condition, like you say you have, may still be there and undermine you emotionally. Also on the basis of your worrying, the emotional state may aggravate the physical state. It's a vicious cycle. It may be important for you to get physical treatment and also important for you to get treatment for your emotional state. *[This is a tentative attempt to soften the patient's resistance to psychiatric treatment.]*

Pt. Well I do feel, doctor, that all this condition is, is because of the continuous years of work I put into a career, like. Well, I've been working since 1919. In all the years I feel that 50 percent of that time I put two days in 1. Let's see, I've been working since 1917, which is 33 years. I put 2 years in 1, probably 10 years of it, so that 10 years I put in approximately 20 years of work. And I do know I have because I've been working at times 13, 14, 15, hours a day. I mean, not these last couple of years, but in this trend before. Because after all your machine is working, and if you put twice as much as you should, you pay for it. *[The patient is trying to justify his condition on the basis of overwork.]*

Th. Now look, do you feel that you want to get psychiatric help for this condition of yours. What do you think?

Pt. Well, I think I feel that when I go to my place of business, I have the desire to go, I have the desire to work, and I know that I have obligations. I've got to work to make a living for the family and to keep the respect of the people I associate with. I know my obligations and all that, and I know that if I don't work here I've got to work somewhere's else.

Th. Would you like to get some sort of help for this trouble of yours? *[Repeating my question that the patient dodged.]*

Pt. Well, the first thing I feel that if I got reassurance as to my physical condition, I'd be all right.

Th. The reason you were sent to me was Dr. _felt that there was perhaps an emotional problem in addition to any possible physical problem that existed. Now let's assume that you have a physical problem such as you say you have, there still might be an emotional condition superimposed on it. But you won't be able to benefit by help for an emotional problem unless you really want it. That's why I ask you, do you want help, do you want me to arrange for help for you? What do you think?

Pt. Well, I'd rather think it over a little. *(pause)*

Th. I tell you what I will do then. You think it over a little and I will get in touch with Dr.____ I will tell him what I feel. And then after you talk it over with him, and you decide you want help, call me.

Pt. You see, I don't know whether it's psychological or physical. You see I say that because I'm not convinced.

Th. Are you interested in what I think?

Pt. But, first, if I can be reassured as to the physical, then probably that can loose up the tension.

Th. Do you feel that that would be enough once you are reassured?

Pt. Well, I don't know. I just don't know.

Th. You know from your experience you've tried that over and over again, and it hasn't worked.

Pt. I've tried, but I still feel that in the physical, I feel there's so many other things that just an x-ray or that—it's just a complete checkup as to every extent of the individual—I haven't had a complete checkup for a long time.

Th. Do you think that the best idea is to go ahead and make arrangements for another complete checkup? Then when you are assured through that complete checkup to your satisfaction that there might be a good reason for you to get psychiatric help, give me a ring.

Pt. That's what I'll do.

Th. All right then. You may call me when you decide.

Pt. Yes, goodbye, doctor.

The contact with the patient was terminated at this point. The referring physician was told that the patient undoubtedly could use psychotherapy, but that he was not ready for it, not being convinced that there was a psychological factor in his ailment. Without a desire for treatment it was doubtful that the patient could derive any benefit from it.

Six months later I received a telephone call from the patient asking for an appointment. He was ready, he claimed, to start therapy. Treatment was started and carried on with satisfactory results.

TREATING THE UNMOTIVATED PATIENT

The unmotivated patient who feels obliged to continue in therapy because of external pressure or who is willing to experiment with treatment against his or her own judgment should be accepted without question. The best way to motivate such a patient for therapy is to start a good relationship immediately—one of frankness and sincerity. The patient, finding value in this relationship, may eventually accept therapy, using the therapist to bring some objectivity into his or her life.

This may be illustrated in the following excerpt of the fifteenth session with a woman of 30 whose husband had forced her to accept treatment under threat of divorce. The patient suffered from a phobic reaction that restricted her movements and caused her to cling fearfully to her husband. She resented his insistence on her getting psychiatric help, and the first sessions were spent accepting her resentment and pointing out to her that her disabling symptoms might provide an adequate reason for her personal acceptance of therapy irrespective of the wishes of her husband. Gradually she concurred with this idea.

Pt. Well, I feel that I am learning a lot. I don't know how it happened. It's been very subtle. I just don't know how it happened, but I don't think the way I used to. That's the only obvious thing that I can see. I think that I'm getting my feet on the ground; I'm thinking more realistically. I know that I did come here because somebody else wanted me to. I'd be telling

a big lie if I didn't admit that. But I had absolutely nothing to say about coming here in the first place, not a thing. And the only reason that I didn't like to come here, I thought of the stigma of having anything wrong with my mind. I'm reminded of it, and John *(her husband)* reminds me of the fact that I'm neurotic all the time, and I know it myself. I think that that has been my phobia, more than some of the other things.

Th. Don't you think you would have thought the same way about treatment if there was something medically wrong with you?

Pt. No.

Th. In other words, you put a special stigma on being neurotic as compared to having any other ailment.

Pt. Well, any other thing, I don't know. But Dad taught us ever since we were children about people being mentally off and that whenever we got married, that the one thing to be sure of always was that the other person was well balanced and didn't have any queer strains in him. That idea has kept on so long, that it has always seemed to me there were cures for physical things, but that something wrong with your mind you had with you until you died. If you think that for a long, long time, and then someone starts telling you you're queer, it accumulates like a snowball.

Th. Well, that made it difficult for you. You then came not of your own free will, but because your husband insisted on it. But you are beginning to see that coming here does not imply that you are seriously mentally ill. Many people come to therapy not because they have symptoms but because they want to improve on their potentialities.

Pt. I realize that they go because they themselves feel that, *(pause)*

Th. Because they themselves feel that.

Pt. And it isn't because someone else says they are queer.

Th. Precisely. If you continue to come to see me on the basis that somebody thinks you're queer, you won't get much out of coming. If you don't come of your own free will and feel that this is your project, that there are problems that *you* have, emotional conflicts that *you* want to work out, your treatment will be delayed.

Pt. No, I don't have that attitude, and you have gotten me over that feeling. I guess it's because of you. Well, your attitude isn't the kind that reminds me that I'm queer, nothing like that at all. It's entirely different. I think that I want to do things about myself.

From this point on therapy proceeded satisfactorily.

The following transcribed recording illustrates some of the processes of an initial interview.

> (The patient telephoned for an appointment stating that he had been referred by a psychiatrist in San Francisco. When he appeared, he presented the appearance of a pleasant, poised young man, somewhat timid in manner.)

Th. Hello, I'm Dr. Wolberg.

Pt. How do you do. *(extends hand)*

Th. Won't you sit down over there, please.

Pt. Yes, mm hmm.

Th. The purpose of this interview is to get a general idea of your problem so that we can decide the best thing to do for it. *[structuring the purpose of the interview]*

Pt. Well, it's a complicated matter, but I feel like I'm not as complete a person as I might be. In my associations with people I mean. *[chief complaint]*

Th. How far back does this go?

Pt. Doctor, now the best way I can preface what I want to say is that I went to see Dr. ____ in San Francisco. I did have a problem, sort of an immediate problem which in turn led to other problems. There was a girl with whom I had been going for the past year, and we had just broken off, and I was very upset about that. And, I had, we had been having an affair, which seemed to complicate the matter considerably, since I wanted to be married and she, in turn, had had a previous engagement which had been broken. She was apprehensive about such things. And my first really severe emotional, what I consider a bust-up, was when she broke off the affair, and I, I lost control of myself pretty well, *[beginning elaboration of the history and development of the complaint]*

Th. How long ago was that?

Pt. This was in early 1948. It just seemed that, as I talked this out with Dr. ____ that *(pause)* that she actually symbolized a type of security which, as we talked over my past and my growing-up process, I never had before.

Th. Mm hmm.

Pt. I can remember very, very well getting little from my stepmother, who raised me with my father since I was 4 or 5. A person who deprecated me and my accomplishments constantly; a person who, of course, took me to the dentist twice a year and performed all of the routine functions of a mother without really letting herself, uh, be a mother, uh … *(pause)*

Th. And your own mother?

Pt. No, my own mother was divorced from my father and she remarried, and my stepmother took care of me.

Th. I see. What about your real mother, did you see your own mother?

Pt. Oh yes, about once a week. We were living in San Francisco.

Th. Hm hmm.

Pt. Uh, I don't know if I've answered your question.

Th. Yes. *(pause)* Now to get back to the immediate problem.

Pt. That was the first time I had this kind of relationship. I had had various relations with a couple of prostitutes, and also with several girls, but they only lasted for a short time. This girl not only, she was, she was a brilliant girl in addition to being a, a wonderful partner sexually. And, uh, this really was the first experience of that intensity that I ever experienced.

Th. How old a girl was she?

Pt. She was younger than I was. She was 19.

Th. I see.

Pt. But very mature, I might add. As I look back on it now it seems to be almost a shadow. Oh, it comes back every so often. I think that my conduct today would be entirely different. I mean I can't visualize myself actually doing some of the incredibly insane things I did at the time, *(pause)*

Th. What did you do?

Pt. Well, I mean I, I persisted, I was jealous, I, I, I, uh, didn't know whether to phone her or not. I put her on the spot. I made things rather miserable for her. I made them miserable for myself. I …

Th. When was this?

Pt. Well, you see, there were actually two stages. About 4 or 5 months after I met her, we went back to college together where I was. We were both doing undergraduate work. And she decided to break off, and that was the first severe reaction I had. I mean, uh, I couldn't see that I was enjoying it too much, and it seemed to represent something very wonderful, and so, I protested loudly at that. I felt I lost everything, and I was very emotional and very, well, it's

just, it's just something that I look back on. It seems totally impossible to reoccur. It never had reoccurred. But we still went on after that, and we resumed the affair after a month, and everything was fine. But, when we finally did break up, it was because she had started going out with another fellow. We had not gone steady during this entire period, and I can remember one Thanksgiving evening—this was at the height of the affair—and she went out with other people. Well, this was absurd to me, since God only knows I couldn't see myself wanting to go out with four different girls for the following nights after Wednesday or Thursday night, whichever it was. I don't know if it was Thanksgiving or Thanksgiving eve. So, it was a pretty insecure relationship for me throughout, and finally when it did break off, it was because she had become interested in someone else, a fellow who had had an article published in a national magazine. She was sort of enthralled by this because she had a creative bug, even though she was a political science major.

Th. You felt inferior to him?

Pt. In terms of, in terms of suaveness, yes. Not in terms, not because he had published something, though I must admit that I imagined off and on that I would publish something someday.

Th. But it must have been a *terrific* blow to you.

Pt. Well, yes. This guy was a very ... he was very tall, slender, good looking guy. He sort of had a uh, uh, worldliness in general, or so it seemed to me, as I imagined, as I noticed him from afar. And I remember being rude to him one day, which, which again is inconceivable for me, because it not only is out of character, but I certainly don't have that confidence. Before I go on, I want to tell you something that the doctor in 'Frisco and I found out after a little while. I have a—I see it coming out of me now—I have a knack for glibness, and, sometimes, I talk —I'm able to talk very slick as I do now—as I seem to be able to do, go into a song and dance. And it's sort of tough to probe. He found it tough, because I, I was a little too glib. And I just want to tell you about that ahead of time.

Th. You want to warn me?

Pt. Yeah! I don't think that it's necessary, but ...

Th. You kind of suspect yourself.

Pt. Yeah, I definitely suspect myself of talking glibly and of underestimating, or trying to underestimate in terms of the person to whom I'm talking. I suspect that I try to make friends with the psychiatrist, instead of, instead of—well, (*laughs*) giving an objective account of my problems. *[This may be an awareness of certain interpersonal operations, and defenses, for instance, of a need to impress, to win people over, to befuddle them. The patient may be warning me not to allow him to fool or beguile me.]*

Th. Well, it's only natural for you to relate yourself to me in a way customary to the way you always relate to people. You might utilize, in talking to me, glibness or any other kinds of attitudes that are so often used. But if you want to be glib, there's no reason why you shouldn't be. If your glibness, however, does make problems for you, that may be something you may want to change. That would be something we could tackle right here in the therapeutic relationship. But let's get on to your problem again, if you'd like to resume the thread, *[accepting his glibness, but pointing out that it might be a focus for exploration]*

Pt. Sure. Uh, it seems that when my girl and I finally did break up, of course, I was, I was pretty crushed for several months, for almost a year. I had planned to go to Europe on one of these student ships. Several friends of mine and I got all the way to New York in the summer, three months after we had broken up, and I had what I call anxiety dreams at night, the dream of Joan, which was the name of the girl.

Th. Do you remember the content of the dreams?

Pt. Yes, I've had them off and on ever since, although they are fading out. I just don't have them too often any more. Uh, yes, uh, dreams in which I would see her marching off with some other guy, not at the altar, especially, but perhaps after they were married, and in which I, I seemed to sense that other people were taking her away. I remember one dream in which my stepmother and she were on the same side, and that was a blow. And, things like that. So I turned in my reservations. I didn't go to Europe, and I turned around and I went back. Meantime, she had split up with this other fellow, who, in turn, had another girl. Circumstances just seemed to create tragedies, at least *(laughs)* temporarily. So, I went back, and we went around that summer.

Th. You went back to the same girl?

Pt. Yes, but we could never pick up the thread. It was just passed. I found it very, I found it just in pieces. You just don't pick those things up again. So, it was one of those things, although she wanted to start all over again. Her parents had thought I was a nice boy, and that was a pressure on her which I think was an unfortunate thing. And when I went back, she became somewhat disillusioned with me. This comes into another issue of—we, together, the two of us, were the officers of a debating society on various issues, including political issues. After listening to the talk back and forth, I had undergone a transformation. I thought I was progressive, but I got disgusted with that philosophy, although I suppose I still am somewhat progressive. I don't know whether to bring it up because I always feel it creates bad feelings.

Th. You don't know whether to bring that up with me?

Pt. Yeah.

Th. You may not know how I might react to your political ideas?

Pt. Yeah. That's exactly it. *[The patient seems to be testing me here to find out how tolerant or judgmental I might be.]*

Th. Do you feel that I might perhaps judge you in a certain light, if you were either conservative or radical?

Pt. Yeah, I'm always scared of people who live too near Park Avenue. This is maybe because I come from a very wealthy family, and didn't like it. These people frighten me. I don't mean frighten me in a conventional meaning of the word.

Th. All I can tell you is that whatever your political convictions may be, they may be right for you. You don't have to tell me if you don't want to, just what your political orientation is. It really wouldn't make too much difference to me. *[attempt at reassurance and at creating an*

atmosphere of tolerance]

Pt. I believe you. This, uh, probably what I said was to, probably because I was grasping for information from *you*. I, actually, I had undergone a transformation.

Th. Uh huh.

Pt. I heard of a forthcoming convention, and I didn't like it. She asked me to participate, and I told her no, that I was at a former convention and I was a little disgusted at the goings-on, and I wasn't going to work in it. Well, that was the last straw. She had imagined me as the sort of person whose beliefs coincided with hers. And they did, actually, pretty much, except politically I suppose.

Th. What happened then?

Pt. Yeah, we broke up. We never started up from then. That was the last straw. We broke up. And that summer, I went to see Dr. _____ (*pause*)

Th. After the second break, you saw Dr._____

Pt. It was during that second break, *(pause)*

Th. What was the *reason* you saw Dr. ___?

Pt. Well, because, because of her in two ways. First, she wanted me to. Both my mother, my real mother, and Joan wanted me to see a psychologist. I had been toying with the idea myself, and one of the things that enraged me particularly was the fact that Joan said that the condition for our rapprochement would be seeing a psychologist.

Th. Why did she want you to see a psychologist?

Pt. Because she, because she, well, she felt—and she was probably quite right—that my emotional attitude was so unstable. I, I jumped back and forth so much that she couldn't see herself living in this, this uncertainty.

Th. I see, Did *you* really think you were unstable?

Pt. Oh, definitely.

Th. Well now, what happened since the breakup of your affair with Joan? Perhaps you could bring the situation up to the present. *[Because the patient may cover many minor facets of his relationship with Joan to the sacrifice of other important aspects necessary to cover in the initial interview, I attempt to focus the material.]*

Pt. Yeah, I shall. There has been one other item of major importance and that recently terminated, but I'll give you that very briefly because I think that's quite important. Well, right after that I transferred to a midwestern school. I missed Joan terribly, and I changed my major. So I changed it without any trouble, since I had another year before I took my Bachelor of Arts degree. So I did that, and I really had a fine time. I lived at the fraternity house, and I was

active there, and I did some debating there.

Th. This was '49?

Pt. This was '49, yeah, late '48 and mostly '49. Well, soon I met a girl named Philly, she shall be called, since that was her nickname. So Philly and I started seeing one another, and we started having an affair. She seemed to me, well, she again had interests much similar to mine. So we started going around together and had an affair, but she turned into, in the last analysis, possibly a repetition of what happened with Joan. She turned out not to know what she wanted, and we went around all summer and all spring of '49 last year. I went to school in the East last fall, and when I went home in December, I found out that in spite of the fact that we had been engaged since last May, she had gone out with a boy whom she had previously gone with when she was at college. This is getting complicated. He had transferred to the Midwest college where she was still a student in her senior year. He transferred there the same month last September that I had transferred East. And she had started going around with him, and she was wearing my ring, and although we had both been going out, I had been, had not been carrying on any promiscuous activities. It turned out that she became worried right after I left. She went to see a doctor, and it turned out that she was not pregnant, but, like a fool, she told him. Then it had got back to me, since we knew him mutually.

Th. Who told you this?

Pt. Well, you see, look, uh, here I go again, I'm skipping. This, this is getting complicated.

Th. We have so much to cover in the interview that it may perhaps be essential to cover highlights and then we'll be able to go into detail later, *[again attempting to focus on material pertinent to the initial interview]*

Pt. This is a highlight I'm going to have to tell you. I'm sorry to interrupt you, but I have to tell you this. She was pregnant last summer. I got her pregnant. And I was pretty shaken by it, and I brought my mother in who is a woman of the world.

Th. During this period was there a lot of turmoil in you, or were you more or less placid?

Pt. Placid, placid, surprisingly. You see, as soon as I met Philly, she was really why I seemed to get so secure, Joan faded from the picture, and it was like, it was like something fell off my back. It was like, I was like the man with the hoe. Well, anyhow, so I got her pregnant. Oh, that was a hell of a summer. So Mother, who had been circulating with the literati for many years, she knew I was carrying on an affair with Philly. Mother had, we, we, mother and I had talked everything out, and I had felt very close to her, so I brought her in on this. And she went down to Philly—it was probably a mistake—and we got her, well we got there, everything was all right. Then we went back together. It was very difficult after that, and I began losing a little interest. Well, when I left in September, right after I left, I phoned her, one night in October, and her landlady said she went to see her aunt.

Th. Mm hmm.

Pt. Well, she has two aunts there, three, so she said. My suspicions grew and when she came back, she told me that she had gone South with this fellow. But it was platonic; he had gone as a

friend. I accepted that. When I got home in December, Mother told me that she talked with Philly, and she said she didn't know if I was the one who got her pregnant or if it was the other fellow.

Th. Mm hmm.

Pt. And my opinion of her decreased considerably, since she had sort of done this thing without any responsibility. So, we broke up in December. It was a very terrible scene 'cause my mother got involved in it. My mother got involved, and she became just like every other mother, very possessive and jealous of her son. I had thought that she had a soul above it before this. But she didn't. She said, "She's no better than a whore." I took great offense to that. I got sore as hell.

Th. Did that knock you for a loop, too—the breakup of that situation?

Pt. Yes, yes, it did, for 2 or 3 weeks. Well, it really didn't by comparison with the first. I don't know whether it was because basically, because Joan was an unusual, extraordinary, uh, uh …

Th. An exceptional person?

Pt. Yeah, or because Philly was just a second. And the second is, didn't bother me so much. So it, so, it's, it's, it's during that time I went to see Dr.____ Now, why am I here today, I mean why I came to see you?

Th. Yes.

Pt. I know you want to get to that. Well, right now I have actually never felt in a way so confident except maybe when I was in high school or in the army. But it may be because I think introspectively. I guess introspection isn't too good either.

Th. Well, now, let me ask you this. What problems do you feel you have now that you'd like to modify?

Pt. Well, there are problems. Mostly they're in terms of pers-, my own personality problems.

Th. Do you want to tell me something about these?

Pt. Yeah, yeah, I will. Well, I find myself feeling at times that I do not, oh, have friends with whom I can possibly associate or, or be at ease with. I feel that I should always be making an impression upon them. Uh …

Th. Do you have any idea as to what goes on?

Pt. I have an idea why.

Th. Yes.

Pt. Well, I, uh, I think it's probably the fact that I had been deprecated; I had been deprecated by my stepmother throughout life. She had pointed to her own son as *the* one.

Th. What age difference is there between you and her son?

Pt. It was a year and a half. He was younger. Well, he turned out to be a complete dunce. (*laughs*) I say that literally. And it, it turned out that, that my father started looking toward me. And later on Dad was, Dad was always the most stabilizing influence in this whole set-up.

Th. Did you like him?

Pt. Oh, yes, Dad was wonderful.

Th. So, to come back to what we were talking about before, the basic problem you'd like help with is your relations with people.

Pt. Yes, and there are several other things I already mentioned that may be concomitants of this or other problems. *[Since the patient is garrulous, to allow him to explore this idea would divert us from important tasks.]*

Th. Now I'd just like to ask you a few questions rapidly.

Pt. Fire.

Th. Your full name is? *[getting statistical data]*

Pt. (Patient spells this out.)

Th. How old are you?

Pt. Twenty-five.

Th. Your address?

Pt. (Patient gives this.)

Th. Telephone?

Pt. (Patient gives this.)

Th. Is it all right to call you there?

Pt. Oh, yes.

Th. Are you living alone?

Pt. Yes.

Th. Now, you are single and a postgraduate student?

Pt. Right.

Th. What are the sources of your income?

Pt. Well, I was left a small amount of money; well, maybe, it isn't small, but it gives me enough to be comfortable with.

Th. You say you were in the army?

Pt. I was in the army, uh, 26 months between 1944 and '46. I think the army was intellectually regressive. I don't recall reading more than 3 or 4 books during that time.

Th. Now I'd like to ask you about other symptoms. How about tension, do you feel tense? *[inquiring about other complaints and symptoms]*

Pt. Well, now, if you are talking about now, I don't. Only when I am in certain situations.

Th. How about depressions, do you get depressed?

Pt. Once in a while when I think of the messes I've been in.

Th. But not habitually.

Pt. No.

Th. How about anxiety?

Pt. Oh, yes, I'm anxious, but I get out of it.

Th. What about physical symptoms?

Pt. Well, no.

Th. Any fatigue or exhaustion?

Pt. Yes, often that.

Th. How about headaches?

Pt. No.

Th. Dizziness?

Pt. I don't think so.

Th. Stomach or bowel trouble?

Pt. No.

Th. Any sexual problems?

Pt. Well, now, it's funny, when I first meet a girl, I can't, I mean I have no confidence, but later it's all right.

Th. I see. Any other problems?

Pt. I would say not.

Th. Any phobias or fears?

Pt. Just of speaking in public. Stage fright, I guess.

Th. Any other fears?

Pt. No.

Th. Any thoughts that crowd in your mind that frighten you?

Pt. No.

Th. Any compulsions—doing things over and over?

Pt. Well, no.

Th. How about sedatives, do you take them?

Pt. Only rarely when I can't sleep.

Th. How about alcohol, do you drink excessively?

Pt. No, but at parties I may have too much.

Th. You say you sleep well?

Pt. Oh, yes.

Th. Any nightmares?

Pt. No.

Th. You remember your dreams pretty well?

Pt. Generally.

Th. Can you tell me a recent dream?

Pt. I had one last night, but I can't remember the details.

Th. Any repetitive patterns in your dreams?

Pt. I couldn't say.

Th. Now a few items about your family. Your own mother is alive and well, *[obtaining family data]*

Pt. Yes.

Th. You say you feel different ways about her?

Pt. Yes, good and bad. I seem to miss her and get furious, infuriated with her. She is sophisticated as I say, but always gets into my life, interferes.

Th. Your father is in good health?

Pt. Yes, he's a person I always admired.

Th. And your stepmother?

Pt. As I said, we were strained. I don't think she ever liked me. She gave me physical care, but it stopped at that.

Th. Now what about brothers and sisters?

Pt. I have a half-brother, three years older than I am. He is a shy fellow. We got along badly, very badly all our lives. I joined in the cruelty kicking him around. It seems I emerged out of all this better than he did. And then I have a younger half-brother who turned into a sort of nonentity. That was fortunate for me because I felt that I had it all over them.

Th. Now previous to the two bust-ups you had with these two girls, were there any previous attacks of the same kind? *[questions as to previous emotional upsets]*

Pt. No, not that way.

Th. How about when you were little, any problems then?

Pt. I suppose I was a nervous kid, but I, uh, I mean, I never had any real trouble.

Th. You have had previous treatments as you said with Dr._____. Can you tell me a little more about these, *[questions as to previous treatments]*

Pt. Well, you see, I saw him for a month when I got upset, then, and then I had to go back to school. So I used to see him vacations, and never more than a couple of weeks at a time.

Th. I see.

Pt. And I saw him when I was in California in December, and, it's, well it's been a very short period.

Th. Did you get any psychologic tests of any kind?

Pt. I took some intelligence tests when I was in high school.

Th. Any Rorschach test at any time?

Pt. No.

Th. I'd like to get one on you. How do you feel about it? *[Securing a psychologic consultation. This is not absolutely essential here but it might give me some data about his ego strength.)*

Pt. Sure, if you think it's important.

Th. All right, then, my secretary will make the appointment and will call you. Now, how would you estimate your present health, physical health?

Pt. I'd say I was all right physically.

Th. Have you had a physical examination during the past year?

Pt. Only three months ago I had an insurance physical. The doctor said I was in good shape then.

Th. So to review, you'd like to get started in therapy for this personality difficulty. How urgent would you say your need for therapy was?

Pt. I'd say it wasn't an emergency, that is, I've lived with it for a time, and I suppose I could survive. But I want to be the sort of individual who can walk around in this complicated world without feeling that I somehow am, well, not apart from it. Now in my studies in school, I, I work in spurts. I find myself unable to study for a week. And, all of a sudden, I'll spurt. I do an enormous amount of work then.

Th. In other words, your efforts aren't consistent. Now, let's look upon the practical issues that are involved. You're up in the country, and you have a commuting problem. If you were to come here to see me, we would have to work out some sort of program for you. First, how would you feel about working with *me? [making practical arrangements for therapy]*

Pt. Fine, I find it easy to talk to you.

Th. Good. I believe I can make time for you on my schedule.

Pt. Well, now I have a car. It wouldn't be too bad. I have no classes Wednesdays and only one class on Friday from which I can come to and then come in. Those are really my best days.

Th. What I would really like to do is spend several sessions with you attempting to formulate a goal in treatment, and then outline a plan. I am not sure yet how deeply we want to go into your personality problem, or how extensive the process would be in terms of time. You know personality problems go so far back in one's life that it might take time to remove them. Sometimes it takes as long as 2 or 3 years. *[Since this is a personality problem, it is likely that therapy will take a long time.]*

Pt. Well, I know it must take time, and I suppose I am too anxious about it. But on the financial end, if I don't have to come too often, I think I can handle it.

Th. As far as frequency is concerned, we could try twice a week and see how things go. You may be able to do well on that. If any unusual resistances occur, you might have to come in more often, at least for a while. But we can't really tell without a trial. As a matter of fact, once we decide to go ahead, it might be a good idea to set up a trial period of say three months to see how we get along in therapy as a team. *[Setting the frequency at twice a week is conditioned partly by the fact that he can come in no more frequently, if he is to continue with all of his classes at school. On the other hand, because of his dependency problem, we may want to cut down on visits to once a week.]*

Pt. I think that's a good idea.

Th. Now my secretary told you my fee. I'd like to tell you about our appointments. They start right on time, and the sessions last three-quarters of an hour. I'll send you a bill at the end of each month. Once we set our regular sessions, you should keep the appointments consistently unless a real emergency comes up. If you have to cancel an appointment, please do so at least 24 hours in advance; otherwise I may have to charge you for the session since I set it aside for you. *[making final arrangements]*

Pt. All right.

Th. All right, then, how would 3:40 P.M. next Wednesday suit you for your next appointment and 2:50 P.M. the Friday after that?

Pt. That would be good for me.

Th. All right, my secretary will call you about the appointment with the psychologist for testing. So I'll see you Wednesday.

Pt. Goodbye, Doctor.

Th. Goodbye.

Tentative diagnosis: Passive-aggressive personality disorder.

Tentative dynamics: The patient seems to suffer from tendencies to relate in an immature way to women who take over a maternal role with him. Hostility is probably a concomitant of this relationship. Inevitably the patient is rejected, perhaps through his own participation. A rupture of the relationship produces great anxiety, with inability to function. The patient may try to avoid deep involvement by a detached relationship with women for whom he may have little respect. The origins of his problem are perhaps rooted in childhood insecurities in relation to an alternately rejecting and overprotective mother and a rejecting stepmother. Latent homosexual tendencies may exist associated with the dependency pattern.

Tentative prognosis: There are many positive things about this man, and he seems to have been able to adjust to many vicissitudes. For instance, his early childhood was not too tumultuous; he adjusted well to army life; he has progressed satisfactorily at school. With adequate therapy the prognosis is probably good.

Reciprocal response of patient and interviewer: The patient was cooperative and seemed to respond well to the interviewer. The latter, in turn, felt positive toward the patient.

Physical appearance: Meticulous, perhaps a little foppish.

Patient's estimate of his present physical health: Good.

Communicativeness: Somewhat garrulous.

Insight and motivation:

    1. The patient is aware of the fact that he has a problem.

    2. He desires to correct the problem.

    3. He is aware that his problem is emotional in nature.

    4. He is willing to accept psychotherapy.

    5. He is willing to accept help from the interviewer.

    6. He seems to be willing to accept the conditions of psychotherapy.

    7. He is able to afford the fee.

Choice of treatment method: Psychoanalytically oriented psychotherapy.

Frequency of visits: Twice weekly at the start.

Most patients harbor misconceptions about psychotherapy and its allied fields as well as about themselves. These are the products of ignorance, fear, superstition, or lack of proper information. The responsibility of the therapist here is to supply the patient with facts (psychoeducation). Although the patient may not believe or be willing to accept such facts at first, offering these facts gives the patient an opportunity to alter misconceptions.

It is often advisable to probe for the reasons behind certain questions before answering them. For instance, if the patient asks, "Do *you think psychotherapy could help me?*" various responses are possible:

    1. *Th.* You seem to have doubts about this.

    2. *Th.* I wonder why you ask that question?

    3. *Th.* Do *you* think psychotherapy can help you?

In the event a patient seems demoralized by fear and by doubts about personal capacities to get well as indicated by his or her questions, the therapist may reply: "Look, your problems are not unique. You are not the only one who has this kind of trouble. You are not weak and hopeless. You have a complex disorder, an illness that has a name. What you are experiencing are attacks of this illness. This is not under your voluntary control. It is not your fault. You are not incurable. With proper help and your willingness to cooperate, you should experience relief."

Once the patient expresses his or her ideas, the therapist may provide pertinent facts. The following questions are commonly asked by patients, and suggested answers to these are indicated:

    1. *Pt. Can I really be helped by psychotherapy?*

Th. Psychotherapy is designed to help a person overcome nervous symptoms, to adjust better to life, and even to modify the inner personality structure so that the person may live more harmoniously. If you have a desire for help and work with a trained professional person, the chances are psychotherapy may be able to help you.

2. *Pt. Can't I get over my trouble by myself?*

Th. Even if your problem is not too serious, it is hard for you to work it out without professional help. It is difficult or impossible to be completely objective about oneself because living so close to one's problems makes it hard to see them. It's like being unable to see the forest for the trees.

3. *Pt. Will not a change in my external life situation produce a cure in my emotional problems?*

Th. Occasionally this happens, but, unfortunately, not enough times. Problems are part of oneself and usually pursue one in all sorts of circumstances. Of course, bad external circumstances aggravate one's difficulties or bring them to the surface. Good environmental circumstances minimize them. But one's problems are always there, and they have to be dealt with therapeutically if any real modification or cure is to occur.

4. *Pt. Why is it that a person is unaware of factors that cause emotional trouble?*

Th. The reason a person is unaware of such factors is that they are associated with such hurtful emotions that they are automatically shut out of one's mind. The mechanism of keeping painful ideas from the mind is known as "repression."

5. *Pt. What is the real cause of emotional illness?*

Th. Emotional illness is the product of bad learning experiences. These create conflicts that interfere with one's relationships with life and with people. Some of these conflicts are unconscious, that is, the person is only partially aware of them. The mechanism of repression operates to push painful conflicts out of awareness.

6. *Pt. Can't I find out by myself what is causing my emotional trouble?*

Th. You might, but most people can't. Not only do we fail to see important issues, but we tend to distort them. For instance, it is hard to discard an image of oneself that one has maintained and enlarged from early childhood, even though the image is an erroneous one. Because we can't be objective about ourselves, we will need professional help.

7. *Pt. Do emotional problems start in childhood?*

Th. The personality structure is built up during childhood as a result of experiences with parents and other significant individuals. When one's early life has been unpleasant, the personality structure may be damaged. This may create trouble for one later on.

8. *Pt. I know my personality has not been what it should be, but how could this cause

my symptoms?

> *Th.* Personality problems create difficulties in getting along with people. They stir up unhappiness and initiate many conflicts. The upshot is tension, fatigue, depression, fears, as well as other symptoms.

9. *Pt. Doesn't my needing psychotherapy mean that I have a weak will or am on the way to a mental breakdown?*

> *Th.* No! More and more people, even those whose problems are essentially normal ones, are seeking help these days because they realize they can better themselves with treatment. The fact that you desire psychotherapy is a compliment to your judgment and is no indication that you are approaching a mental breakdown.

10. *Pt. If I have a nervous problem, doesn't that make me different from other people?*

> *Th.* All people have some neurotic problems. Their ability to live with these problems and to fulfill themselves creatively in spite of these problems constitutes the difference between "normality" and emotional maladjustment. Most persons whom we call "normal" actually have neurotic problems that do not interfere with their life adjustment or happiness. When such interference occurs, individuals will want to do something about themselves and their problems.

11. *Pt. Why do so many people have neuroses?*

> *Th.* It is impossible to escape conflicts in the process of living. The very act of growing up involves sacrifices and the yielding up of individual pleasures for the group interest. There are many deprivations and disciplines to which we all have to adjust. The price of such an adjustment is often frustration and tension. Mild neurotic symptoms are present in all of us; indeed, they are more common than the common cold.

12. *Pt. Am I not indulging myself by seeking treatment?*

> *Th.* If you were suffering from a physical ailment, you would not believe that you were indulging yourself by getting help for it. An emotional problem may be equally disabling or more disabling than a physical problem. It will need expert help and should not be regarded as a form of indulgence.

13. *Pt. Can all persons with emotional problems be cured by psychotherapy?*

> *Th.* All people can be helped in some way by psychotherapy. The extent of help will depend largely on how much the person desires help, and how much the person resists being helped. Some people do not really wish to be cured of their neurosis because it yields important dividends for them. Those who are willing to exchange health for the spurious pleasures of a neurosis have gone more than half way to a cure.

14. *Pt. Why are there so many different theories about emotional conditions?*

Th. The field of mental health is relatively new, and, consequently, new findings are constantly being uncovered. Actually, there are more areas of agreement than there are differences.

15. *Pt.* There is a history of mental illness in my family. Does this mean that *I will have a mental breakdown?*

Th. There is scarcely a family in the country that doesn't have some member or progenitor who has suffered from a serious mental illness. There is a great deal of disagreement in scientific circles as to the exact role of heredity in emotional problems. However, it is generally conceded that even though a person has a strong history of hereditary illness, this does not necessarily mean that he or she will develop a mental breakdown.

16. *Pt. Shall I get treatment now, or shall I wait?*

Th. The longer you wait the more ingrained your patterns may become. As in physical illness, so in emotional illness: it is prudent to get help as early as possible.

17. *Pt. Can physical symptoms be caused by emotions?*

Th. Many physical symptoms are psychosomatic in nature, which means that they have an emotional or nervous basis. When you come to think of it, it is not really so strange that emotional strains or worry should produce physical symptoms. After all, every organ in your body is connected with your brain by nerve channels; and so it is logical that when your nervous system is upset by some crisis or conflict, you may feel the effects in various organs of the body.

18. *Pt. What is a psychoneurosis?*

Th. A psychoneurosis is a very common form of emotional illness that indicates that the person is not adjusting to all phases of life. Among the more common symptoms of psychoneurosis are feelings of panic or anxiety, depression, fears of various sorts, compulsive acts, and physical symptoms.

19. *Pt. What is a character disorder?*

Th. Many people have a character disorder that consists of a warping of the personality brought about by early training. Character disorders are associated with feelings of insecurity, devaluated self-esteem, and other traits that prevent the individual from being as happy and productive as possible.

20. *Pt. Are alcoholism and drug addiction emotional problems?*

Th. Yes.

21. *Pt. What is insanity?*

Th. Insanity is a severe mental illness in which a person loses the capacity to distinguish between what is real from what is imaginary. While most people who are emotionally upset believe

they are going insane, they very rarely do so. Insanity, or psychosis as it is more properly called, is treatable even in its end stages with modern methods of therapy.

22. *Pt. How can I get the proper help for my problem?*

Th. It is extremely important that the therapist who treats you be a responsible person with sufficient training. Unfortunately, there are many charlatans who have had little or no real training and who advertise themselves falsely as "psychotherapists," "hypnotists," "counselors," and "psychoanalysts." It is unwise to consult any person for treatment unless referred to such a person by a physician or other professional person or by a reputable agency.

23. *Pt. Who is qualified to do psychotherapy?*

Th. Psychotherapy is an extremely complex skill and requires a great deal of specialized training. Psychiatrists, clinical psychologists, clinical social workers, and psychiatric nurses can do psychotherapy if they have had proper postgraduate training.

24. *Pt. What is a psychiatrist?*

Th. A psychiatrist is a medical doctor who specializes in the handling of nervous and mental illness.

25. *Pt. What is a neurologist?*

Th. A neurologist is a medical doctor who handles organic diseases of the brain and spinal cord, such as brain tumors.

26. *Pt. What is a psychoanalyst?*

Th. A psychoanalyst has had special training in the field of psychoanalysis. This involves an extended period of study and includes a personal psychoanalysis.

27. *Pt. What is a clinical social worker?*

Th. A clinical social worker is a graduate from a school of social work who has specialized in helping persons with emotional difficulties. Because of specialized training, the social worker is often used as a consultant in interpersonal, family, social, and community problems.

28. *Pt. What is a clinical psychologist?*

Th. A clinical psychologist is a graduate of an approved school of training in this discipline. The training of the psychologist enables him or her to handle emotional difficulties. The psychologist is often used as a consultant in diagnostic testing, rehabilitation, vocational guidance, and research.

29. *Pt. How does psychotherapy work?*

Th. Nervous symptoms and unwarranted unhappiness are caused by inner emotional conflicts, faulty learning, or objectional environmental circumstances. In psychotherapy you are helped to understand your troubles, whatever their nature. In this way it is possible for you to do something constructive about solving them.

30. *Pt. What kind of treatment will I need?*

Th. Different kinds of treatments are helpful in emotional problems, just as different kinds of medicines and operations are suitable for physical illnesses. But the goal is the same— to get the patient well. It's like the roads that lead to Rome. There are many different routes one can follow, and one can get there by different vehicles, from donkey cart to airplane. The goal, however, is Rome. The kind of treatment best suited for you can be determined only by a careful evaluation of your problem.

31. *Pt. What different types of psychotherapy are there?*

Th. Roughly, psychotherapy falls into three broad categories: first, supportive therapy, which aims for the correction of symptoms and problems in living without necessarily producing deeper changes; second, reeducative therapy, which helps a person to relearn and to correct certain patterns of behavior; and third, reconstructive therapy, which has as its goal some modification of the individual's personality. Needless to say, the latter kind of therapy is much more extensive and difficult.

32. *Pt. What are the most common approaches in psychotherapy?*

Th. Within the broad supportive, reeducative, and reconstructive groupings there are countless varieties of approach—for instance, interview psychotherapy, nondirective therapy, Freudian psychoanalysis, non-Freudian psychoanalysis, psychoanalytically oriented psychotherapy, group therapy, behavior therapy, and hypnoanalysis. These are different ways and means toward the same objective of helping a person get well.

33. *Pt. What is the best kind of psychotherapy?*

Th. The best kind of therapy is that which suits the needs of the person best. A good therapist modifies methods to suit the patient. Sometimes supportive therapy is most indicated; sometimes reeducative therapy is needed; sometimes reconstructive therapy is best. The type most suited for you will depend on the nature of your problems.

34. *Pt. What is psychoanalysis?*

Th. The word "psychoanalysis" has become so popularized that it has lost its original meaning. Psychoanalysis is the name given to a theory and a technique by Sigmund Freud. The original theory and technique, which is still in use, has been modified by some of Freud's contemporaries and students. Some of the principles of psychoanalytic thinking have been incorporated into modern psychotherapy, and the product is often called "dynamic psychotherapy" or "psychoanalytically oriented psychotherapy," which must be distinguished from formal or "classical" psychoanalysis.

35. *Pt. What is involved in a psychoanalysis?*

> *Th.* Formal psychoanalysis is a special treatment procedure that can be conducted only by those who have had specialized training in this particular field, that is, psychoanalysts. A psychoanalysis requires that a patient have at least 3 and preferably 4 to 5 treatment sessions weekly. Whether a patient should undergo a psychoanalysis rather than some other form of psychotherapy has no relation to the seriousness of the patient's case. Some very serious cases respond well to formal psychoanalysis, whereas others do much better with some other form of psychotherapy.

36. *Pt. What is the difference between psychoanalysis and other types of therapy?*

> *Th.* One of the fundamental differences is the emphasis in psychoanalysis on unconscious conflict as the source of emotional problems. The elucidation and understanding of unconscious conflicts, and the tracing back of conflicts to their origins in childhood, are the chief tasks in psychoanalysis.

37. *Pt. Isn't psychoanalysis the best kind of treatment there is for emotional problems?*

> *Th.* The best kind of treatment for an emotional problem is the treatment that is best for the patient. Sometimes the best treatment is psychoanalysis; sometimes the best treatment is another kind of psychotherapy such as behavior therapy, cognitive therapy, hypnosis, medicinal (drug) treatments, and others that are preferred in certain kinds of problems.

38. *Pt. If psychoanalysis goes deeper into a problem than any other kind of psychotherapy, isn't psychoanalysis to be preferred?*

> *Th.* Not necessarily; other techniques may be better for a person. We can take examples from the field of medicine. Most abdominal conditions can be handled with medicinal treatment; some require surgery. Those that need surgery should get surgery. Those that do not need surgical interference should not get surgery. While some emotional problems need psychoanalysis, others definitely do not. They should, therefore, get the kind of treatment that is best suited for them.

39. *Pt. What is the difference between psychotherapy and psychoanalysis?*

> *Th.* Psychotherapy is the general term applied to the overall treatment of emotional problems. One kind of psychotherapy is psychoanalysis. Psychoanalysis is helpful in certain kinds of emotional problems and not so helpful in others. Because it takes so long (3 to 5 times a week for from 1 to 3 years) and is so expensive, it should be used only where it is definitely required. Not all people can use psychoanalysis, nor do they need it.

40. *Pt. What is Freudian psychoanalysis?*

> *Th.* This is the technique originated by Dr. Sigmund Freud. It is helpful in certain kinds of emotional illness.

41. *Pt. What is non-Freudian or neo-Freudian psychoanalysis?*

> *Th.* This is a modified approach to psychoanalysis, which in the hands of competent, well-trained therapists yields good results in certain emotional problems.

42. *Pt. Which is superior, Freudian or non-Freudian psychoanalysis?*

> *Th.* More important than the kind of psychoanalysis is the experience and skill of the analyst. A good psychoanalyst can get good results with either procedure, while a poor analyst will probably fail irrespective of the kind of approach employed. Some psychoanalysts find that a Freudian psychoanalysis works better for them; others hold a modified psychoanalysis in higher esteem.

43. *Pt. What is psychobiologic therapy?*

> *Th.* This is an approach to psychotherapy originated by Dr. Adolf Meyer that uses a number of different techniques. It is helpful in certain kinds of emotional illness.

44. *Pt. What do you think about behavior therapy?*

> *Th.* The principles on which behavior therapy was founded have been known to psychologists and psychiatrists for years. Behavior therapy can be effective in certain conditions, and to remove symptoms, for instance, as in pathological fearful (phobic) states, and to modify bad habit and behavioral patterns.

45. *Pt. Is group therapy helpful?*

> *Th.* Yes, in many conditions both by itself and in conjunction with individual therapy. Sometimes an entire family, or selected members, are seen together in a group. This is called "family therapy." A husband and wife may also be treated together in certain marital problems in what is called "couples therapy" or "marital therapy."

46. *Pt. Won't hypnosis shorten my treatments?*

> *Th.* In certain conditions hypnosis is helpful; in others it seems to do no good.

47. *Pt. Will I need special treatments, like psychodrama or "truth serum"?*

> *Th.* That will depend on the nature of your problem. If your therapist believes any special treatments to be indicated, he or she will tell you about it.

48. *Pt. Will I need shock therapy?*

> *Th.* Very few people need shock therapy. Its use is limited to only special conditions. The probabilities are that you will not require this form of treatment.

49. *Pt. Will I get medicine for relief, for example, tranquilizers or antidepressants?*

Th. If your therapist believes that medicine will be of any benefit to you, he or she will prescribe it or have it prescribed.

50. *Pt. Are there any shortcuts to treatment?*

Th. A number of experimental methods are in process to see whether it is possible to cut down the long period of time required for treatment. This work is not entirely complete, but sufficient progress has been made to indicate that it may be possible to cut down on the treatment time in some cases. However, there are some forms of emotional problems in which time itself is the essence in treatment and shortcuts are not possible. Personality problems have been so much a part of an individual since childhood that it may take time to unravel them.

51. *Pt. Can psychotherapy make a person happy no matter how bad the person's situation may be?*

Th. Psychotherapy will not stop a person from reacting to a bad situation. It should, however, make it easier to deal with this situation in a more constructive manner.

52. *Pt. Am I going to be forced during therapy to give up pleasures in my life situation that I find valuable now?*

Th. Nobody is going to force you to do anything. If any of the pleasures that you enjoy at the present time are destructive to you, you have a right to know this. Once you are aware of all the facts, you will then be in a better position to judge for yourself whether you want to continue or discontinue certain pleasures. Many people have the misconception that psychotherapy will make them terribly serious and prevent them from enjoying themselves. On the contrary, psychotherapy releases inhibitions to enjoyment and pleasure.

53. *Pt. Is treatment likely to make a person immoral?*

Th. This mistaken notion is caused by the fact that in therapy an individual discusses problems of deepest concern to one, including sexual problems. Immorality is never produced by a proper understanding of emotional problems and drives. On the contrary, immorality is usually the product of misunderstanding. Once the individuals survey themselves honestly, healthy and constructive attitudes toward themselves and toward their basic impulses will develop.

54. *Pt. Will therapy break up my present marriage?*

Th. Therapy actually preserves many marriages. It is interesting that therapeutic changes occur not only in a person getting therapy, but also in the person's mate. This is because a personality alteration in one member of a family always affects the adjustment of people in close contact with the person. When a marriage seems hopeless, for example, the patient will be able to evaluate better its good and bad points.

55. *Pt. Will I lose my creative abilities if I get therapy?*

Th. Such an idea arises from a misconception that creativity comes from neurosis. Actually,

creative work is one of the most normal of human drives. It is crippled by neurosis. Experience shows that people are liberated from their blocks and actually become more creative after therapy.

56. *Pt. Are people supposed to fall in love with their therapist?*

Th. This is a notion that most people have from reading the existing literature. Actually, transference feelings, positive or negative, occur in varying intensities. The particular form that the transference takes will be dependent upon the individual's unique problems.

57. *Pt. What is transference?*

Th. Transference is the carrying over of emotions and attitudes from the past into relationships with present-day people. It is inspired not by the reality situation, but by previous happenings in former relationships that go as far back as childhood.

58. *Pt. Is transference necessary?*

Th. Transference is a part of every human relationship. For instance, you may have had initial impressions of people; these impressions are caused by the fact that the persons resemble somewhat those you have known. Sometimes one can get angry at a stranger, or one can like a person, for no apparent reason. Such irrational attitudes and feelings toward others go on all the time. They are caused by transference. Transference may be present in the therapeutic relationship. It enables us to see what unconscious attitudes and feelings are constantly being projected out toward other people and are stirring up troubles in adjustment.

59. *Pt. Can transference be at the basis of one's emotional problems?*

Th. Transference distorts logic and judgment and causes unfair and destructive attitudes toward people. These may actually interfere with one's ability to relate in a realistic way to people with whom one requires a good contact.

60. *Pt. Do I have to report my dreams in therapy?*

Th. Yes, if your therapist believes you should do so. All people dream; but not all people remember their dreams. Dreams are thought processes during your sleep that embody symbols and bizarre language forms that may seem meaningless. But woven into the fabric of dreams are attitudes, feelings, and memories that yield clues, to an experienced observer, regarding the individual's basic difficulties and conflicts.

61. *Pt. Can dreams really be interpreted?*

Th. Dreams are condensed symbols that can be interpreted by an experienced therapist. Do not expect that all your dreams will be interpreted for you by your therapist. This is both impossible and unnecessary. You may learn to understand the meaning of your own dreams, and you will then be able to see how closely related your dream structure is to your emotions and feelings.

62. *Pt. But my dreams seem so bizarre. How can they mean anything?*

    Th. The language of the dream, the peculiar symbols that dreams use may seem weird, but these can often be translated by trained therapists, and the significant meanings thereby understood. Freud called dreams the "royal road to the unconscious." The surface story told by dreams (manifest content) is not so important as what underlies the dream (latent content).

63. *Pt. What causes dreams?*

    Th. Dreams are a normal part of the sleep process. Some dreams serve as an outlet of tensions in expressing open and secret hopes as well as fears and conflicts. Such dreams are the mind's attempt to solve problems that disturb the individual, not only in present-day life but also those problems that had upset the person as far back as childhood.

64. *Pt. Is it necessary to recline on the couch for treatment?*

    Th. Reclining on a couch for treatment is usually desirable in formal psychoanalysis. It permits the person to concentrate much better on thought processes by minimizing the influence of external stimuli. It is usually unnecessary in most other forms of psychotherapy.

65. *Pt. What is free association?*

    Th. Free association is a technique used in formal psychoanalysis to discover certain deep unconscious associative links in the person's thoughts by letting the person's mind wander at random, verbalizing without restraint. Free association is not used in most forms of psychotherapy.

66. *Pt. Do I need psychological tests?*

    Th. Psychological tests are often helpful in arriving at a better understanding of the sources of tension and emotional stress. The fees for tests may sound expensive; however, in the long run, tests may prove economical, since by helping in the diagnosis they may facilitate the treatment process. Among the more common tests are the Rorschach, Thematic Apperception, Szondi, and Man-Woman Drawing tests. Your therapist will decide if any of these or other tests will be most helpful to you.

67. *Pt. Do I have to tell my therapist everything, even those thoughts and experiences that make me feel guilty and ashamed?*

    Th. Complete frankness and honesty are the keynotes in psychotherapy. While in ordinary relationships you are subject to existing moral and ethical judgments, this does not happen in the unique kind of relationship during psychotherapy. It may take you a while before you realize that the function of the therapist is not to judge or to criticize you, but rather to help you get well. The therapist actually does not regard your attitudes, your impulses, and your experiences as bad or wrong, but rather as items that yield clues about your basic conflicts and difficulties. An example may make this clear. If you were to visit a friend and tell that person that you had, prior to seeing him or her, an impulse to murder someone, your friend

might express horror and even be tempted to call the police. If you were to say the same thing to your therapist, the therapist would neither condemn nor condone your thoughts but merely inquire about the reasons why you felt inclined to act as you did. This example is grossly exaggerated to indicate to you the difference between a relationship with your therapist and any other relationship you have ever had. It is important to reveal as much about yourself to your therapist as you can, and your confidences will not be betrayed.

68. *Pt. Why does a therapist act so unemotional?*

Th. Psychotherapy involves participation on the part of the patient in arriving at the sources of a problem as well as in resolving it. To inspire the patient toward activity, the therapist may assume a passive role, guiding the patient only when the patient becomes blocked in thinking things through. Actually, the therapist is not so much detached but rather is purposefully withholding from carrying the chief responsibility for therapy, which, while temporarily reassuring to the patient, would ultimately hamper the patient in the quest for assertiveness and independence.

69. *Pt. Will my therapist tell me what to do and how I can best conduct my life?*

Th. Understandably you would want such guidance since life now seems to be so frustrating and difficult. When it is absolutely necessary, your therapist will help you decide on alternative courses of action. However, the primary object in therapy is to help you achieve a level of growth and development such that your own choices and decisions will bring happiness to you rather than grief. To do this, your therapist will have to help you understand what is behind your problems and the reasons it has been difficult for you to conduct your own life. You will also have to achieve a level of development in which you can make your own decisions rather than depend on others. In this way you will attain the most active and satisfying growth.

70. *Pt. Are there any rules I must follow in therapy about making crucial decisions that will alter my life situation ?*

Th. There are several rules. It is essential to understand that in the treatment process many aspects of your life will come up for review. It is important, therefore, not to make any crucial decisions or changes until the meaning of such a choice is fully understood. If you contemplate any significant alteration in your position or life situation, it is essential to talk it over with your therapist first to make sure that you are not being influenced by temporary emotional feelings stirred up during treatment.

71. *Pt. Is it all right for me to see my therapist socially?*

Th. One of the basic rules in therapy is that the relationship between patient and therapist be kept on a professional basis. This is extremely important inasmuch as you have a specific task to achieve in your treatment, and this task may be watered down by associations such as may occur in a nonprofessional relationship. Experience shows that treatments proceed most rapidly where the relationship is kept on a purely professional level. A social relationship with your therapist may create many stumbling blocks in your treatment that may actually destroy its effectiveness.

72. *Pt. How many times a week must I come for treatment?*

Th. There are some persons who come once a week and there are others who desire, or find it necessary, to come 2 or 3 or 4 times a week. Sometimes it is better to come more frequently than once a week to cut down the interval between visits and to gain the advantages of more concentrated work. At other times this is unnecessary. The frequency will depend upon the nature of your problems and the kind of therapy that is used. In most cases treatments can be administered on the basis of once, twice, or three times weekly. When Freudian psychoanalysis is used (that is, where your problems are such that your therapist believes a formal psychoanalytic technique is indispensable for you), you may have to come as frequently as five times weekly.

73. *Pt. Aren't charges for psychotherapy excessive?*

Th. It takes longer to make a good psychotherapist than a good surgeon. Fees for surgery and other specialities are so much higher than fees charged for psychotherapy that we cannot even make a comparison. Although the fees that are charged may seem high, they actually are reasonable considering the extensive training of the therapist.

74. *Pt. After starting therapy, will I be charged for broken or canceled appointments?*

Th. Since your appointment times are set aside and reserved exclusively for your use, you may be charged for a canceled or broken appointment, unless illness or a real emergency interferes with your getting to the therapist's office. Most therapists do not charge for canceled appointments when sufficient notice has been given them in advance so that they can fill in the session with another appointment. Another reason for charging for broken appointments is to overcome resistance to coming for treatment when basic problems are under discussion. As a general rule, group therapy sessions are charged for whatever the reason for canceling them.

75. *Pt. How long does it take to get well?*

Th. It is hard to estimate this. Much depends on how much you want to get well. Much depends, also, on how deeply it is necessary to influence your basic personality makeup. If you have a special problem or symptom that is not too complicated, this may be helped in not too long a time. If, however, extensive changes in your personality are required, treatment will take more time.

76. *Pt. Does it usually take a long time to influence personality in depth?*

Th. Emotional illness associated with personality problems that go far back in one's life, so as to produce habit patterns of a stubborn nature, take a long time to influence, sometimes 2, 3, or more years. It is impossible to estimate the length of therapy since this will depend upon the severity of the problems and upon the goals one wishes to achieve. In many cases alterations achieved in a short period of treatment will continue after treatment has stopped as a person puts into action things that have been learned.

77. *Pt. I would like to expedite my treatment.*

> *Th.* Your impatience is understandable. But your trouble did not begin last Tuesday. It may have been with you most of your life. It took time to develop your problem, and it may take a little time for you to get over it.

78. *Pt. Why does it take so long to get well?*

> *Th.* If you are like the average person who undergoes psychotherapy, you will probably be puzzled or upset when, after several weeks of treatment certain kinds of problems are not materially improved. You will wonder why this is so, and you may even believe that your treatment is not successful. There are two things you must consider in evaluating your progress. First, certain emotional problems go far back in one's life, even as far back as one's childhood. Therefore, it takes time to get to the core of the trouble. Second, even though your symptoms are still with you, progress is being made nevertheless. Before a seed can sprout, it is necessary to prepare the soil. Before all your symptoms disappear and you achieve health, it is necessary to work at and overcome resistances that block your progress. Often an understanding of oneself helps.

79. *Pt. Why do I need an understanding of myself?*

> *Th.* The first step in becoming well is to become aware of your basic problems—in other words to identify them. Your difficulty may be that your environment is bad and you are trying to adjust to an impossible situation; or it may be that you have inner conflicts and fears that make for difficulties in your relationships with people. Whatever your problem, your therapist will help you to understand it clearly. Then you will be better able to do something constructive about it. It is hard to fight an enemy who attacks you from ambush. It is the same with emotional conflicts. As long as these are only partially known to you, you are helpless. Becoming aware of them makes it possible to take a stand to overcome them.

80. *Pt. Is it possible that I may exhibit resistances to understanding myself?*

> *Th.* There is always resistance in tackling the real source of one's difficulties. The reason for this is threefold. First, a person may have absolutely no inkling that what he or she is doing is not normal. For instance, an individual who has acted submissive from childhood may do so because it is the only way the person knows of getting along with people. It may cause the individual anxiety, yet it constitutes the only way of life the person knows. It may take a long time before the person realizes that he or she does not have to be submissive automatically. Second, a person may be very reluctant to face inner conflicts because of a fear that he or she will find out something that is too horrible to face. This fear is universal and it may take a while before the patient overcomes it. Third, one may actually derive a benefit from being sick and for this reason be unwilling to explore existing difficulties. It may seem paradoxical, but being sick often yields dividends one may refuse to give up. An example of this is the person who keeps failing in work or studies and, as a result, becomes extremely insecure. On the surface the person wants to stop failing; yet deep down what is desired even more is sympathy and help from people. And the reason for this failure is that in failing, the person can be dependent on others. Such a person may be resistive to understanding these tendencies toward failure because it requires giving up a technique that yields many neurotic benefits.

81. *Pt. After I get an understanding of my problems, what else do I have to do to get well?*

Th. Getting insight into certain kinds of problems is the first step toward getting well. You must use this insight to achieve a more productive and happier life. An example may make this clear. Suppose you desire to fly an airplane. The first thing you need is the vehicle—the airplane itself. But having procured the airplane does not mean that you can fly. You still have to learn how to work the airplane. Insight is the vehicle that can transport you to health. But having insight alone will not give you health. You must learn how to use this insight toward a constructive end.

82. *Pt. What can I do to aid the process of recovery?*

Th. Most people are confused about what is supposed to happen in treatment. In a physical ailment, once the doctor knows your complaint, he or she can give you a medicine. But emotional complaints are not helped in that way. *You, yourself, must participate in the cure.* Your therapist will help you to help yourself. One of the best ways to cooperate is to tell your therapist about yourself—your fears, your hopes, your fantasies, and your expectations. If you have any dreams, report them. You will probably also have certain feelings about your therapist. Bring these to the therapist's attention—no matter how irrational they may seem.

83. *Pt. Can I expect to have ups and downs during treatment?*

Th. You can. A feature of all nervous problems is that they try to repeat themselves. Even when you gain insight into them and begin to readjust yourself to life and to people, they will still crop up from time to time. The reason for this is that they are like bad habits. You know how difficult it is to break so simple a habit as excessive smoking. Faulty patterns of living that are part of your neurosis are complicated habits of long standing and will try to cling to you stubbornly. With patience and determination you can overcome these patterns. The important thing is not to regard a recurrence of your symptoms during treatment as a setback. Take the attitude that temporary flair-ups are to be expected and that you will learn something valuable about yourself each time they occur.

84. *Pt. Need I have conflicting feelings about my therapist?*

Th. Some persons do; some don't. In a relationship situation, which is the essence of psychotherapy, it is possible that you may run the entire gamut of emotions in response to your therapist. The experiencing of these emotions is an invaluable part of the treatment process. Do not be ashamed to tell your therapist exactly how you feel about him or her, no matter how irrational your feelings, demands, or expectations may seem. At certain stages in treatment you will be very much tempted to discontinue therapy because of how you feel about your therapist. Sometimes these feelings may not even be conscious. Consequently, whenever you reach a decision to stop treatment before your therapist thinks that treatment should be ended, examine how you feel toward the therapist and, more important, mention these feelings. There are times, of course, when you may become angry at your therapist for realistic reasons. It is also possible that your therapist has a personality to which you are unable to respond. In the latter instance it may be necessary for you to change therapists. Do not hesitate to tell your therapist about these feelings and

to mention any complaints you may have. The therapist will help you analyze whether your feelings are rational or irrational.

85. *Pt. Is it advisable to talk things over with people other than my therapist?*

Th. It is generally not wise to confide your innermost thoughts to other people because it may prevent you from mentioning important things to your therapist.

86. *Pt. Is it all right to talk about what happens in my treatment to other people?*

Th. No, this is not advisable since an outside confidant may hurt the therapeutic work. You should consider the therapeutic relationship a completely private situation, in which confidences will not be betrayed.

87. *Pt. Doctor, do you really believe I can be helped?* [To tell the patient that help is a certainty would be false reassurance. The therapist may reply in the following way.]

Th. The desire to be helped is nine-tenths of the battle. If you really want help, you will probably be able to be helped.

88. *Pt. What do you think it is that has made me sick?*

Th. There are always reasons why you feel upset. Those reasons may not be clear to you because you are living too close to your troubles. During therapy your ideas, and particularly your feelings, will be explored and, in not too long a time, you should discover what is behind your difficulty.

89. *Pt. In psychotherapy how can you get well by mere conversations?*

Th. In discussing your reactions, your ideas, and your feelings, you will better be able to understand what is happening to you, and this understanding will permit you to take definite steps to correct your difficulties.

90. *Pt. What will my therapist do to help me if all I do is talk about myself?*

Th. The therapist will help you with your difficulty by acting as your third eye or third ear. Since you are living so close to your problem, you may not be able to see your basic troubles as clearly as someone who can be more objective and more realistic about what is happening to you.

91. *Pt. How can I be sure I can be helped through psychotherapy?*

Th. There is no guarantee that you can, except insofar as you make a positive effort to cooperate with your therapist. In a short time you will get a better idea about whether you can be helped or not. Most people can.

92. *Pt. Are you sure I can be cured if I cooperate?*

> *Th.* It is difficult to answer that. Much depends on how much you want to be cured. If you really have the desire to get well, there is no reason why you should not make good progress. Many persons with severely disabling emotional and mental problems have gotten well. Your progress will depend also on how well you work together with your therapist as a team.

93. *Pt. Won't I lose my independence and get dependent on my therapist?*

> *Th.* One of the aims of treatment is to expand your independence and make you less dependent.

94. *Pt. Won't I find out terrible and loathsome things about myself?*

> *Th.* The fear of finding out contemptible things about oneself is frightening to most people. In exploring your difficulty you may be surprised to find that things are not as horrible as you imagine. Indeed, you may discover that your guilt feelings are not justified by the facts.

95. *Pt. How well is a person after completing psychotherapy?*

> *Th.* If treatment is successful, the person should be relatively free from symptoms and healthier and happier than ever before.

96. *Pt. Why shouldn't treatment always be successful?*

> *Th.* Success depends on many factors, including how much the person wants to get well. If a person really desires health, he or she will be willing to endure the time and effort required to get well.

97. *Pt. Is it possible to rebuild an immature personality through psychotherapy?*

> *Th.* In reconstructive psychotherapy a prominent goal is resolving blocks to personality development so that the individual may proceed to emotional maturity.

98. *Pt. If a person is cured of symptoms and is made happier by psychotherapy, does this mean the person will never again be nervous?*

> *Th.* No, neurotic problems may develop later, but the person will be better able to cope with them and even to solve them without further professional help.

99. *Pt. What happens to the information about me?*

> *Th.* In scientific work, records are necessary because they permit a more thorough dealing with one's problems. It is understandable that you might be concerned about what happens to the information about you because much or all of this information is highly personal. Case records are confidential. No outsider, not even your closest relative or family physician, should be permitted to see your file without your written permission.

100. *Pt. How can I help to cooperate with the treatment plan?*

> *Th.* The general practitioner has medications; the surgeon works with instruments; the heart specialist has delicate recording apparatus. But for the most part, the therapist has only one aid besides knowledge—YOU. Your cooperation and trust in the therapist are essential. You must feel free to take up with your therapist anything about the treatment process that disturbs you or puzzles you in any way. By doing this you have the best chance of shortening your treatment and of ensuring its fullest success.

35
Establishing a Working Relationship

One great disappointment to the beginning psychotherapist is that painstaking and elaborate exploration of a patient's problem and a most thorough endeavor to reinforce constructive behavior may fail to influence the emotional ailment in the least. Even though the therapist seemingly has an understanding of the patient's difficulties and of the contingencies that aggravate them, the patient continues to suffer symptomatically, and there is no abatement in the distorted way that the patient relates to people. The therapist, as a consequence, may become frustrated and perhaps dismiss the patient from treatment on the basis of "unsuitability," or "severe resistance," or "negative therapeutic reactions," or "latent schizoid tendency."

When the causes of such treatment failures are explored, it is often found that the patient has been unable to take advantage of the benefits of therapy because of anxiety or because of the refusal to make any effort on the basis of an infantile magical expectancy. This militates against evolving more effective ways of adjusting to new modes of behavior by therapy. Further investigation usually shows that what is basically lacking in the therapeutic situation, and what probably has been missing from the inception of therapy, is the proper kind of working relationship between the patient and the therapist. This relationship ideally is a unique interpersonal experience in which the patient feels a quality of warmth, trust, acceptance, and understanding such as he or she has never before encountered with any human being. Patients who have in the past established mature, unambivalent associations with people are usually capable of developing working relationships with most therapists. Those whose contacts have been characteristically disturbed will require therapists who are skilled, experienced, and truly able to deal with transference distortions and their own countertransference (Kernberg et al., 1972).

A neurosis imposes on the individual distortions in the individual's sense of values that undermine security, depreciate self-esteem, and make the average pursuits of living

vapid and meaningless. Before any significant change can occur in the system of neurotic balances and counterbalances that has been erected, it is necessary to win the patient over to a willingness to experiment with a new way of life.

The cultivation of the proper working relationship between patient and therapist is indeed the primary objective of the first treatment phase. Without a working relationship the patient will not resolve basic resistance to the meaningful resolution of problems.

In some cases a working relationship develops as a projection of the patient's need for an idealized authority. In other cases the therapist will have to work hard at securing rapport. To illustrate, we shall consider an example from the sales field. In selling a product the salesperson is confronted with the universal phenomenon of sales resistance. Experience has taught that any attempt to force the product on the customer before this resistance is overcome will be futile. The salesperson has learned that the best way of resolving sales resistance is to sell oneself to the prospect. Once the prospect has developed confidence in the acumen and integrity of the salesperson, the prospect is more prone to accept any statements that the latter makes about the advantages of the product.

Although the therapist is not a salesperson who is trying to sell the patient a product in the form of a new way of life, there is still the problem of resistance even though the patient may seem eager to get well. Such resistance is often fashioned by a desire to maintain the status quo and yet rid oneself of suffering. The patient must be persuaded to accept conditions that will lead to health in the face of his or her resistance. To do this, the therapist must first win the patient's trust and confidence by establishing a working relationship. The relationship hopefully will enable the patient to overcome initial reluctance to face his or her problems and work toward rehabilitation. Without this the therapist may not be able to achieve the therapeutic goal, whether it be symptom relief, problem solving, restoration of a shattered sense of self-mastery, elimination of destructive feelings and attitudes, acquisition of a healthier feeling about oneself and one's past experiences, or achievement of more adaptive interpersonal relationships.

In reconstructive therapy, until a working relationship is constituted, the patient will

be particularly unable to handle anxieties associated with unconscious conflict, investigate genetic origins, resolve archaic defenses, challenge the spurious pleasure values of the neurosis, or develop more constructive modes of adjustment.

VARYING NEEDS OF THE PATIENT

Militating against the establishing of a working relationship is the fact that the patient always seeks to use therapy in a variety of ways, some of which are inimical to good rapport. Thus, the patient may desire dependence on the therapist to receive guidance, reassurance, and other bounties. The patient may search for unqualified sympathy and acceptance. The patient may seek factual understanding and objectivity to help evaluate his or her thinking and behavior patterns. The patient may want to express feelings that are turbulent and to act out impulses, demands, and other strivings customarily held in check. Finally, the patient may yearn for a cooperative give-and-take relationship without domineering or being domineered. Not only must the therapist be equipped, by virtue of personality makeup, to accept the patient's varied strivings but must be able to react to them in a therapeutic manner. The therapist must provide the patient with an experience that will act as a prototype of a different kind of human relationship—one that inspires new and constructive attitudes toward people. To do this, the therapist must deal with the constituents of each of the patient's needs.

The Need to Be Dependent

Because the emotionally ill person usually feels helpless, he or she wants a kindly agency to relieve distress, to give support and guidance, and to restore health. These regressive needs, conspicuous in many patients, are most extreme in those who are severely sick. It is impossible for the therapist to escape fulfilling some measure of dependency need. While the therapist may not wish to perpetuate the infantilism of the patient by playing the part of a "giving" authority, except perhaps in supportive therapy, this may temporarily have to be accepted without resentment, fear, detachment, or aggression. Astuteness will be required in diagnosing how much active help the patient

needs, matching the support given to the severity of the sickness, and imposing on the patient as much responsibility as can be tolerated. The therapist must know when to resist dependency demands and how to convince the patient that their fulfillment may interfere with the patient's capacities to develop assertiveness, strength, and independence.

The Need for Unqualified Understanding, Acceptance, and Condonation

Such yearnings are part of the social nature of a human being. They may be especially urgent in the emotionally sick individual who constantly anticipates rejection and condemnation. In response to the patient's need for understanding and acceptance, it is essential that the therapist be capable of empathizing with the patient, of giving warmth and understanding no matter how destructive and disturbed the patient may be. At the same time, the therapist must avoid overprotecting and smothering the patient with cloying kindness, which will tend to rob the patient of self-sufficiency. Any personality characteristics in the therapist, like detachment or hostility, that interfere with this empathic ability to feel and to communicate warmth will constitute insurmountable handicaps to the establishing of a relationship.

The Need to Relieve oneself of Painful Feelings and Ideas

The desire to unburden oneself of guilt, fear, and anxiety will often be overwhelming for the patient. Ventilation of suppressed and repressed feelings, attitudes, and past experiences is usually accompanied by immediate but temporary relief. The therapist must be able to endure cathartic outbursts of painful emotion that are delivered by the patient, displaying a non-judgmental, objective attitude, neither condemning nor sanctioning the behavior of the patient. Since some of the material divulged may be of an immoral or antisocial nature, the therapist must be able to handle personal untoward feelings that are inspired by such destructive and perverse recitations, avoiding rebuke and other culturally accepted responses to the material.

The Need for Factual Understanding

The patient always has a need for an understanding of what is happening to him or her in order to neutralize fears of the unknown. This requires objectivity on the part of the therapist. The ability of the therapist to remain objective helps to inculcate in the patient a factual appreciation of the existing problem in relation to inner beliefs and external reality. Essential is a good understanding in the therapist of human dynamics, interviewing techniques, methods of bringing to the awareness of the individual the meaning of the individual's behavior, and helping the patient work through resistance to insight and to the translation of insight into action. This knowledge must be tempered in the therapist with intelligent self-awareness to avoid contaminating the patient with personal prejudices and to allow the patient to develop a personal sense of values.

The Need for a Transference Relationship

Many patients seek media in which they can project and act out tendencies and feelings that relate to actual or idealized parental personages. The projection of attitudes and feelings that originate in past relationships (transference) requires for its appropriate handling an understanding of this phenomenon by the therapist as well as the ability to perceive, use, and manage manifestations of countertransference. The therapist must be able to manage any intense dependency needs, sexual demands, hostilities, and manifold misinterpretations that will be expressed by the patient in the course of therapy.

One of the fallacies in practice is the idea that it is possible to resolve past parental deprivations that have acted as the basis for the patient's psychopathology by supplying remedial nurturing or unconditioned love within the therapeutic situation or by encouraging the patient to indulge and gratify infantile need deficits. Sandor Ferenczi's original and failed attempts to put this principle into practice has not discouraged some therapists from repeating his disappointing experiments (Ferenczi 1950a, b, & c). A host of reparative procedures have evolved, ranging from open expressions of praise and affection to holding the patient on one's lap, bottle feeding, stroking, and using other physically soothing maneuvers. The result of these efforts, though temporarily reassuring, have failed miserably to relieve patients' pathology. Early deprivations and parental

malfeasance are so structuralized and stabilized by defenses within the intrapsychic organization that they defy alteration through environmental manipulation. Indeed, attempts to unsettle the neurotic equilibrium may threaten repressive mechanisms that have enabled the individual to function up to this time, albeit with neurotic safeguards, precipitating strong anxiety. The defenses that protect against anxiety and maintain the patient's illness yield slowly, and only as the rigid internalized object representations change their fearsome and punishing quality through constructive cognitive alterations and congenial sustained interpersonal relationships. Translated into clinical practice, this means that the therapeutic encounter, though empathic and understanding, avoids cloying, intimate parenting. It should be intellectually and emotionally appropriate to the patient's present age, not regressively patterned to some presumed past age level, however much the patient may want to live at this level. This does not preclude role playing and revival of past traumatic memories through psychodrama, narcosynthesis, or hypnotic regression and revivification, when such techniques are deemed essential to loosen repression. But the basic patient-therapist relationship should be reality, rather than phantasy, oriented.

The therapist's capacity to display warmth and to remain tolerant and yet firm and objective in the face of transference must be coordinated with skill in minimizing the intensity of transference and of working it through toward the objective of self-understanding such that it does not interfere with treatment objectives.

The Need for a Cooperative Human Relationship

Irrespective of how distorted previous relationships with people have been, the individual earnestly desires a wholesome relationship bereft of neurotic encumbrances. The effective management of the myriad demands of the patient will help to fulfill this basic need for a cooperative human relationship.

MULTIPLE ROLES OF THE THERAPIST

What then is a psychotherapist? A doctor who heals. A friend who consoles. An

authority who guides. A teacher who educates. A catalyst who accelerates growth. These and other pursuits constitute the tasks of the creative professional.

Therapists may show different responses to patients with varied personality constellations. For instance, one may be able to express warmth and to remain remarkably objective toward submissive and dependent persons, while being totally unable to express therapeutically constructive feelings when in contact with domineering or hostile patients. Understandably, the more thoroughly therapists have worked through their own personal problems, and the greater awareness they have of their own relationship difficulties, the more flexible each will be in responding to a variety of patients. Therapists who have little awareness of interpersonal difficulties will find therapeutic effectiveness circumscribed to those patients with whom they can feel most comfortable.

In order to express his or her diverse needs, the patient usually strives to force the therapist into multiple impersonations, namely, the following:

1. A helping authority

2. An idealized parental image

3. An actual parental representative

4. A representative of other important past personages

5. A cooperative partner

The Therapist as a Helping Authority

The traditional patient-doctor relationship is that of the therapist as a helping authority. As an expert, the therapist is credited with knowledge and skills that can help the patient out of the patient's dilemma. The therapist succeeds or fails in this role in accordance with the degree of manifest skillfulness and the patient's interpretation of the therapist's maneuvers.

The Therapist as an Idealized Parental Image

The patient seeks an idealized parental figure who will grant bounties without stint. The character of this giving image varies with the personal biases of the patient. It ranges from omniscience and omnipotence to mere kindliness and acceptance. Often there is combined in the fantasy image a fusion of ideal paternal and maternal qualities. Accordingly, the patient may desire paternal firmness, strength, wisdom, and power as well as maternal lovingness, support, and protection. The intensity of such attitudes as well as their specific content, will be determined by the kinds of early frustrations experienced by the patient. These attitudes will be enhanced if the therapist seems to be the sort of individual who fits the patient's designs. It will be minimized by the therapist's refusal or inability to play this role.

The Therapist as an Actual Parental Representative

On the basis of previous experience, the patient may project into the therapeutic situation expectations of being treated by the therapist as the patient had previously been treated by his or her parents. The patient will then adopt defenses against the therapist in accordance with these expectations and fears. Under certain circumstances the patient will even act out with the therapist a rather extensive series of situations representative of those that the patient experienced as a child. Such transference attitudes will be reinforced by a passive attitude on the part of the therapist or by the therapist's actually playing the kind of role with the patient that parallels the role of the parent. Transference will also be expedited by the use of certain techniques, such as the couch position, concentration on dreams, the use of free association, frequent visits, and a focusing on the past history and on conditionings in childhood. It will be minimized by the therapist's increased activity with the patient, the playing of a role opposite to that anticipated by the patient, infrequent visits, the use of the face-to-face position, the avoidance of dreams, fantasies, and free association, and a focusing on the current life situation and present relationships.

The Therapist as a Representative of Other Important Past Personages

The therapist may be employed as an object onto whom transference attitudes may

be projected related to other important individuals besides the parents. The therapist may, for instance, be identified with a sibling, an important relative, a teacher, or a friend who has played a signal part in the early life of the patient. The therapist's manner, behavior, and physical appearance may expedite the display of such attitudes.

The Therapist as a Cooperative Partner

The therapist may be regarded as an individual with whom the patient is able to establish a friendly, unambivalent relationship. The patient probably desperately seeks such a relationship, but, on the basis of previous conditionings, may feel that it cannot possibly come to fruition. An objective attitude on the part of the therapist sponsors this kind of relationship.

A blend of several of the above attitudes toward the therapist is usually present at the beginning of treatment. Conflict is inevitable by virtue of the mutual contradictory nature of such disparate attitudes. Which attitudes will prevail will depend on both their intensity and how they are handled by the therapist. It is important that the therapist be equipped by training and experience to recognize and to deal with the patient's multiple strivings so that a cooperative working relationship may eventually develop.

RESISTANCES TO A WORKING RELATIONSHIP

The length of time required to establish a working relationship will depend upon the skill of the therapist and also on the intensity of resistance exhibited by the patient. Among common resistances are defects in motivation and misconceptions about psychotherapy. Ways of handling such obstacles have been suggested in Chapter 32 "The Initial Interview: Dealing with Inadequate Motivation" and Chapter 34 "Answering Questions Patients Ask About Therapy." Even more important as a source of resistance are character problems that are parcels of the patient's habitually disturbed attitudes toward people.

Perhaps the most obstinate of these characterological, resistances is a clinging,

dependent attitude toward the therapist, who is overvalued as the embodiment of all that is good and strong and noble in the universe. This kind of striving is rooted in an intense feeling of helplessness, escape from which is sought in an alliance with a being who can in some magical way lead the person onto paths of health, glory, and accomplishment. Building this being into a power figure who can satisfy one's magical expectations, and allying oneself with the object of one's creation, provides a spurious sense of security and heightened self-esteem.

The patient must be weaned from the attitude toward the therapist as an omniscient personage who can produce a fanciful Nirvana in which all needs are gratified. It is important to convince the patient of his or her own abilities and strengths.

Although recognizing and accepting a patient's dependency need and refraining from insisting on a completely mature relationship, the therapist may give the patient a rational reason for refusing to take the bulk of responsibility and making godlike decisions for the patient. The therapist, in exhibiting an understanding of the patient's need, may explain that supplying the patient's demands will inhibit the patient's self-growth and that it is out of respect for the patient's growth potentials that the therapist is not more active. Such an explanation may help resolve some of the hostility at what the patient otherwise might consider negligence and rejection.

Another unfavorable form of relationship is fear of the therapist as a potentially destructive or malevolent being who threatens to injure or to engulf the patient by interfering with the patient's autonomy. Here the patient retreats whenever the patient feels the therapist is getting too close. A "testing period" precedes a final acceptance of the therapist as one who bears only good will toward the patient. During this period the patient will be torn between a desire to establish a gratifying relationship and an overpowering fear of injury. The outward manifestation of this struggle may be hostility to the therapist. Some patients may even attempt to provoke and to incite the therapist into acts of aggression to prove to themselves that all human beings are alike and are not to be trusted. This "testing period" will be especially prolonged in patients with immature

personality structures, and it may be many months before the therapist is accepted as a friend.

Because of hostility, fear, and guilt, the patient may automatically expect the therapist to be condemning, prohibiting, or punishing for past behavior as well as for present attitudes and impulses. The patient may, therefore, display fear, distrust, or rage toward the therapist as well as defenses against these emotions. When fragmentary revelations of the patient's inner life fail to bring forth the expected punishment or condemnation, the patient may feel contempt for the therapist for failing to respond as a strong authority should respond and may evidence a desire for a more competent—more punitive—therapist.

The patient will usually anticipate criticism from the therapist as merciless as the patient's self-criticism. Furthermore, while the patient has managed to conceal from people personal elements that he or she considers vicious or contemptible, it is difficult to do this with the therapist. The patient will, therefore, constantly anticipate attack or condemnation and will be nonplussed when attack is not forthcoming. The patient may await the evil day when the expected blow will fall or may even become resentful at the delay of the "inevitable." As the patient recognizes that he or she can speak freely and that the therapist considers such revelations as neither good nor bad, the patient may begin to reevaluate concepts of the therapist as an arbitrary authority. A feeling of warmth emerges that is mingled with confidence.

Other strivings in the patient that interfere with a good working relationship are intense sexual feelings toward the therapist, submissiveness, masochistic impulses, and detachment. The handling of a patient's detachment is of particular importance because of its prevalence as a defensive character pattern. With perseverance and tolerance, detached individuals may eventually be helped to enter a working relationship.

For example, a woman with a personality disorder of detachment comes to treatment because of depression, tension, and feelings of lonesomeness and isolation. She is aware of the fact that close relationships fill her with a sense of foreboding and that

soon after a relationship has started, she becomes anxious and wants to run away. In therapy, as she develops confidence in the therapist, the same kind of anxiety and terror emerges, and the patient is seized with an impulse to stop treatment. Her respect for the therapist, however, and her incentive to get well halt the escape. Manifesting warmth, acceptance, and understanding, the therapist interprets what is happening. From a dream in which she crosses a bridge and becomes the target of sharpshooting snipers, the patient learns of her fears of attack in a confining relationship. She recognizes that this fear has been with her for years—as far back as she can remember—and has created the impulse to escape from entangling alliances and even from the threat of coming close to a person. This knowledge enables her to discriminate her feelings in relationship to the new kind of authority that she has perceived in the therapist, to test her anachronistic fears of hurt against her knowledge that the therapist does not desire to injure her. She then veers in her struggle between her old conviction and her new. Temptation to break away from treatment is compelling, but the therapist forestalls escape by pertinent interpretations. Eventually, perhaps for the first time, the patient is capable of accepting a person, the therapist, as a friend rather than a foe. She takes a bold step toward a working relationship.

In helping a patient master fears of a working relationship, the therapist must allow the patient to set the pace. The therapist must respect the patient's hesitation and other defensive mechanisms issuing from the patient's terror of discovering the same destructive potentialities in the therapist that the patient has found in other human beings. The realization of a different type of authority permits the patient to abandon compromising facades that have up to this time served unsatisfactorily to keep anxiety in check.

BUILDING THE RELATIONSHIP

Skill as a therapist is measured to a considerable degree by the ability to establish relationships with patients that will be therapeutically meaningful to them. While no one is capable of establishing rapport with all people, the therapist should, if equipped with

the proper training and personality, be able to relate to the majority of persons who come for help.

Knowledge of interviewing techniques will foster confidence in the therapist and expedite a working relationship. Thus, by appropriate facial expressions, gestures, and sub vocal utterances, the therapist may convey an attentive and accepting manner. By asking pointed questions, restating, summarizing, and other techniques, one may demonstrate to the patient that one is interested and observant. By reflecting feelings and making cautious interpretations geared to the level of the patient's current capacities for understanding, the therapist may exhibit an astuteness and perceptiveness about knowing what is going on in peripheral areas of the patient's awareness.

Specific personality problems of the therapist may, however, inhibit the establishing of such a relationship. For instance, an inability to tolerate hostility may make it difficult for the therapist to develop rapport with a patient who displays hostile outbursts. Or personal sexual problems may cause the therapist to respond with anxiety when the patient tells of sexual fears or impulses with which the therapist is preoccupied or is avoiding. The therapist may then fail to show the necessary warmth, objectivity, and empathy.

From time to time the therapist may experience emotions toward the patient that, if unchecked, may hurt the relationship. Hostility, boredom, apathy, uneasiness, fear, or sexual interest may be provoked by the patient's behavior or inspired by countertransference. Should such emotions emerge, self-searching will be indicated. The following self-directed questions are important:

1. Is the patient doing anything that causes these emotions?

2. Does the patient resemble or remind the therapist of anyone the therapist knows or has known in the past?

3. What does the therapist really feel about a person like the patient?

4. Does the therapist anticipate that the patient will do anything disturbing or

upsetting while in therapy?

Arriving at answers to these questions requires a great deal of self-exploration in an attempt to understand any projections that are operative. For example, a patient talks about his deep problems of intolerance with people. As the patient relates several episodes illustrating his intolerance, the therapist becomes aware of a personal feeling of boredom and of not wanting to pay attention to what the patient is saying. She asks herself why such attitudes exist toward the patient, and she suddenly realizes that she considers the patient an extremely hostile person. She recognizes then that she fears a demonstration by the patient of hostility toward her. Knowing of her own problem in handling hostility, the therapist realizes that her boredom is a defensive means of avoiding closer contact with the patient and thus of circumventing any expressed hostility. Challenging the reality of her fear, she finds that she is able to overcome the response of boredom, and she becomes attentive to the productions of the patient. Another therapist may, in feeling irritable with a patient, examine this emotion. In so doing he realizes that he has had similar feelings of irritability with a brother with whom he was competitive and whom the patient resembles slightly. This insight results in a dissipation of the emotion of irritability. A third therapist observes that she feels resentful during a session. Thereupon she notices that the patient is talking about material that is stirring up anxiety within her. Under these circumstances, she may be able to handle her anxiety directly and thus overcome her resentment.

Where the therapist is unable to control disturbed emotions and attitudes by processes of self-observation, in fairness to the patient a referral to another therapist should be made.

There are a number of things that the therapist can do to sponsor a working relationship. Among these are communicating to the patient an understanding of the patient's problem and expressing toward the patient tolerance, empathy, and objectivity.

Communicating an Understanding of the Problem

Every patient wants his or her therapist to be intelligent, sagacious, and perceptive. It is generally not difficult to convince the patient of the therapist's competence by such simple techniques as reflecting unverbalized feelings and attitudes, putting into words the unexpressed worries and concerns of the patient, and displaying sensitivity to the patient's moods and conflicts. Although the therapist is fallible, it is essential to try to avoid expressions of confusion, such as acting bewildered and forgetting important items of information about the patient. Since merely mortal, the therapist is bound to make mistakes sometimes, but these are not fatal if they do not occur too frequently, and if there is a fairly good relationship with the patient.

An excellent way of demonstrating an understanding of the patient's turmoil is available to the psychoanalytically trained therapist through dream interpretation. Dreams during the first phase of therapy are never interpreted deeply. Since dreams are condensations of a variety of items, including early traumatic experiences, basic conflicts, habitual mechanisms of defense, and present characterological strivings, it is usually easy to select from the dream the kind of content that will satisfy the goals of a particular phase of therapy. In the first phase of treatment important goals relate to a recognition of attitudes and impulses that act as resistance to a working relationship. For instance, a patient presents a dream in which he is traveling on a subway, sitting next to a man who is busily engaged in reading a newspaper. The patient tries to attract the man's attention, but all of his efforts are rebuffed. He finally gets up and leaves the train feeling humiliated.

In examining the dream, we observe the patient attempting to make contact with a man who, detached and disinterested, virtually rebuffs the patient. The dream may reflect a general fear in the patient of being rebuffed by people. We may speculate further that the patient is expressing in the dream a feeling that he is being rebuffed by the therapist. Riding on the subway would then indicate the therapeutic situation. These formulations are, naturally, not communicated to the patient. The method by which they are brought to his attention is illustrated in the fragment of the actual interview that follows:

> *Th.* What thoughts come to your mind as you think about the dream?

> *Pt.* Why nothing. I don't particularly like riding on the subway, but that's nothing. It's the quickest

way of getting any place.

Th. Mm hmm.

Pt. And when you're in a hurry it gets you there, *(pause)*

Th. Any other thoughts about a subway?

Pt. No.

Th. Now, how about your feelings in the dream: what were your feelings?

Pt. I was anxious to talk with him, make friends, you see, but he was one of these types of people who was busy with his own things.

Th. What type?

Pt. Well, I should say studious type, not interested in me.

Th. Now what about this man; did he resemble anybody you know or knew?

Pt. Yes, he was like an uncle of mine. He is not too much older than I am. When I was a kid, he used to bring me things. I called him my second father.

Th. Mm hmm.

Pt. And when I was in boarding school, one of my roommates reminded me of him. That was the one I had that homosexual experience with I told you about.

Th. Was there any sexual feeling in the dream?

Pt. No, just that I wanted to know this person better.

Th. And when he didn't respond, how did this make you feel?

Pt. Terrible. I wanted to get out of the train.

Th. Angry?

Pt. No, just irritated.

Th. Now it's possible that when a person isn't responsive enough and giving enough, this may make you want to get out of the situation.

Pt. Yes.

Th. And that might also apply to me. [*a tentative probing for transference*]

Pt. Why … (pause) why … I don't think I should feel that way.

Th. After all, there is no reason why you shouldn't. But have you felt this way about me?

Pt. As you said, I shouldn't expect you to do everything for me.

Th. But you may resent the fact that I don't take over more responsibility.

Pt. I know I shouldn't feel that way.

Th. But you *might* feel that way *(pause)*

Pt. (*laughs*) Well I do ... sometimes.

Th. And even want to leave treatment.

Pt. (*laughs*) I did feel that I wanted to quit.

Th. Like you wanted to get out of the subway train in the dream.

Pt. (*laughs*) Yes, you mean you could be the man on the subway? Come to think of it, I do think it's you.

Th. Do you want to stop therapy?

Pt. Of course not.

Th. Do you feel that I don't want to relate to you, that I don't pay attention to you, or like you?

Pt. Well, as you say, I must think that, but it isn't true.

After several weeks the patient exhibited evidences of greater security in the relationship. This was accompanied by a dream in which the patient saw himself trying to use a pencil that had no lead. A man nearby offered him a new pencil, which he accepted. The patient associated having "no lead in the pencil" to his vitiated masculinity. The man nearby was the therapist who was offering him new masculinity.

Communicating Interest

Showing interest in the patient as a person rather than as a laboratory of pathological phenomena is an important way of helping the relationship. By paying close attention to what the patient is saying about his or her personal life, ambitions, likes, dislikes, and goals, the therapist may indicate nonverbally that the patient is considered a worthwhile individual. Remembering and repeating to the patient personal details that

the patient revealed in previous sessions impresses the patient with the genuineness of the therapist's interest. Sometimes the greater part of a session may profitably be spent talking about the patient's work, hobbies, or other random subjects, not for the purpose of eliciting information but to show the therapist's interest. Making necessary financial and time allowances for the patient, and a demonstrated willingness to do what one can for the patient within the bounds of therapeutic propriety, are other manifestations of interest.

Damaging to the relationship are evidences of disinterest, such as forgetfulness about important details that the patient has previously mentioned, reading of one's mail during a session, telephoning in the patient's presence, and other shifts of attention.

The therapist's attitudes toward the patient will, of course, not be the same from day to day. On some occasions, when feeling happy, inspired, and active, one will be responsive, alert, and sensitive to what is going on in therapy. At other times, when feeling slightly depressed, dull, and inactive, one will find one's mind wandering and will be somewhat insensitive to nuances in the therapeutic situation. Sometimes one will be pleased with the patient. Occasionally one may be irritated, particularly when the patient is hostile, aggressive, or accusatory. These ups and downs need not interfere with the setting up of a working relationship, provided that the therapist likes the patient and manages to communicate adequate interest.

Communicating Tolerance and Acceptance

The average patient comes to therapy at the mercy of a medley of moods and attitudes. Helpless in the grip of symptoms that are difficult to control, unable to conceal the resulting turmoil, alternating between arrogance and self-devaluation, the patient may interpret coming to psychotherapy as an insignia of defeat. Yet there is hope that the therapist will somehow magically wipe out existing troubles. Many defenses are mobilized against progress such as minimizing the seriousness of the problems, denying the depth of one's illness, plaintive self-abasing, diffuse expressions of resentment, and masochistic submissiveness.

No matter how mature appearing, the patient will always project into therapy some childish demands, needs, and misinterpretations. In casual relationships the patient may have these under control and may be able to disguise them with various blinds. But the therapeutic relationship will activate suppressed and repressed emotional foci. The patient's usual stratagems will be revealed for what they are. It is for these reasons that consummate permissiveness and understanding must prevail in therapy, with absolute avoidance of indignation and moralistic judgment. If the therapist is able to treat the patient as an adult in spite of the patient's immature feelings, respecting the patient's needs to display childish emotions and strivings and accepting them temporarily as inevitable, the patient will best be helped to a more mature expression of feeling.

In dealing with the ambivalent emotions of the patient, the therapist must express as lenient understanding and acceptance as possible, neither condemning nor condoning the patient for drives and desires but accepting the patient's right to experience them in their current form. Irrespective of how provocative the patient may act, it is essential that the therapist control personal feelings. Some patients will subject the therapist to a barrage of hostility, accusations, and demands. To respond with counterhostility may prove fatal to the establishing of a relationship. Criticizing the patient for the inability to verbalize or to think clearly about himself or herself must also be avoided. The therapist must evade considering the patient's problems as "faults."

Other activities that sponsor convictions in the patient of the therapist's tolerant, non-punitive, nonjudgmental attitudes are attentiveness to everything the patient says, a calm and accepting facial expression, absence of irritability and emotional outbursts, and lack of expressed or implied condemnation or reproach. The continuing or stopping of therapy should be regarded as a choice of the patient, and the patient should be encouraged in the point of view that coming for treatment is predicated solely on his or her getting something positive out of the experience. Should the patient actually decide to discontinue treatment, this must be handled by the therapist as a manifestation of resistance.

Respect for the patient's defenses and resistances is another way of expressing tolerance. There may be the temptation to charge the patient's resistance to displays of ignorance or stubbornness. But if the therapist realizes that the patient is guarding against a flood of anxiety, it may be possible to display greater forbearance. The therapist must be content at the start of therapy to move at as slow or as rapid a pace as the patient's reactions dictate. There are times, nevertheless, when outrageous and destructive behavior go beyond one's capacities for complacency. Here discriminative confrontation, non-condemning challenges, and interpretation will be necessary.

Communicating Objectivity

Objectivity is insured by a non-punitive manner in the face of any attitudes, demands, or ideas expressed by the patient. A sense of humor, the ability to take criticism, and an unflagging respect for the patient are other traits that help establish the therapist's objectivity. In handling personal feelings, the therapist should keep in mind the fact that the attitudes of the patient are not necessarily permanent ones.

Acknowledging the patient's right to opinions, even though they may be faulty, helps to convince the patient that he or she is not dealing with a despot. Other ways of demonstrating one's objectivity are by abstaining from imposing on the patient one's personal opinions, philosophies, judgments, and values and by observing the patient's right to self-determination, once the patient has become cognizant of internal motives. At all costs the therapist should avoid situations that make the patient feel that the patient must yield to the bias of a superior authority. This does not mean that the therapist condones or encourages neurotic tendencies; the therapist merely tolerates them temporarily, as long as they do not interfere with the treatment process. Should they obstruct therapy, the therapist deals with them actively as manifestations of resistance.

Communicating Empathy

All people have the craving to be liked. Neurotic problems make them feel unloved and incapable of evoking sympathetic responses from others. Yet they long to be

appreciated in spite of their convictions of having no worth. By communicating empathy, the therapist attempts to convey to the patient a feeling that the patient's turmoil is understood. But communicating empathy presupposes that one *feels* empathic. There are no general rules about how to turn on such feelings. When interviewing a patient for the first time one may ask: (1) What is there about this person that I dislike—facial expression, manner of speaking (complaining, attacking, obsequiousness, pleading), content of communications, bodily movements, eyes, gait, aggressiveness? (2) What is there about this person that attracts me—physical appearance, manner, seductiveness?

Analyzing those reactions, one speculates how these may impair one's judgment, objectivity, and neutrality. The therapist may ask: "How would I feel if I had gone through what the patient has experienced, and if I were in the patient's situation now?"

Among the measures that may be employed toward this end are verbalizing for the patient how upset the patient must feel; elaborating on some of the obvious conscious conflicts that plague the patient, explaining why these may be disturbing; recognizing the patient's feelings and seeing things from the patient's point of view; being frank and sincere with the patient and accepting him or her in spite of any "bad" qualities that present; and expressing warmth, not in words, but by gestures, facial expressions, and other types of nonverbal behavior. Nothing is more damaging to the relationship than displaying a stilted, detached, and cold attitude toward the patient. Sometimes such an attitude is practiced by certain therapists in an effort to maintain anonymity. Usually this kind of behavior is interpreted by the patient as evidence of the therapist's unfeelingness.

The therapist must be able to extend support and reassurance to the patient when these are needed. Such measures are, of course, graded to the degree of shattering of the patient's adaptive powers and are not to be confused with domination or overprotection. A strong deterrent to the giving of necessary support is a fear in the therapist of making the patient dependent on the therapist. At the inception of therapy all patients are dependent to a greater or lesser degree, irrespective of the activity of the therapist. The dependency is not avoided by a detached attitude, nor does it necessarily become

hypertrophied by a display of interest or warmth.

Empathy must also be demonstrated when the patient manifests hostility. One way of handling undifferentiated hostile feelings is by accepting them as inevitable. A casual explanation such as the following may be very reassuring to the patient: "People who suffer a great deal may become resentful toward the world and toward themselves. You may be angry at the fact that you are suffering, or that you need help, or that you have to come to see me. You may be angry at me for various reasons. And this is to be expected." Further responses will be determined by the reactions of the patient to this explanation.

Once empathy is communicated, the patient may experience considerable relief or there may be an abatement of symptoms. This may be due to a certain measure of psychological appeasement or to a feeling in the patient that he or she no longer is alone and helpless. It may be due to a concomitant emotional unburdening or because of the reassurance gained through contact with the therapist. This improvement, sometimes called a "transference cure," is usually temporary, lasting as long as the relationship with the therapist yields important satisfactions. The improvement may continue indefinitely if coincidentally there is an amelioration of the stress-producing circumstance or if the patient has been able to master the stress situation in some way. This may be the sole goal in supportive therapy. In reeducative and reconstructive therapies, however, any relief achieved by this means is considered inadequate unless it is accompanied by more substantial behavioral changes.

Not all patients respond eagerly to a caring attitude evinced by the therapist. There are some, admittedly few, who prefer to work with a distant and impersonal therapist. But here we usually find that this need for a detached therapist is probably a defense against involvement, dependency, and being controlled, the analysis and working through of which may be highly productive. Being caring and empathic, however, does not justify overly supportive and smothering behavior.

It must be remembered that years of bitterness in the patient's human relationships may have eroded the patient's confidence in people in general. The therapist should,

therefore, not be disappointed if the patient does not immediately become a confidant. It is necessary to prove to the patient by demonstrating through actions that the therapist is worthy of acceptance and trust. This may take time, particularly with the sicker patients and those who have severe problems with authority. Whether the therapist is capable of demonstrating empathy toward all patients is another matter. There is no valve that one can turn on to permit the flow of this feeling. The best one may be able to do if there is little interest in the case is to examine one's feelings.

SUNDRY RULES' FOR BUILDING OF THE RELATIONSHIP

It is not necessary to employ special tricks to establish a good working relationship. This will be readily forthcoming if the therapist has the proper training and personality. There are a number of rules that may help build a relationship more rapidly, however. These are illustrated in the following group of "unsuitable" and "suitable" responses to sundry questions asked by patients.

1. *Avoid exclamations of surprise.*

>*Pt.* I never go out on a date without wanting to scream.

Unsuitable responses

>*Th.* Well, for heaven's sake!

>*Th.* That's awful!

>*Th.* Of all things to happen!

Suitable responses

>*Th. I wonder why?*

>*Th.* Scream?

>*Th.* There must be a reason for this.

2. *Avoid expressions of overconcern.*

Pt. I often feel as if I'm going to die.

Unsuitable responses

Th. Well, we'll have to do something about that right away.

Th. Why, you poor thing!

Th. Goodness, that's a horrible thing to go through.

Suitable responses

Th. That must be upsetting to you.

Th. Do you have any idea why?

Th. What brings on this feeling most commonly?

3. *Avoid moralistic judgments.*

Pt. I get an uncontrollable impulse to steal.

Unsuitable responses

Th. This can get you into a lot of trouble.

Th. You're going to have to put a stop to that.

Th. That's bad.

Suitable responses

Th. Do you have any idea of what's behind this impulse?

Th. How far back does this impulse go?

Th. How does that make you feel?

4. *Avoid being punitive under all circumstances.*

Pt. I don't think you are helping me at all.

Unsuitable responses

Th. Maybe we ought to stop therapy.

Th. That's because you aren't cooperating.

Th. If you don't do better, I'll have to stop seeing you.

Suitable responses

Th. Let's talk about that; what do you think is happening?

Th. Perhaps you feel I can't help you.

Th. Is there anything I am doing or fail to do that upsets you?

5. *Avoid criticizing the patient.*

Pt. I just refuse to bathe and get my hair fixed.

Unsuitable responses

Th. Are you aware of how unkempt you look?

Th. You just don't give a darn about yourself, do you?

Th. That's like cutting off your nose to spite your face.

Suitable responses

Th. There must be a reason why.

Th. Do you have any ideas about that?

Th. How does that make you feel?

6. *Avoid making false promises.*

Pt. Do you think I'll ever be normal?

Unsuitable responses

Th. Oh, sure, there's no question about that.

Th. In a short while, you're going to see a difference.

Th. I have great hopes for you.

Suitable responses

Th. A good deal will depend on how well we work together.

Th. You seem to have some doubts about that.

Th. Let's talk about what you mean by normal.

7. *Avoid personal references or boasting.*

Pt. My six-year-old child is balking at going to school. It annoys me.

Unsuitable responses

Th. I know exactly how you feel; I went through that myself with my youngster.

Th. I'd feel exactly the way you do under the circumstances.

Th. I'm glad you bring that up because I'm kind of an expert on managing problems of this kind.

Suitable responses

Th. Annoys you?

Th. Do you have any idea why your child is balking?

Th. It must be upsetting to you.

8. *Avoid threatening the patient.*

Pt. I don't think I can keep our next two appointments because I want to go to a concert on these days.

Unsuitable responses

Th. You don't seem to take your therapy seriously.

Th. If you think more of concerts than coming here, you might as well not come at all.

Th. Maybe you'd better start treatments with another therapist.

Suitable responses

Th. I wonder why the concerts seem more important than coming here.

Th. Maybe it's more pleasurable going to the concerts than coming here.

Th. What do you feel about coming here for therapy?

9. *Avoid burdening the patient with your own difficulties.*

Pt. You look very tired today.

Unsuitable responses

Th. Yes, I've been having plenty of trouble with sickness in my family.

Th. This sinus of mine is killing me.

Th. I just haven't been able to sleep lately.

Suitable responses

Th. I wouldn't be surprised, since I had to stay up late last night. But that shouldn't interfere with our session.

Th. I've had a touch of sinus, but it's not serious and shouldn't interfere with our session.

Th. That comes from keeping late hours with meetings and things. But that shouldn't interfere with our session.

10. *Avoid displays of impatience.*

Pt. I feel helpless and think I ought to end it all.

Unsuitable responses

Th. You better "snap out of it" soon.

Th. Well, that's a nice attitude, I must say.

Th. Maybe we had better end treatment right now.

Suitable responses

Th. I wonder what is behind this feeling.

Th. Perhaps there's another solution for your problems.

Th. You sound as if you think you're at the end of your rope.

11. *Avoid political or religious discussions.*

> *Pt.* Are you going to vote Republican or Democratic?

Unsuitable responses

> *Th.* Republican, of course; the country needs good government.

> *Th.* I'm a Democrat and would naturally vote Democratic.

Suitable responses

> *Th.* Which party do you think I will vote for?

> *Th.* Have you been wondering about me?

> *Th.* I wonder what you'd feel if I told you I was either Republican or Democrat. Would either make a difference to you?

> *Th.* I vote for whomever I think is the best person, irrespective of party, but why do you ask?

12. *Avoid arguing with the patient.*

> *Pt.* I refuse to budge an inch as far as my husband is concerned.

Unsuitable responses

> *Th.* It's unreasonable for you to act this way.

> *Th.* Don't you think you are acting selfishly?

> *Th.* How can you expect your husband to do anything for you if you don't do anything for him?

Suitable responses

> *Th.* You feel that there is no purpose in doing anything for him?

> *Th.* Perhaps you're afraid to give in to him?

> *Th.* How do you actually feel about your husband right now?

13. *Avoid ridiculing the patient.*

> *Pt.* There isn't much I can't do once I set my mind on it.

Unsuitable responses

> *Th.* You think a lot of yourself, don't you?

> *Th.* Maybe you exaggerate your abilities.

> *Th.* It sounds like you're boasting.

Suitable responses

> *Th.* That puts kind of a strain on you.

> *Th.* Have you set your mind on overcoming this emotional problem?

> *Th.* You feel pretty confident once your mind is made up.

14. *Avoid belittling the patient.*

> *Pt.* I am considered very intelligent.

Unsuitable responses

> *Th.* An opinion with which you undoubtedly concur.

> *Th.* The troubles you've gotten into don't sound intelligent to me.

> *Th.* Even a moron sometimes thinks he's intelligent.

Suitable responses

> *Th.* How do *you* feel about that?

> *Th.* That's all the more reason for working hard at your therapy.

> *Th.* That sounds as if *you* aren't sure of your intelligence.

15. *Avoid blaming the patient for his or her failures.*

> *Pt.* I again forgot to bring my doctor's report with me.

Unsuitable responses

> *Th.* Don't you think that's irresponsible?

Th. There you go again.

Th. When I tell you the report is important, I mean it.

Suitable responses

Th. I wonder why?

Th. Do you know why?

Th. Perhaps you don't want to bring it.

16. *Avoid rejecting the patient.*

Pt. I want you to like me better than any of your other patients.

Unsuitable responses

Th. Why should I?

Th. I don't play favorites.

Th. I simply don't like a person like you.

Suitable responses

Th. I wonder why you'd like to be preferred by me.

Th. Perhaps you'd feel more secure if I told you I liked you best.

Th. What *do* you think I feel about you?

17. *Avoid displays of intolerance.*

Pt. My wife got into another auto accident last week.

Unsuitable responses

Th. Those women drivers.

Th. Women are sometimes tough to live with.

Th. The female of the species is the more deadly of the two.

Suitable responses

> *Th.* How does that make you feel?

> *Th.* What do you think goes on?

> *Th.* How did you react when you got this news?

18. *Avoid dogmatic utterances.*

> *Pt.* I feel cold and detached in the presence of women.

Unsuitable responses

> *Th.* That's because you're afraid of women.

> *Th.* You must want to detach yourself.

> *Th.* You want to destroy women and have to protect yourself.

Suitable responses

> *Th.* That's interesting; why do you think you feel this way?

> *Th.* How far back does this go?

> *Th.* What feelings do you have when you are with women?

19. *Avoid premature deep interpretations.*

> *Pt.* I've told you what bothers me. Now what do you think is behind it all?

Unsuitable responses

> *Th.* Well, you seem to be a dependent person and want to collapse on a parent figure.

> *Th.* You've got an inferiority complex.

> *Th.* You never resolved your Oedipus complex.

Suitable responses

> *Th.* It will be necessary to find out more about the problem before I can offer a valid opinion of it.

Th. We'll continue to discuss your attitudes, ideas, and particularly your feelings, and before long we should discover what is behind your trouble.

Th. That's for us to work on together. If I gave you the answers, it wouldn't be of help to you.

20. *Avoid a dogmatic analysis of dreams.*

Pt. I had a dream the other day. I was sitting in the kitchen and food was being spilled on the floor by someone. When I tried to pick it up, someone kicked me in the face, and then I saw a man standing with a knife ready to stab me in the back.

Unsuitable responses

Th. This dream indicates fear of a homosexual attack.

Th. You must feel orally deprived.

Th. Your mother must have been a depriving woman.

Suitable responses

Th. What does this dream seem to indicate to you?

Th. What associations come to your mind?

Th. How did the dream make you feel?

21. *Avoid the probing of traumatic material when there is too great resistance.*

Pt. I just don't want to talk about sex.

Unsuitable responses

Th. You'll get nowhere by avoiding this.

Th. You must force yourself to talk about unpleasant things.

Th. What *about* your sex life?

Suitable responses

Th. It must be hard for you to talk about sex.

Th. All right, you can talk about anything else that you feel is important.

Th. Sex is always a painful subject to talk about.

22. *Avoid flattering and praising the patient.*

Pt. Do you like this dress?

Unsuitable responses

Th. You always show excellent taste in clothes.

Th. I think you make a very excellent appearance.

Th. Any man would find you attractive.

Suitable responses

Th. Yes, but why do you ask?

Th. Do *you* like it?

Th. Perhaps you wonder what I think of you?

23. *Avoid unnecessary reassurance.*

Pt. I think I'm the most terrible, ugly, weak, most contemptible person in the world.

Unsuitable responses

Th. That's silly. I think you're very good looking and a wonderful person in many ways.

Th. Take it from me, you are not.

Th. You are one of the nicest people I know.

Suitable responses

Th. Why do you think you feel that way?

Th. How does it make you feel to think that of yourself?

Th. Do others think the same way about you?

24. *Extend reassurance where really necessary.*

Pt. I feel I am going insane.

Unsuitable responses

Th. Maybe you are.

Th. Sometimes this happens even with treatment.

Th. If you do go insane, you still can be treated.

Suitable responses

Th. I find no evidence of insanity in you.

Th. The feeling of going insane is one of the most common symptoms in neurosis. Fortunately, it rarely happens.

Th. I wonder if you aren't really worried about what may happen to you in other ways too.

25. *Express openmindedness, even toward irrational attitudes.*

Pt. I think that all men are jerks.

Unsuitable responses

Th. That's a prejudiced attitude to hold.

Th. You ought to be more tolerant.

Th. With such attitudes, you'll get nowhere.

Suitable responses

Th. What makes you feel that way?

Th. Your experiences with men must have been disagreeable for you to have this feeling.

Th. Understandably you might feel this way right now, but there may be other ways of looking at the situation that may reveal themselves later on.

26. *Respect the right of the patient to express different values and preferences from yours.*

Pt. I don't like the pictures on your walls.

Unsuitable responses

> *Th.* Well, that's just too bad.

> *Th.* They are considered excellent pictures by those who know.

> *Th.* Maybe your taste will improve as we go on in therapy.

Suitable responses

> *Th.* Why?

> *Th.* What type of pictures do you like?

> *Th.* What do you think of me for having such pictures.

27. *Clarify the purpose of the interview as often as necessary.*

> *Pt.* But what am I supposed to do to get well?

Unsuitable responses

> *Th.* Well, you just let me take care of that.

> *Th.* Once you get confidence in me, you'll start getting well.

> *Th.* The more cooperative you are, the quicker you will get well.

Suitable responses

> *Th.* We will talk over your problems and your ideas about them. Things will then gradually clarify themselves, and you will get a better idea of what to do about your problems.

> *Th.* In discussing your reactions, your ideas, and your feelings, you will be better able to understand what is happening to you, and the understanding will permit you to take definite steps to correct your difficulty.

> *Th.* It may puzzle you as to how talking things over helps, but that is the way to understand yourself and your problems. When all the facts are known to you, the solution to your troubles will become clearer.

28. *Make sympathetic remarks where indicated.*

> *Pt.* My husband keeps drinking and then gets violently abusive in front of the children.

Unsuitable responses

> *Th.* Why do you continue living with him?

> *Th.* Maybe you do your share in driving him to drink.

> *Th.* He's a no-good scoundrel.

Suitable responses

> *Th.* This must be very upsetting to you.

> *Th.* It must be very difficult to live with him under these circumstances.

> *Th.* You must find it hard to go on with this kind of threat over you.

SIGNS OF A WORKING RELATIONSHIP

Evidence of a working relationship are, on the part of the therapist, liking the patient, making emotional contact with the patient, eliciting good response from the patient, feeling able to help the patient irrespective of the syndrome or the severity of the condition. On the part of the patient there are verbal and nonverbal evidences of liking, feeling relaxed with, and being confident in the therapist.

The length of time it requires to establish a relationship will vary. With some patients a working relationship can be established in the first session. With many patients a dozen sessions may be needed. Occasionally, with patients who are fearful, detached, hostile, or unmotivated or with therapists who have problems in relating to patients, one or more years may be required before a relationship develops. When severe transference and countertransference reactions interfere with the setting up of a working relationship, they will have to be dealt with before any progress can be made.

The following is from a session illustrating the beginning of a working relationship. It is an excerpt from the sixth session with a divorced woman of 32, who came to therapy because of anxiety, tension, and feelings of detachment from people. The first four sessions were spent discussing her problem generally. During the fifth session she

introduced with some anxiety the idea that she believed her problem to be due to suspected sexual experiences in her childhood, when she might have been seduced by her father, her mother, and perhaps her sister. She has no recollection of such experiences, but this was, in her opinion, due to amnesia, since her dreams were often about sex with members of her family. Although I was tempted to underplay the possibility of such a situation, I listened attentively to her theories and remarked that a situation about which she felt so strongly must be taken seriously. The attitude I evinced was one of neither endorsement nor rejection of her theory, but one of acceptance of her right to entertain the ideas that she had, which we were obliged to explore. This attitude seemed to precipitate the working relationship since it apparently meant that I was tolerant and accepting.

> *Pt.* I don't know exactly where to begin because I don't feel as desperate as I did the last few times.

> *Th.* Mm hmm.

> *Pt.* I certainly have a feeling. I'm grateful for the last, the last session because you went out of the way, as far as I was concerned. I'm glad you had me speak it out, because if I hadn't done it, I probably wouldn't have mentioned it again, because it was fresh then and it did mean a lot to me.

> *Th.* In what way?

> *Pt.* That you understand what I'm thinking about and how I feel about things, and so on.

> *Th.* I see.

> *Pt.* And you took me seriously. Whether you believed it or not is beside the point, but you did take me seriously, which is very important to me.

> *Th.* Mm hmm.

> *Pt.* And I felt relieved that you understood me. It's so hard to find anybody who really understands. I realized that the fact that you took me seriously was important to me. If you take *me* seriously then I can take *you* seriously. Not that I didn't think that before, but it gave me a certain base. Then I went further and realized something I had, of course, known before, and that is if a person has faith in me, or believes in me, not me, but in me, that's the biggest compliment they can give me. And then I will do anything for them. It must be I want to have that feeling toward you.

> *Th.* Mm hmm.

> *Pt.* And then I can in turn respond. But I can't give it first. I mean I have to see that my basis for

exposing myself emotionally, so to speak, is respected.

Th. Yes.

Pt. So that's how it is. *(pause)*

Th. Apparently you had a suspicion when you came here that I might not understand how you feel, that I might not understand you.

Pt. Yes, I was aware of that, and the reason I felt anxious about it was that I just didn't know if you would reject me. And another thing, when you keep emphasizing that I should tell you about anything I feel about you, whether you do anything in any way to annoy me, I felt, it occurred to me, that maybe you meant that you wondered how I felt about you being Jewish. I don't know if you are or not, but you know it would be a sensible thing to think about. But I wouldn't think two minutes about it. Each time I come it is a good experience. I thought maybe you were referring to whether I had any feelings for, or against, or about Jewish people. *(laughs).*

Th. Do you?

Pt. Why no, of course not.

Th. Actually I didn't have that in mind, but it's important to express whatever thoughts you may have about our relationship.

Pt. That's interesting. I'm very glad.

Th. It is possible that you might have certain prejudices about Jewish people, which are, as you know, common; or, it may be, as you say, that you do not have prejudices.

Pt. Oh, those feelings are nonexistent in me.

Th. Do you have other feelings about me?

Pt. My feelings about you are very good. I have come in contact with other people. I am opinionated. But nothing could have set us on firmer ground than by my walking in here, and you took me as I was. You didn't question, you didn't probe about all sorts of things. I mean my seriousness about it; many things that you could have in the best of faith, but you didn't. That could not have made me feel better. I walked in as a stranger, and you accepted me. I know you are important in your profession, and you have to be selective in a certain sense. I didn't come here with any recommendations. I didn't write you a letter; I just picked up the phone, feeling I've got to do something, and I got an appointment. I walked in and felt very relaxed and very easy. I know that I can feel that way, and I know that I'm not unselective myself. There were things, many things that were bothering me, but you let me choose my words and didn't interfere.

Th. Your feeling is a good one and will help us work more readily with your problem.

Pt. I feel that if a person has faith and respect for me and I can give it back, that I will really be able to get help. I have a full acceptance of you. There are things within me, but they don't

concern you. You, yourself, don't cause me anxiety.

Th. Well, if I ever do, I'd like to have you tell me so that we can try to iron out our relationship.

Pt. It's very necessary to keep myself straight in all relationships, and I'm sure it would be doubly necessary with you. I feel I can do it with you although maybe things may happen later on in our relationship. [*It is possible that the patient is anticipating transference, which actually developed quite strongly as we began exploring her problem in the second phase of therapy.*]

Th. What do you think may happen?

Pt. I don't know, *(pause)*

Th. Something I may say or do?

Pt. I have no idea except that anything I would tend to take exception to would be something you would say. *(pause)*

Th. Mm hmm. *(pause)* About you?

Pt. No not necessarily. You seem to be very sensitive, and you seem to have omitted all the little difficulties that could arise from a person being somewhat insensitive and not being aware of the condition the patient is in, being pretty much on the defensive. You never violated anything like that. And what I like about it is that you act natural, as if you're not putting on an act to get along.

Th. All right, now that we seem to have a good understanding, we can talk about what we will do in approaching and understanding this problem of yours. *[The therapeutic situation is structured for the patient at this point.]*

36
Structuring the Therapeutic Situation

During the first phase of therapy the patient becomes aware of the routines, requirements, and responsibilities of psychotherapy. The patient relinquishes the idea that things will be done for and to him or her and accepts the patient's role as active participant in the therapeutic process.

Some patients assume the obligations of the therapeutic situation with scarcely any direction from the therapist. Other patients balk every inch of the way, resisting the conditions with a doggedness that seems borne of perversity. Research data exist which that certain procedures as facilitative of a therapeutic alliance (Goldstein, 1980, Goldstein & Wolpe 1971). First, preparatory structuring for the patient by the initial screener of what to expect from the assigned therapist and from therapy itself, couched in enthusiastic constructive terms, has a beneficial influence on the patient. If the initial interviewer will not continue with the case, but will make an assignment of a therapist after the patient describes the kind of therapist desired, assurance that the therapist to whom one will be assigned actually possesses the desired qualities appears to promote expectant trust. The screener, in further describing the assigned therapist, makes the patient additionally receptive by indicating the latter's expertise, warmth, and capacities to help. When the therapist comes from the same background as the patient, a statement to that effect has also been shown to facilitate the forthcoming relationship. Finally, role-expectancy structuring can be useful in terms of what the patient and therapist will do and what the patient may expect from therapy. This helps eliminate surprise, confusion, and negative feelings.

A recommended article is that by Orne and Wender (1968), which details the words to use in a structuring interview. In my 1980 (pp. 41-42) book there are also precise ways of structuring the therapeutic situation. Sometimes a cassette tape is given to the patient that contains clarifying instructions of how the patient and the therapist are to behave

with each other. Research studies show that modeling or observational learning can add to the attraction potential the patient has for the therapist. Here an audio-or videotape that is played containing an actual or simulated session that brings out the therapist's sympathetic and caring qualities in relation to a patient seems to have an impressive effect on some patients. According to some studies, the higher the expertise and status of the therapist in the mind of the patient the greater the patient's confidence in what the therapist is doing; the stronger the activity level and degree of demonstrable conviction, the more manifest the empathy with the patient's feelings, the more attracted the patient will be to the therapist and hence the more likely a therapeutic alliance will develop.

As long as the patient is observing the "rules" of therapy, there is no need to emphasize any aspect of procedure. When, however, the patient seems confused or shows resistance, clarification will be necessary. Among areas that may require structuring are the manner of communication, the general routines of therapy, the responsibilities of the patient, the role of the therapist, and a description of the psychotherapeutic process.

EXPLAINING THE MANNER OF COMMUNICATION

The Focused Interview

The kind of communication that is used in psychotherapy is generally that of the focused interview, which has been described in Chapter 19, "The Conduct of the Psychotherapeutic Interview." It is usually unnecessary to instruct the patient on what to say and how to say it since the therapist will, by skillful focusing and by the use of other techniques that have been described, manage any problems in this area that develop. If the patient does specifically ask what topic to bring up, the therapist can say to report on any present thoughts and ideas including those that are fleeting, seemingly insignificant, or repulsive, or might ordinarily be suppressed. Also, the patient may be told that it is important to mention any tensions or physical symptoms that occur during the session as well as anxieties, fears, or feelings of resentment. The patient may be enjoined to observe the relationship between symptoms and environmental happenings. The patient may also

be asked to indicate if he or she has ever had thoughts, feelings, and anxieties similar to those being experienced at present, and, if so, under what circumstances these occurred.

The following are excerpts from sessions with patients who required instruction in the manner of communication:

Example 1:

    Pt. I don't know what I should say.

    Th. It is important to talk about anything that is immediately pressing on your mind no matter what it might be. This refers to your feelings and your ideas. If there is an immediate problem you are facing at your job, with your family, or in any other area, talk about that. The best rule to follow is to talk about things that are bothering you most.

Example 2:

    Pt. Is there anything special you want me to talk about?

    Th. I want you to tell me what is mostly on your mind. You may have to face yourself to tell me things that are painful or shameful. Talking about these things may be hard, but it will be most helpful to you.

    Pt. But how do I do this?

    Th. Try to "think out loud" and not hold anything back. In the process of "thinking out loud," you may want to express what you have been thinking or feeling about me.

Example 3:

    Pt. What should I talk about?

    Th. Anything that is on your mind is important.

    Pt. Like what?

    Th. Well, any factual observations that you make as well as irrational ideas or feelings that come to you. For instance, you may go out with your girl and then get furious with her or indifferent to her, for little apparent reason. Mention these things to me. If you are emotionally bothered by anything at all, talk about it. If you have fantasies or daydreams or dreams at night, these are very important. If there is anything good or bad that you feel about your treatments here, or good or bad thoughts about me, bring these up too.

Example 4:

Pt. I just don't know what's causing these feelings. I get so frightened and upset, and I don't know why.

Th. That's why you are coming here, to find out the reasons, so you can do something about your trouble.

Pt. But why is it that I can't sleep and concentrate?

Th. That's what we'll begin to explore.

Pt. But why?

Th. What comes to your mind? What do you think?

Pt. I don't know.

Th. You know, there are reasons for troubles like yours, and one must patiently explore them. It may take a little time. I know you'd like to get rid of this trouble right away, but the only way one can do this is by careful exploring.

Pt. Yes.

Th. And to take your anxiety feelings, for example, you may not be aware of the reasons for them now, but as we talk about you, your ideas, your troubles, and your feelings, you should be able to find out what they are.

Pt. How do I do this?

Th. When I ask you to talk about your feelings and thrash things around in your mind, you won't be able to put your finger on what bothers you immediately, but at least you will have started thinking about the sources of the problem. Right now, the only thing you're concerned with is escaping from the emotion. That's why you're just going around in a circle. While you're operating to seal off anxiety, you're doing nothing about finding out what's producing this anxiety.

Pt. It sounds sort of clear when you say it. (*laughs*)

Th. Well, do you think you understand what I mean?

Pt. What you're explaining now?

Th. Yes.

Pt. Yes. *(pause)* The point is that I keep thinking about myself too much. It's that I feel inferior to everyone. I must win at rummy. When I play golf, I practically beat myself red if I don't get the low score. And this is silly.

Th. What happens when someone beats you at golf?

Pt. I get upset and these feelings come.

Th. Now there seems to be some kind of connection here; let's talk some more about that.

Free Association

Except in Freudian psychoanalysis, free association will rarely be employed. When the therapist uses it as a means of communication, the patient may be given the following explanation:

> The kind of communication that we will use here is different from the ordinary back-and-forth talk. It is called "free association." To do free association, you just talk about whatever comes to your mind without censoring anything. Try not to hold things back, including any ideas, feelings, or impulses, no matter how insignificant or ridiculous they may seem. If you think that something is too trivial to report, it may be doubly important to mention it. If you notice any tension in your muscles or if you experience fear, happiness, excitement, or resentment, tell me about these. In other words, I'd like to explore with you thoughts and feelings that are sort of on the periphery of awareness. In this way we will be able to understand some of the problems and conflicts that are hard to get at by ordinary conversations.

In using free association, it will be necessary to give the patient a reason why the therapist does not respond constantly to the patient's productions with comments and explanations. The following exemplifies how this may be done:

> Another important thing for you to know is that I will not interfere with your flow of ideas by interrupting with comments. This may puzzle you, but if I don't keep up a conversation with you and enter into back-and-forth talk, there's a good reason for it. I will, of course, occasionally bring important things to your attention. But don't be upset if I fail to respond to everything you say.

Dreams

When the therapist uses dreams, it will be necessary to request that the patient recount dreams. The patient may be told:

> I should like to have you try to remember your dreams and tell me about them in as full detail as possible.

In the event that the dreams cannot be remembered, the patient may be asked to keep a pad of paper and a pencil next to the bed and to jot down any dreams the first thing

in the morning before they are forgotten. Often this safeguard helps the patient to remember dreams that otherwise would be forgotten.

Should the patient ask why dreams are important, the following might be the reply:

> Dreams are important because the mind asleep thinks thoughts in dreams that tell a story about inner problems and conflicts. Sometimes dreams tell us a clearer story than can be told in ordinary conversations. It's hard to understand this, but the best way you can find out how dreams work is to bring them in so we can talk about them.

It is generally not wise to encourage the patient to write dreams down in detail unless there is a tendency to forget them. Some patients get so immersed in detailed dreaming, which they record painstakingly, that the entire session may be spent on dream material to the neglect of other aspects of the psychic life. This activity may be a subtle form of resistance by the patient to avoid talking about anxiety-provoking reality situations.

EXPLAINING GENERAL ROUTINES IN THERAPY

Explaining the Time Limits of the Interview

A brief explanation may be given the patient regarding the duration of a treatment session, the fact that sessions begin and end promptly at the appointed time, and the need to keep appointments regularly. If the patient challenges these limits or defies them, the resistance must be handled.

Informing the Patient of Expected Delays in Getting Well

Early in treatment the therapist may discuss the expected ups and downs in treatment and the possibility of temporary relapses. The patient may also be told that alleviation of symptoms may not come immediately and that there might even be a slight setback before improvement occurs. This helps to forestall untoward reactions to delays in achieving relief, and to mollify the inevitable suffering associated with the giving up of neurotic patterns.

Discussing the Confidential Nature of Communications

It is usually advisable to explain to the patient that any information revealed to the therapist is completely confidential and will, under no circumstances, be divulged. This allays the patient's fear that the therapist will discuss the patient with others. The same reassurance may be given the patient about the patient's case record, pointing out that it will not be released, even to the patient's personal physician, without his or her permission.

Explaining the Use of the Couch When It Is to Be Employed

There are advantages and disadvantages to the recumbent position in psychotherapy. Lying on the couch out of visual range of the therapist enables the patient to delve into personal aspects without restraining the thought processes. Reality is tempered for the time being, and the patient is less apt to respond to what he or she believes the therapist demands or to modify thought content in accordance with the facial responses and nonverbal gestures of the therapist. However, the couch position is not indicated in most forms of psychotherapy because of the very fact that it removes the patient from reality. Lying on a couch may furthermore mobilize anxiety in some patients. It may foster silence or a senseless rambling of fantasy material. Face-to-face interviewing, thus, is generally preferred, and, since this is the natural conversational position, it will not have to be explained to the patient. In reconstructive therapy, however, when free association is to be employed, the couch position may be desired. Here the patient may be told:

> Now in talking about yourself, it is helpful to use the couch. The reason for this is that when you face me you are apt to be distracted by what I say and do, and by my facial expressions. This restricts you and makes it hard for you to concentrate on deeper feelings. We can make faster progress by your reclining while you talk.

Planning for Vacations

It is necessary to inform patients well in advance regarding any vacations or extended absences the therapist plans to take. This enables patients to handle their

emotions in advance and minimizes their feeling of being deserted when the time comes for vacation. "Springing" a vacation or recess on a patient without prior notice is apt to precipitate anxiety and to stimulate conceptions of the therapist as a rejecting or irresponsible person. Most therapists urge their patients to plan for their own vacations at a time that coincides with the therapist's absence.

Smoking during the Interview

The presence of ash trays generally invites the patient to smoke, should the patient desire. Sometimes the patient asks permission when it is noticed that the therapist does not smoke. To forbid the patient to smoke imposes what to the patient may look like authoritarian pressure. Should the therapist be sensitive or allergic to smoking, a good ventilation system will be helpful. If the therapist is unable to tolerate smoke or is dead set against smoking, the reasons should be explained to the patient and the patient asked how he or she would feel about not smoking. If the matter is tactfully presented, the patient may willingly forego the indulgence during the treatment session.

The Taking of Notes

Some patients object to the taking of notes. If the therapist explains the purpose of note taking and confines it to recording only important data such as dreams, the patient will generally adjust to this practice. If the patient continues to object, even after such feelings have been discussed and the reasons for the objections explored, the therapist should confine entries in the case record to the period following the session.

Accounting for the Long Time It Takes to Get Well

If the patient is insistent on knowing how long it will take to get well and if, as in some cases, long-term therapy is necessary, an explanation is helpful, such as the one given to the patient in the following excerpt:

> *Th.* Now your problem seems to have originated way back in your life, as far back as childhood. It will, therefore, require a little time to correct.

Pt. How long would I need?

Th. That will depend on your cooperation and desire to get well.

Pt. I do, I mean I want to get well. But could you tell me approximately how long it will be?

Th. Now, because the problem goes so far back it may need 2 or 3 years of treatment.

Pt. As long as that?

Th. Unfortunately, deep change takes time. Actually, it's not so long. It took you all your life to get tangled up in a knot. It's been with you for a long time. And a couple of years of treatment is short compared to how long you've had it.

Pt. Aren't there any shortcuts like hypnosis?

Th. Yes, there are, and we'll use whatever techniques are best for you to cut down the time. But hypnosis does not shorten the period of treatment in a problem such as yours. Time itself seems to be an element of cure. You know how hard it is to overcome a tobacco habit?

Pt. Yes, I know.

Th. Well, personality habits require even more time, because they are part of a person from childhood on.

Pt. Yes, I see.

Handling Consistent Lateness

If the patient is consistently late, this may indicate resistance and will necessitate an inquiry. The therapist may ask, "I wonder if there is any reason why you have come so late the last few times." The patient may possibly then bring up an area of resistance. If the patient is defensive and insists on explaining the lateness on the basis of a reality factor, it is best not to challenge this. Instead one may say, ''Let us see what happens in the future." If lateness persists, the patient may be more directly challenged.

Handling Broken Appointments

If the patient breaks an appointment without telephoning, this must be considered seriously and discussed thoroughly at the next session. If two successive appointments are broken, the therapist may advantageously telephone the patient and inquire as to the

reasons. Should the patient remark that he or she has decided to terminate therapy, it is advisable to invite the patient to come in to talk things over. Consistent breaking of appointments is a critical matter and calls for active analysis of prevailing resistances.

Handling Too Frequent Cancellations

When the patient calls in advance to cancel an appointment, there is generally no charge for the session, provided the reasons for the cancellations are valid emergencies. Should cancellations be too frequent, resistance is probably operative, and the patient may be reminded that interruptions in therapy are not only expensive but also detrimental to the progress of treatment.

Handling Nonpayment of Bills

Most patients pay their bills promptly if, during the initial interview, mention is made of the fact that bills are sent out at the end of the month. Should a considerable time elapse without payment, and without mention by the patient of the reasons for this deficiency, the therapist may discuss the matter frankly in a manner such as the following:

> *Th.* I noticed that you haven't paid your bill for the past two months. I wonder if there are material reasons for this or whether you have forgotten.

> *Pt.* Oh, I just don't think of it; haven't gotten around to it.

> *Th.* Do you have any feelings about paying the bill?

> *Pt.* Why no. It's that so many other expenses have come up.

> *Th.* Well, look into it anyway. There may be emotional reasons for your forgetting. Are you at all irritated with me or uncertain about your treatment?

> *Pt. (pause)* Maybe, in some ways. I feel we haven't been going fast enough.

> *Th.* Let's talk about that.

The subject of nonpayment of bills may open up a pocket of transference. Should there be realistic budgetary problems, it is incumbent on the therapist to make as liberal allowances for the patient as circumstances permit. On the other hand, not too much time

should be permitted to elapse without some arrangement being made for the liquidation or other disposal of the bill, otherwise the therapist may become resentful and lose therapeutic objectivity.

DELINEATING THE PATIENT'S RESPONSIBILITIES

Most patients will proceed to work actively in therapy without too much prodding or too extensive a definition of their responsibilities in the treatment situation. In some patients, however, confusion about their role or resistance to activity may require that the therapist delineate their obligations.

How best to present the matter of the patient's responsibilities will depend on the kinds of resistances displayed. In addition to dealing with a specific resistance, the patient may be told that comprehending the problem is the first step in its control. It is often hard for the patient to do this independently because of a lack of objectivity. In treatment the therapist can help the patient find out the cause of the trouble by guiding the patient along certain paths of thinking. The patient and therapist act together in a sort of partnership in the project of exploring the patient's patterns. Knowing what is behind the difficulties will help the patient to do what is necessary to be rid of them. The therapist may say:

> Perhaps we can regard therapy as an arrangement in which we both are participants. You will help me understand you by telling me about your thoughts and feelings, and I will help you understand what goes on inside of you that creates your trouble. Together we can work this thing out.

When the therapist informs the patient that the therapeutic situation is one in which the patient is expected to work out the problems independently, resentment, depression, or panic may be mobilized, because the patient feels that this has already been attempted and not been unsuccessful. The patient may then look upon the therapist's refusal to take complete responsibility as a dereliction. Consequently, it is best not to stress too much, at the start, the obligations that the patient must assume. Instead, it is best to let the relationship develop naturally, helping the patient slowly to accept more and more responsibility. It is, of course, essential that eventually the patient come to an understanding that the extent of his or her participation will determine the ultimate goal.

If the therapist makes decisions for the patient and gives directives on how to conduct his or her life, this will delay the development of essential inner resources that enable the patient to manage problems constructively. If the aim is for goals of assertiveness and independence, it will, therefore, be necessary for the patient to treat the treatment situation as a medium in which independent decision-making capacities can be developed.

One way of insuring the patient's cooperation is to present the process of working in psychotherapy in terms that will be at least partially cogent to the patient. For instance, a patient during the third interview expresses confusion about what to say. He then expostulates that he would like the therapist to do something positive for him. An excerpt of the interview follows:

> *Th.* I know how difficult this has been for you. Were it possible to remove your trouble immediately, I would want to do it. But this thing has been with you for some time, and it may require a little time to get at the bottom of it.

> *Pt.* How can I get well, then, how?

> *Th.* There are ways of working in psychotherapy that will help you get well. Let's look at it this way: you've learned patterns of feeling and behaving that have gotten you into trouble. These patterns are part of you. What we'll do is examine these patterns and see why they've failed and have gotten you into a mess. After that you'll be able to learn new patterns that will make it possible to enjoy life.

> *Pt.* But how do I do this?

> *Th.* Now, learning new patterns is like learning a new language. If you were going to learn a new language, you would have to start talking that language. It would be difficult at first and you would make mistakes, but you would eventually learn it through practice. I'll be like a teacher helping you when you make mistakes. But if I were to do all the talking in this new language, you would never learn how to talk.

> *Pt.* I see, but how do I start?

> *Th.* The best way is to tell me what is on your mind, what you feel, what bothers you. I'll ask you questions from time to time. Now I'm not going to give you the answers, for if I did, it wouldn't help you. But I'll help you find the answers for yourself.

> *Pt.* I see.

> *Th.* It's like doing algebra. To learn algebra it wouldn't help you if I gave you the answers. The important thing is to learn how to get the answers. In problems like yours, learning *how* to arrive at the answers to your disturbing feelings and patterns is as important as getting the

answers themselves.

Pt. Yes.

Th. This may sound mysterious, but as we go on, it will become clearer.

Assigning Tasks to the Patient

Sometimes it is feasible to assign certain tasks to the patient to work on between sessions, such as observation of dreams, and attitudes toward the therapist, which situations exaggerate or alleviate symptoms, and to execute certain behavioral assignments essential to acquire new patterns. The patient may deny that there is any connection between his or her life circumstances and symptoms, but the therapist must insist that the patient keep watching for a relationship between the severity of the symptoms and provocative environmental happenings. Whenever the patient brings up the circumstance of exacerbation of symptoms, it will be important to explore the conditions associated with it. Should the patient balk at performing this assignment, the resistance must be thoroughly explored.

Explaining the Need Not to Make Important Decisions without Discussing These with the Therapist

During therapy the patient's values are in more or less of a transitional state. Extremely important decisions, like changes in occupation or marital status, must be considered very carefully before acting on them. Tragic consequences may follow impulsive decisions. For these reasons the patient may be told that a rule in therapy is that the patient must not spontaneously and impulsively make any radical changes in his or her life situation and that all important actions be discussed with the therapist first.

DEFINING THE ROLE OF THE THERAPIST

In supportive therapy it is usually unnecessary to define the role of the therapist, since the latter consciously functions as a "giving" authority. In deeper therapy, on the other hand, as has been explained above, the therapist's role may have to be delimited

when the patient protests the apparent lack of direction. The patient must be apprised of the fact that the therapist's giving advice and guidance will block the patient's development and prevent achievement of strengths essential to independent functioning.

Psychotherapy calls for respectful listening and a communicating to the patient of an understanding of the patient's turmoil and of a desire to help the patient's plight. This process is different from an artificial cultivation of dependence on the therapist. No promises are made to the patient, nor is the therapist held out as a savior. Rather, the therapist indicates that there are ways of getting relief for one's problems contingent on the patient's active cooperation in therapy.

Partly because the patient puts the therapist in the traditional role of magical healer and partly because the patient's helplessness inspires regressive dependency impulses, he or she demands or secretly expects immediate and dramatic relief. The patient is bound to feel resentful and hopeless if this relief is not immediately forthcoming. The patient may be unable to understand why a rapid cure is not possible, why therapy requires frequent sessions over a prolonged period, and why the therapist displays minimal activity, expecting the patient to shoulder the brunt of the work.

As soon as possible, the therapist must clarify these doubts and hopes to help prevent the experiencing by the patient of too great disappointment and to thwart the patient's leaving therapy in confusion.

The following excerpts from early sessions illustrate the defining of the therapist's role:

Example 1:

> *Pt.* I'd like to know, doctor, what makes me feel so sick.
>
> *Th.* There are reasons why you feel the way you do. Those reasons may not be clear to you, because you are living too close to your difficulties. We will discuss your ideas and particularly your feelings, and in not too long a time, we should discover what is behind your problem.
>
> *Pt.* Yes, but what would you like to know? I mean what do you want me to talk about?

Th. Just anything that bothers you, that's on your mind. In discussing your ideas, reactions, and feelings, we will gradually be able to understand what is happening to you, and this understanding will permit you to take definite steps to correct your difficulty.

Pt. And you'll tell me what is wrong?

Th. Not exactly. I'll, of course, help you with your problem, by acting as your third eye, so to speak. You may not be able to do this for yourself because, as I said, you are living too close to your problem to see the forest for the trees. But I can be more objective, and I shall direct your thinking along certain lines.

Pt. You mean you will not do the work for me; you'll just show me what to do.

Th. Yes. You see, if my doing the work and telling you what to do would really help you, I'd do it. But experience shows that emotional problems are not helped this way. In being told what's wrong with you and what to do, you may never be able to develop as much personality strength as in working things out with my help. Together we can work out a logical and constructive solution for your problem.

Example 2:

Pt. But aren't *you* able to take these fears away from me?

Th. Your fears bother you a great deal, and you want to get rid of them as soon as possible, don't you?

Pt. Yes.

Th. Now it would be natural for you to expect me to give you medicines or some other remedy, or to do something forceful to make your troubles disappear. Believe me, I would do this for you if they *would* disappear this way. But experience shows that you *can* get rid of them by first finding out what they mean, how they got started, and why they continue to bother you. This will take time, and you're likely to get impatient with the slowness of the process.

Pt. (*laughing*) I hope it isn't too slow.

Th. (*smiling*) Well, we'll go as fast as *you* can travel.

Verbalizing the permissive nature of the relationship is not advisable since the patient may interpret this as a lure. Rather, it is important that the patient, on the basis of personal experience, spontaneously arrive at the conclusion that the therapeutic situation is unique in its permissiveness, that things that are ordinarily censored can be talked about, that he or she will not be held in judgment, and that reprimand and punishment will not be forthcoming. The permissiveness of therapy does not presuppose that the

patient will receive unmitigated support and reassurance. Things will not be done for the patient; rather, the patient will be helped to decide the best course of action. As has been mentioned previously, in reeducation and reconstructive therapy especially, it is important to explain to the patient, as soon as the patient expresses disappointment with the amount of direction the therapist is giving, the reasons for the seeming passivity of the therapist. To delay this explanation is apt to result in feelings of helplessness, hopelessness, and despair. Dependent patients will, of course, be loathe to accept the defined limits in therapist responsibility, but they will be much less hostile if they understand that the role of the therapist is a deliberately cultivated one rather than one of neglect.

Limits of Demonstrativeness

Displaying acceptance does not mean that the therapist should behave too demonstratively toward the patient. Such acts as putting one's arm around the patient, comforting the patient solicitously, helping with the patient's coat, and other pleasantries are not to be encouraged. Should the patient wait for such attentions or show expectation of amenities from the therapist, the therapist may briefly explain that it is not the custom in psychotherapy to treat the patient in a conventional sense. For example, a female patient, having placed her wrap on a chair in a male therapist's office, walks over to it at the end of a session and then waits for the therapist to help her with her coat. To respond by doing this would be a normal thing in the ordinary social atmosphere or when purely supportive approaches are employed. To act this way, however, may cause the patient to regard the therapist as a person who should act in other conventional ways toward her. Generally, when the therapist, at the end of the session, does not offer to help the patient with her coat, the patient will do this for herself. Should she ask the therapist to help her, the therapist may do so, remarking, "Much as I'd like to do this regularly, it is customary not to do this in therapy. It tends to put the therapist and patient in a sort of conventional relationship that may interfere with your progress. If I don't help you with your coat from now on, you'll know that it's because it isn't wise to do so."

Limits in Gift Giving

The same taboo is extended toward giving the patient gifts. There are times in supportive therapy when a small gift may be tendered the patient as a demonstration of the therapist's thoughtfulness and desire to bring comfort to the patient. In insight therapy, gift giving puts an artificial bias on the relationship and may be harmful. Similarly, accepting gifts from the patient must be handled carefully. Even small gifts must be questioned. Should the patient offer the therapist a small gift, the therapist may accept it appreciatively but ask why the patient gave it. An excerpt from a session illustrates this point:

> *Pt.* I thought you would like this necktie.
>
> *Th.* Thank you very much. I appreciate your thoughtfulness, but I wonder why you got it for me.
>
> *Pt.* (*blushes*) Oh, I just thought you'd like it.
>
> *Th. (smiling*) You know in therapy one has to look a gift horse in the mouth, and inquire into the meaning of everything that happens, including bringing gifts. For instance, let's try to figure out why you gave me this tie.
>
> *Pt.* (*laughing*) I suppose it's because I wanted to. I noticed that you wear drab ties.
>
> *Th.* You thought I might look better in a snappy tie?
>
> *Pt.* (*laughing*) Not that you haven't good taste, but ... *(pause)*
>
> *Th.* Perhaps you're not quite sure of my taste.
>
> *Pt. (laughing)* Come to think of it, maybe I'm not.

Under no circumstances should the therapist accept a large gift, for this is generally a manifestation of resistance or a way of bribing the therapist. When a patient offers the therapist such a gift, the therapist must refuse it without rejecting the patient. The following excerpt is illustrative:

> *Pt.* I brought you a little something, *(gives therapist a box)*
>
> *Th.* Thank you, very much, but I wonder why you got it.
>
> *Pt.* Oh, I know you'll like this. It's a very nice thing.

Th. What is it?

Pt. A fine watch.

Th. Well, now I do appreciate your thoughtfulness, but one of the rules of therapy is not to accept gifts. It may interfere with your treatment. If I don't accept it, it's because of this rule. But tell me, why did you get it for me?

Pt Well, does there have to be a special reason?

Th. There usually is. You know, in therapy one looks a gift horse in the mouth. Mind you, I think it's very fine of you to bring me a gift, but let's explore this a little. We may learn something important from it.

Avoiding Social Contact

Meeting the patient on a social basis may be destructive to the relationship. The patient may employ his or her observations of the therapist's behavior as a weapon to reinforce resistance. The patient may use the social relationship as a means of neutralizing the therapist's effectiveness. On the other hand, if the therapist happens to meet the patient at a party or function, there is no reason to make a hasty retreat, although there may have to be some restraint on the therapist's spontaneity.

Avoiding Physical Contact

It goes without saying that physical contact with the patient is absolutely taboo. Rubbing, stroking, or kissing the patient may mobilize sexual feelings in the patient and therapist or bring forth violent outbursts of anger. Should the patient approach the therapist sexually, this must be handled as a manifestation of transference, and the patient should be encouraged to verbalize his or her feelings. Were the therapist to respond to the patient's gesture, therapy would terminate immediately with perhaps disastrous consequences for both patient and therapist. The utmost care must be exercised to avoid mobilizing guilt in the patient if the patient makes a physical gesture toward the therapist. Occasionally an enthusiastic patient may embrace and kiss the therapist. This embarrassing situation will call for the greatest tact. If the patient is pushed away harshly and scolded, the patient will feel rejected and resentful. To respond by embracing the

patient may be interpreted as a seductive lure for which the therapist will pay dearly later on. The best way to handle this contingency is to stand one's ground, smile, and ask, "Now, I wonder why you did that?" By facial expression the therapist must convey no embarrassment, fright, hostility, or excitement. If the embrace is during a session, the focus of the session should be on the meaning of the gesture to the patient. If it is at the end of a session, the therapist may add to the statement made, "Suppose you think about why you kissed me, and we'll talk about it next time." Therapists who advocate sexual relations with their patients as a therapeutic measure deceive themselves about their designs, which are usually countertransferential and exploitative.

Avoiding Business Dealings

Sometimes patients will offer the therapist opportunities to enter into business dealings with them. The temptation may be great, since the therapist may assume that an investment in the patient's enterprise will be helpful to both of them. Such business arrangements will usually be very destructive to therapy and should be resisted unequivocally. Similarly, one must never take advantage of patients' professional or social contacts, if they happen to be prominent because this again will dilute one's therapeutic impact.

<div align="center">EXPLAINING HOW PSYCHOTHERAPY WORKS</div>

A case history explaining how another patient developed an understanding of oneself in therapy, and of how that patient achieved relief or cure, is a dramatic way of persuading the patient to accept the treatment situation when it is stubbornly resisted. The following is an example of such a history. Undoubtedly, the therapist will be able to present examples from personal experience. These should be sufficiently disguised so that the discussed patient's identity will not be revealed. In the case that follows, of a patient with migraine, symptomatic treatment along medical lines and brief supportive therapy with a counselor had failed to bring relief.

The patient was referred to me for treatment of migraine headaches that did not

respond to medication. It was apparent to me that the patient did not really want psychotherapy because he was not convinced that the headaches were caused by psychological factors. What he really wanted from me was a prescription for another more powerful medicine. When I suggested that there might be a connection between his tension and his headaches he replied that this might be so, but that the headaches came first and gave him tension.

At the next visit he described his having suffered from an especially bad headache during the past week. When I asked him to describe the circumstances that immediately preceded his headaches, he said, "I can see no reason why I had the headache from the different things that happened during the day. I went to work, and everything went along pretty well. I did a job that was assigned to me with no trouble at all. That night I had a bowling date with a friend. Now this friend called me up, and we were supposed to go out on a date. He said, 'Suppose I meet you at eight o'clock.' Right at that point my wife, who had been coming down with a head cold, says to me, 'Why don't you postpone your going out until later on, after the kids are in bed or tomorrow?' And she did have a terrible cold. So I told my friend we'd go out the next day. I didn't want the youngsters to catch my wife's cold, so I helped them. Then I sat on my wife's bed. She was sniffling, and I began getting an awful headache right at that point. And there was no reason for it." When asked whether he might have resented the fact that he had to stay home and put the children to bed, he remarked, "No, why should I? The kids would have gotten a cold, I could have bowled the next day; there's no reason why I should." The patient was assured that perhaps there was no cause for the headache that we could see at this time but that it was necessary to continue observing the circumstances under which his headache developed.

One week later the patient reported a severe migrainous attack. "Again I had an awful headache. Things went around. I had a bunch of junk last night, and it was probably what I ate." When asked to talk about the events that had occurred, he said, "We went over to call on some people we know. They are nice people, but I don't care very much for them. But my wife thinks that because he is my superior at work, we've got to cultivate them; and I suppose if I really want to go along, get ahead in my job, that I might as well try to be

friends with him. So I went over there, and sat there, and we drank a while and we talked. They're terrible bores. I really don't like being with them. Then it started, an awful headache."

When asked whether he resented making the visit, the patient replied, "Sure, I didn't want to be there. I just resented being there." He was then reminded that he had presented two instances in which his wife had asked him to comply and that in each case a headache followed. "Yes," he admitted, "I don't know; maybe you've got something."

That he had made a connection was evidenced by his reaction to his next headache. He said, "By George, you know what happened? My wife asked me to stay at home again and not go bowling, but afterward I got a bad headache." Almost excitedly he continued, "When I look back, I can see the headache just comes like that. There have been innumerable times when automatically I feel as if I have to do what my wife asks me to do, that I can't say no. I say she is a reasonable person and a nice person, and I get a bad headache every time. Now, why should that be?" What we had done was to make a connection between the patient's symptoms and some life events that at the time did not seem too important.

Therapists can refer to cases such as this and note to their patients: "This is what we shall try to do in your case in the event there is such a connection. We will also try to figure out if we can deal directly with the symptom and with problems in your life situation through various symptom-relieving or problem-solving interventions, or whether it is necessary to deal with some carry-overs in your early development that are causing your trouble now."

In the case of the man with migraine, it became apparent that he had never gotten over his strong dependency on his mother whose dictates and demands he followed punctiliously, even though he resented yielding to her wishes. His passivity led to the choice of a wife who was strong and who, with his cooperation and even insistence, took him over the way his mother did. This wife, of course, had gotten herself into a no-win situation. Because he idealized his mother, his wife could never come up to his

expectations. When he forced her to make decisions, he resisted her interfering with his independence. When she tried to shift responsibility onto him he resented her ineffectuality. The resulting anger was not expressed outwardly but was turned back on himself and resulted in tension and migraine. Naturally he acted the same way with other people, and he did it even with me. This is a transference reaction, and it was possible to point out during our sessions how he was trying to force me to make decisions for him and then resenting whatever I did. Sometimes these activities are not at all conscious to the person. This is what happened to our man, but he was able to recognize from his dreams, fantasies, and feelings toward me that his world was populated with good mothers, bad mothers, and in-between mothers who dominated or rejected or loved or hated him and that he was responding to all their actions, good and bad, with physical symptoms.

Knowing this was only half the battle. The important thing was doing something with this insight. This involved changing habit and behavioral patterns that were about as old as he was. First, he had to get over his demand that I act like his mother. Next we had to involve his wife in treatment so that she could resist his demands that she be like a mother figure. We worked together, the man, the wife, and I in "couples therapy" and some of the sessions were stormy, resulting in *her* getting headaches. But before her husband could get well, she also had to get over her own bossiness so that she would not reinforce her spouse's passivity. The end result was a better and much less headache-ridden marriage. The man achieved enough personality reconstruction so that he functioned, for the first time in his life, with freedom and assertiveness and without debilitating headaches.

The therapist may remark, "This prolonged description illustrates how psychotherapy works. What happened to this patient naturally does not apply to you. But by examining *your* ideas and feelings, and talking about *your* problems, we should be able to help you too."

SIGNS OF ACCEPTANCE OF THERAPEUTIC STRUCTURING

Signs of acceptance of the structuring of the therapeutic situation are reflected in greater participation and activity. This is illustrated in the following excerpt. The patient is a 40-year-old married woman with a hysterical symptom of vaginal burning, which, since its inception eight years previously, had been increasing in severity until she could no longer tolerate it. It was apparent that she had magical expectations of my removing her difficulty in a few sessions. When I structured the ideal way of working in psychotherapy, she responded with silence. At the sixth session, she complained of intense burning and remarked that she was thinking of stopping therapy. I attempted to analyze her resentment at my passivity and tried to justify my stand on the basis that if I could remove her trouble by waving a wand, I would do so. I explained that emotional problems like hers could be resolved—but that it was necessary for the patient to work hard and to cooperate actively. During the next session, the seventh, she seemed to be resolving her resistance to accepting the way that we were supposed to work together. A part of the session follows:

> *Pt.* Today I'm 40 years old.
>
> *Th.* Are congratulations in order?
>
> *Pt.* No, nor commiserations. But I never thought I'd spend it here in New York getting treatment away from home. (*laughs*)
>
> *Th.* You never realized 10 years ago, or even 5, that at your fortieth birthday you'd be sitting opposite a psychiatrist.
>
> *Pt. (laughs*) I finally had a dream. I didn't have that dream until this morning. It was the silliest thing. I was living in this large room. I was living there with a man. He looked like a combination of an old boyfriend and a man who works in the same place I do. And we weren't sharing the same bed for some strange reason. And there was a double cot over on one side of the room and a double cot on the other side. And there was a sink, and there was a bunch of people there having a party for some reason. I was supposed to wash up the dishes, and I was very resentful of the fact that everyone was having a good time and I wasn't. In fact, I had to go out to go to work, and the dirty dishes were going to be left for me to do. And all of a sudden I realized that the man in the room had taken the sink out and put it up so high that I had to stand on my toes to reach it. Then I realized that one of the cots had been taken out. I was shocked, as if I was being eliminated. *[This dream seems to reflect a feeling of rejection and resentment at being made to do "dirty work." The idea occurs to me that this is a transference dream.]*
>
> *Th.* What does that make you think of? Do you have any associations?

Pt. Why no. I just awoke and was going to go to work.

Th. But the emotion in the dream. What was that like?

Pt. Well, there didn't seem to be any love involved.

Th. Here was a man doing peculiar things?

Pt. Well, it didn't seem to be a man I was emotionally involved with, yet I was sharing the room with him. *(pause)*

Th. And what was he trying to make you do?

Pt. The dirty dishes while the others were standing around, talking and having a good time. *[Could this possibly refer to my wanting her to do the "dirty" work in therapy?]*

Th. Mm hmm.

Pt. And I was under strain. I had to stand on my toes to do that, and it was hard. He had put the sink up too high. I could see the bolt holes where the sink had been before. He put it up too high, *[indicating that I was making the therapeutic task impossibly hard for her?]*

Th. He was making you do the work.

Pt. Yes, and when I noticed the other cot gone, I said, "What the hell does he think he's doing?"

Th. Why would he take the cot away?

Pt. I don't know; maybe so the woman sharing the room would sleep with him.

Th. What kind of person was he?

Pt. He reminds me of two people I know: one, handsome and charming; the other, boorish and vulgar. He clowns around, but he's a good Joe.

Th. I see.

Pt. And something very peculiar happened last week, something I couldn't quite figure out. First, I realized I wasn't so frightened as I used to be. And I wasn't complaining as much. And I said, "Won't Dr. Wolberg be pleased to hear that," and all of a sudden this vaginal burning that I have went away completely. It made me chuckle. (*laughs*)

Th. All right, how do you make the connection?

Pt. I don't make any connection *(laughs)* except that maybe the treatments are doing me good in spite of myself.

Th. In spite of the fact that you may be a little annoyed at the way the treatments are going. *(pause)* *[It was hoped here that the patient would verbalize her feelings of resentment or*

disappointment. Because she did not do so, the next comment was made.] Perhaps you feel disappointed that so much responsibility is being put on you?

Pt. Possibly, possibly. (*laughs*)

Th. Like being made to do the dirty dishes. *[interpreting one aspect of the dream]*

Pt. (*laughs uproariously*) I just hate to do dishes. That's my mother's fault. She wanted me to be a pianist and not spoil my hands. I was always annoyed at doing dishes. What you say is right; I don't want, didn't want, the responsibility of figuring things out myself.

Th. Are you annoyed at accepting responsibility?

Pt. Well… not exactly, that is, when I am not under tension, I don't mind responsibility. But since this tension started, I have tried to evade responsibility as much as possible, because I felt I couldn't accept it or carry it out.

Th. And how do you feel about accepting responsibility in our therapy here?

Pt. I am a little confused about that. (*laughs*) Less than before though. I just didn't feel as if I was capable.

Th. You see, if it were possible for me to remove these symptoms from you myself, I would do it. I would want to do it. But we find that cures are not accomplished this way. As a matter of fact, the more active a person is in working out the sources of a problem, even though the person has to sweat it through a little, the quicker one gets well. In the long run this is what strengthens the person. The ability to understand the sources of one's problem and to handle the resistance in working things out for himself or herself … [*I continue to structure the therapeutic situation.]*

Pt. (*laughs*) It's not conscious resistance I assure you.

Th. I know.

Pt. I want to tell you what happened last night. This symptom that I have had is associated with sex in my mind, for some reason. I started thinking about my husband and all of a sudden this burning began to loosen up and to become a sexual feeling. Ordinarily I would have stopped thinking right there, because in the past if I started thinking about the person involved and couldn't do anything about it, the burning would keep on, and keep on, and only go away when I slept. So I just decided that I would keep on thinking about it just to see what would happen. *[This is an excellent sign of her beginning to accept responsibility by working on a problem.]*

Th. Good.

Pt. And I didn't get a sexual craving and I started being able to think about something else and I wasn't afraid of what would happen … and, for heaven's sake, the burning went away.

Th. It sounds as if you've been afraid to let your mind wander in the past.

Pt. I see. You mean if I'm afraid to think about sex, I might get pain there instead.

Th. Yes, perhaps in the future you could let your mind wander and see what you think about.

Pt. I guess I'm afraid to think because, after all, it's been seven years that I've lived with this thing. If I thought it would clear things up, I wouldn't be afraid to think anything I want. Mother was very moral about sex, and I could never bring it up. Oh, yes, after I left you, I went to the store to get groceries. I wanted to get out so I got in line ahead of other people and the burning started. Then it went away. I went to sleep and had a dream I forgot. When I tried to remember the dream, the burning returned and my mind got hazy.

Th. Now it's important for you to continue thinking about yourself, like making a connection between your symptoms and your thoughts, you may not at first see the connection, but you will, after a while, see a trend developing, a connection. Now one impression I get that I can offer to you is that every time you feel you've done anything that's "bad," the burning comes on you.

Pt. When I ever did anything bad as a child, mother would scream, bang her head against the wall, and practically have a breakdown. *[Patient continues to associate to her early relations with her mother.]*

From this session on the patient accepted the conditions of therapy and worked actively and successfully.

37
Selecting a Therapeutic Focus

Psychotherapy is much more effective when a focal topic is selected by the therapist. Once the therapist has determined why the patient has come for therapy and explored the patient's account of the situation and the patient's treatment goals, the focal topic can be chosen. A too early concentration on the patient's psychopathology and past conditionings that have created the troubles, however important this inquiry may be, will support regression and encourage long-term lingering in treatment. Rather, the therapist should begin to focus on what is of *immediate* importance to the patient, such as incidents in life that have precipitated the symptoms for which the patient seeks help. In focusing on precipitating factors one must gauge the patient's vulnerability to stress as well as the virility of the stress factors themselves. In focusing on symptoms the therapist should view them as an assembly of reactions to anxiety as well as consequences of defense mechanisms elaborated to control the symptoms.

During the explorations it is important try to actuate to problem solving, while examining, encouraging, and helping the release of whatever positive adaptive forces are present in the patient, as well as studying the resistances that block their operation. In the course of doing this the therapist may be confronted by the patient with some early formative experiences, but these are not explored in depth. They are handled in the context of explaining obstructions to effective functioning in the present. Ample opportunities will be found later on to switch the focus to areas related to some central dynamic theme by establishing a connection between it and current problems and concerns, should this be deemed desirable. In some cases, powerful initial resistance to treatment may make an early focus on dynamics essential. Obviously, the therapist will deliberately have to select dynamic aspects that can be worked with expediently, while avoiding or dealing tangentially with even noticeable conflicts that do not seem too noxious or would be difficult or impossible to handle in the first part of therapy. In most cases, however, dynamic causative issues are not concentrated on during the first part of

treatment.

FOCUSING ON PRECIPITATING EVENTS

Many patients come to therapy convinced that their problems were brought about by some precipitating factor in their environment. An alcoholic husband, a disastrous investment, a broken love affair, a serious accident, these and many other real or exaggerated calamities may be blamed. What people usually want from treatment is help in getting rid of painful or disabling symptoms that are often ascribed to such offensive events. The symptoms are varied and include anxiety, depression, phobias, insomnia, sexual difficulties, obsessions, physical problems for which no organic cause can be found, and a great many other complaints and afflictions.

Even though the therapist may be correct in assuming that the basic troubles reside elsewhere than in environmental or symptomatic complaints, to bypass the patient's immediate concerns is a serious mistake. Later when there is firm evidence of the underlying causes, for example, faulty personality operations or unconscious conflict, a good interviewer, as has been mentioned, should be able to make connections between the precipitating events or existing symptoms and the less apparent dynamic sources of difficulty. There will then occur a change in focus. This shift, however desirable it may seem, is not always necessary because it may be found that therapeutic objectives are reached with symptom-oriented and problem-solving methods and that the patient achieves stabilization without delving into corrosive conflicts or stirring up ghosts of the past. It is only when goals go beyond symptom relief or behavioral improvement that the therapist will, in the hope of initiating some deeper personality alterations, delve into dynamic problem areas. Even when the objective is mere symptom relief or behavioral improvement, however, resistance to simple supportive and reeducative tactics may necessitate a serious look at underlying personality factors that are stirring up obstructive transference and other interference to change.

In practically all patients some immediate stress situation, usually one with which the individual is unable to cope, sparks the decision to get help. Usually the patient feels

like the victim rather than perpetrator of his or her identified troubles. This, in some cases, may be true; in most cases it is false. It is necessary, therefore, in all patients to appraise the degree of personal participation in their difficulties.

Since we are actually dealing with situations that generate tension and anxiety, it is essential to view environmental incidents through the lens of their special meaning for the individual. What may for one person constitute an insurmountable difficulty may for another be a boon to adjustment. During World War II, for instance, the London bombings for some citizens were shattering assaults on emotional well-being; for others they brought forth latent promptings of cooperation, brotherliness, and self-sacrifice that lent a new and more constructive meaning to the individual's existence. Indeed, wartime with its threat to life marshalled an interest in survival and subdued neurotic maladjustment, which returned in peacetime to plague the individual.

The understanding of stress necessitates acknowledging that there is no objective measure of it. One cannot say that such-and-such an environment is, for the average adult, 70 percent stressful and 30 percent nurturant. No matter how benevolent or stressful the environment, the individual will impart to it a special meaning as it is filtered through the individual's conceptual network. This shades the person's world with a significance that is largely subjective. Conceptual distortions particularly twist feelings toward other human beings and especially toward the self. A self-image that is hateful or inadequate may plague the individual the remainder of his or her life and cause self-devaluing interpretations of events. Most of what happens to the patient will be viewed as confirming a sense of low self-worth and that nothing that he or she does will amount to anything. Such a pervasive belief, of course, makes nearly any occurrence productive of considerable stress.

It is rare then that environmental stress alone is the sole culprit in any emotional problem. Inimical, frightening, and desperate situations do arise in the lives of people, but the *reactions* of the individual to happenings are what determine their pathological potential. Under these circumstances minor environmental stress can tax coping

capacities and break down defenses so that an eventuating anxiety will promote regressive devices such as protective phobias. It is, therefore, essential that any precipitating incident that brings a patient into therapy be regarded as merely one element in an assembly of etiological factors, the most important variable being the degree of flexibility and integrity of the personality structure. It is this variable that determines a harmonious interaction of forces that power intrapsychic mechanisms when security and self-esteem are threatened by adversity from the outside and by common developmental crises that impose themselves from within. Through focusing on what is regarded as a precipitating incident, the therapist may be able not only to initiate remediable environmental corrections but also to open a window into hidden personality resources.

From a practical viewpoint, therefore, any environmental stress warrants close examination for its influence, good or bad, on the total resources of the patient. An understanding of the how and why of its impact may prove invaluable. Sometimes the initiating factor may seem like a trivial spark to the therapist, but an exploration of the patient's history, attitudes, and values may reveal the emotionally explosive mixture that awaits detonation.

FOCUSING ON SYMPTOMS

Most patients are concerned with disturbing symptoms, which is the chief reason for their coming to treatment. The relief of such symptoms sometimes constitutes a legitimate beginning objective, particularly if the therapist employs a systems theory design that focuses on the causative link responsible for the current difficulty. One reason a systems approach has been resisted by some authorities is that in describing it, confusing language has been employed that is closer to theories of engineering and communication than to psychological constructs (e.g., "morphostatic principles," "negative feedback loops," "cybernetic regulation," "servomechanisms," "morphogenesis"). In the mental health field, a systems viewpoint shorn of these vertiginous linguistics can prove useful. Such a viewpoint would consider behavior a long chain of a number of operative units linked

together. In psychotherapy, the focus can be on the particular unit link in the chain that is creating the greatest disturbance for the individual: biochemical, neurophysiological, developmental, conditioning, intrapsychic, interpersonal, social, philosophical-spiritual. Thus if the symptom is a product of a biochemical problem that produces an imbalance of neurotransmitters and hormones, the therapist may, after establishing a proper diagnosis that implicates biologic factors, attempt to deal with the *biochemical link* by prescribing appropriate corrective medications. In this way the therapist may relieve some disturbing symptoms of schizophrenia with neuroleptics, of depression with antidepressant drugs, mania with lithium, and anxiety with antianxiety medications. The mechanism of the action of psychotropic drugs in panic, bulimia, obsessive-compulsive, and attention disorders is not known, but apparently the biochemical link is somehow involved and antidepressant medications may be effective. More is being discovered about how the mind and brain work through modem neurophysiological research (e.g., nuclear magnetic resonance, imaging techniques, position emission tomography (PET), and studies of neuropsychological deficits brought about by lack of coordination of the right and left hemispheres, defective brain metabolism, and impaired cerebral circulation. Psychopathology brought about by structural defects and malfunctions of the *neurophysiological link* has been ameliorated through psychopharmacology, relaxation techniques, and biofeedback.

Problems related to the *developmental-conditioning link,* e.g., disorganizing patterns due to improper early child-rearing practices and disruptive conditioning, and which manifest themselves as phobias, habit disorders, behavior problems, adjustment difficulties, and developmental retardation are sometimes definitively helped by behavior therapy, cognitive therapy, and hypnosis. Problems in the quality and flexibility of defenses, which are mediated by the *intrapsychic link* and register themselves as disturbances in the self-system and other components of the psychic apparatus, are best approached with dynamic psychotherapy. Insofar as the *interpersonal link* is concerned, personality, as well as marital, family, and other relationship factors may be optimally engaged by cognitive learning, transactional analysis, experiential therapy, psychodrama, dynamic psychotherapy, and group, marital, and family therapy. The *environmental-social*

link involved in situational problems may best be dealt with by counseling, social casework, environmental manipulation, and milieu therapy. Finally, the *philosophical link* of belief systems, values, standards, and ideals when distorted make for a wealth of problems and may require concentrated attention through techniques like cognitive therapy and existential analysis.

Behavior can be looked upon as a mixture of these intimately connected systemic links, each of which is bracketed to specific areas of dysfunction and pathology for which special corrective modalities, as indicated above, are suggested. Rarely if ever is pathology confined to one system alone. Because biochemical, neurophysiological, intrapsychic, interpersonal, social-environmental, and philosophical-spiritual systems are interrelated, difficulties in one system inevitably will by feedback involve some or all of the others. By the same token, disruptions in any one system that have been corrected through therapy will probably have a congenial effect throughout the systemic continuum. An example of how approaches on different system levels may accomplish similar results is provided in depression. Cognitive and pharmacological approaches deal with opposite ends of the behavioral continuum, and yet, from the available research, depression is relieved with both methods. This lends credence to the hypothesis that a feedback occurs throughout the behavioral chain. Alteration of one link influences the other links. As Beck and Young (1985) have expressed it, "Our experience suggests that when we change depressive cognitions, we simultaneously change the characteristic mood, behavior, and (we presume) biochemistry of depression." It is for this reason that an organizing framework such as suggested above can be useful in treatment planning and in providing a productive focus for therapeutic intervention. Moreover, such a framework substantiates multifaceted therapeutic modes that are targeted on specific zones of pathology. This can be especially helpful in short-term therapeutic approaches in which time is of the essence. It can also be useful in longer kinds of treatment.

FOCUSING ON DYNAMICS

Sometimes an individual presents a problem during the initial interview that

ostensibly is the product of intrapsychic malfunctioning (i.e., the intrapsychic link). As an example, the most effective therapeutic focus is one that deals with a basic repetitive conflict, the manifest form of which is being expressed through the immediate complaint factor. To illustrate, consider the situation of a patient of mine, the mother of two small children, who was insisting on a divorce because of continuing disenchantment with her marriage. The divorce decision appeared to be the terminal eruption of years of disappointment in her husband's failure to live up to her ideal of what a man should be like. After we cut through endless complaints, it became apparent that the standard against which she measured her husband was her father, whom she worshiped as the epitome of success and masculinity. This idealization I discovered later, actually had little basis in fact, being the remnant of an unresolved Oedipal conflict. Be this as it may, her idealization had thwarted her ability to make a proper adjustment to her marriage, and with the decision of a divorce the integrity of her family was being threatened. She came to therapy at the urging of her lawyer, who realized that she was too upset to make reasonable decisions.

A therapist who minimizes the importance of dynamic conflicts may attempt to deal with a situation of this nature by invoking logic or appeals to common sense. The therapist may suggest ways of patching things up, insisting that for the sake of the children a father, however inadequate, is better than no father. The therapist may, upon consulting with the husband, point out various compromises the husband can make, and after the wife has verbally disgorged a good deal of her hostility in the therapeutic session, she may be willing to cancel her divorce plans and settle for half a loaf rather than none. The reconciliation is executed through a suppression of her hostility, which finds an outlet through sexual frigidity and various physical symptoms. On the other hand, should the therapist recognize the core conflict that is motivating her idea of divorce, there is a chance that the patient may be helped to an awareness of her merciless involvement with her father and the destructive unreasonableness of her fantasies of what an ideal marriage is like. She may then allow herself to examine the real virtues of her husband and the true advantages of her existing marriage.

A dynamic focus should, therefore, be prospected in the course of exploring the immediate complaint factor. Such a focus is often arrived at intuitively (Binder, 1977). The more empathic, skilled, and experienced the therapist, the more likely he or she will be to explore the actual operative dynamics. No matter how firmly convinced the therapist is in his or her immediate assumptions, however, it is with a realization that these are being predicated on incomplete data. The therapist theorizes the patient may deliberately withhold important information, or though the patient may recognize certain conflicts, she is still oblivious to their significance or completely unaware of their existence. Whatever tentative theories come to the therapist's mind, he or she will continue to check and to revise them as further information unfolds. Interviews with relatives and friends are extremely valuable since they may open facets of problems not evident in conversations with the patient. Moreover, once the patient during the first encounter has divulged data, later interviews will help uncover rationalizations, projections, and distortions that will force the therapist to revise the thesis and concentrate on a different focus from the one that originally seemed so obvious.

No matter how astute the therapist has been in exposing a truly momentous focus, the patient's reactions will determine whether the exposure turns out to be fruitful or not. For example, even though an underlying problem is causing havoc in a person's life and is responsible for the crisis that brings the person to therapy, this does not imply that the patient will elect to do anything about it. Its emotional meaning may be so important to the patient, the subversive pleasures and secondary gains so great, that suffering and misery are easily accepted as conditions for the indulgence of destructive drives even when the patient has full insight into the problem, recognizes its genetic roots, and realizes the complications that inevitably indemnify the indulgence. I recall one patient whose yearning for revenge on a younger sibling produced a repetitive series of competitive encounters with surrogate figures toward whom retaliatory hostilities and violence brought forth punishment by employers, colleagues, and friends. A series of abuses culminated in a disastrous incident in which a physical assault on a fellow employee resulted in the patient's discharge from a promising executive position. This happening was so widely publicized in the industry that the patient was unable to secure

another job. During therapy the patient was confronted with the meaning of his behavior and particularly his revenge and masochistic motives; he readily recognized and accepted their validity. This did not in the least deter his acting out on any occasion when he could vent his rage on a sibling figure. At the end of our brief treatment period, it was recommended that he go into long-term dynamic therapy, which he bluntly refused to do. He seemed reconciled to pursue a damaging course for the momentary joy that followed an outburst of aggression.

Experience with the addictions provide ample evidence of the futility of focusing on the dynamics of a dangerous and what appears on the surface to be a disagreeable way of behaving. But that some patients disregard logic does not nullify the need to persist in making careful interpretations in the hope of eventually eroding resistance to the voice of reason.

We may expect that a patient seeking help will communicate sufficiently to supply essential material from which a focus may be extrapolated. Understandably, there will be differences in emphasis among therapists, even among those who have received similar theoretical grounding. The available material is usually sufficiently rich to enable therapists to identify ample aspects that synchronize with their intuitions, ideas, and biases.

Since all people share certain conflicts that are basic in our culture, some of these can constitute the dynamic focus around which interpretations are made. Thus manifestations of the struggle over separation-individuation following the ideas of Mann (1973), persistence of Oedipal fantasies as exemplified in the work of Sifneos (1972), and residues of psychic masochism such as described by Lewin (1970) are some of the core conflicts that may be explored and interpreted. Sensitized to indications of such conflicts as they come through in the patient's communications, the therapist may repeatedly confront the patient with evidence of how the patient is being victimized by the operations of specific inner saboteurs. There is scarcely a person in whom one may not, if one searches assiduously enough, find indications of incomplete separation-individuation,

fragments of the Oedipal struggle, and surges of guilt and masochism. It is essential, however, to show how these are intimately connected with the anxieties, needs, and defenses of each patient and how they ultimately have brought about the symptoms and behavioral difficulties for which the patient seeks help.

Lest we overemphasize the power of insight in bringing about change, we must stress that to a large extent the choice of a dynamic focus will depend on the therapist's seeing the presenting problem of the patient through the perspective of certain theoretical convictions. A Freudian, Jungian, Adlerian, Kleinian, Horneyite, Sullivanian, Existentialist, or behavior therapist will focus on different aspects and will organize a treatment plan in accordance with personal ideologies. Although the focus, because of this, will vary, there is considerable evidence that *how* the focus is implemented and the quality of the relationship with the patient are at least as important factors in the cure, if not more so, than the prescience of the therapist and the insightful bone of dynamic wisdom given the patient to chew on. That implantations of insight sometimes do alter the balance between the repressed and repressive forces cannot be disputed. How much the benefits are due to this factor and how much are the product of the placebo effect of insight, however, is difficult to say. When a therapist is firmly convinced of the validity of the focus chosen and convinces the patient that neurotic demons within can be controlled through accepting and acting upon the "insights" presented, tension and anxiety may be sufficiently lifted to relieve symptoms and to promote productive adaptation. Even spurious insights if accepted may in this way serve a useful purpose. Without question, nevertheless, the closer one comes in approximating some of the sources of the patient's current troubles, the greater the likelihood that significant benefits will follow.

In this respect for some years I have employed a scheme that I have found valuable in working with patients. This, which is certainly not original with me, consists of studying which resistances arise during the implementation of any of the techniques that I happen to be employing at the time. The resistances will yield data on the existing dynamic conflicts, the most obstructive of which is then chosen as a focus.

Experience with large numbers of patients convinces that three common developmental problems initiate emotional difficulties and create resistance to psychotherapy—first, high levels of dependency (the product of inadequate separation-individuation), second, a hypertrophied sadistic conscience, and, third, devaluated self-esteem. Coexisting and reinforcing each other, they create needs to fasten onto and to distrust authority, to torment and punish oneself masochistically, and to wallow in a swamp of hopeless feelings of inferiority and ineffectuality. They frequently sabotage a therapist's most skilled treatment interventions, and, when they manifest themselves, unless dealt with deliberately and firmly, the treatment process will usually reach an unhappy end. Dedicated as the therapist may be to their resolution, the most the therapist may be able to do is to point out evidence of these saboteurs, to delineate their origin in early life experience, to indicate their destructive impact on the achievement of reasonable adaptive goals, to warn that they may make a shambles out of the present treatment effort, and to encourage the patient to recognize his or her personal responsibility in perpetuating their operation. The tenacious hold they can have on a patient is illustrated by this fragment of an interview.

The patient, a writer 42 years of age, who made a skimpy living as an editor in a publishing house, came to therapy for depression and for help in working on a novel that had defied completion for years. Anger, guilt, shame and a host of other emotions bubbled over whenever he compared himself with his more successful colleagues. He was in a customarily frustrated, despondent mood when he complained:

> *Pt.* I just can't get my ass moving on anything. I sit down and my mind goes blank. Staring at a blank piece of paper for hours, I finally give up.
>
> *Th.* This must be terribly frustrating to you.
>
> *Pt.* (*angrily*) Frustrating is a mild word, doctor. I can kill myself for being such a shit.
>
> *Th.* You really think you are a shit?
>
> *Pt. (angrily)* Not only do I think I am a shit, I am a shit, and nobody can convince me that I'm not. [*The self-devaluation could not be more clearly expressed.*]
>
> *Th.* Frankly, Fred, I'm not even going to try. But you must have had some hope for yourself,

otherwise you never would have come here.

Pt. I figured you could get me out of this, but I know it's no use. I've always been a tail ender.

Th. (*confronting the patient*) You know, I get the impression that you've got an investment in holding on to the impression you are a shit. What do you think you get out of this?

Pt. Nothing, absolutely nothing. Why should I need this?

Th. You tell me. *[In his upbringing the patient was exposed to a rejecting father who demanded perfection from his son. The father was never satisfied with the even better than average marks his son obtained at school and compared him unfavorably with boys in the neighborhood who were prominent in athletics and received commendations for their school work. It seemed to me that the paternal introject was operating in the patient long after he left home, carrying on the same belittling activities that had plagued his existence when he was growing up.] Pt. (pause)* There is no reason, *(pause)*

Th. You know I get the impression that you are doing the same job on yourself now that your father did on you when you were a boy. It's like you've got him in your head. *[In the first part of the session the patient had talked about the unreasonableness of his father and his own inability to please his father.]*

Pt. I am sure I do, but knowing this doesn't help.

Th. Could it be that if you make yourself helpless somebody will come along and help you out? [*I was convinced the patient was trying to foster a dependent relationship with me, one in which I would carry him to success that defied his own efforts.*]

Pt. You mean, you?

Th. Isn't that what you said at the beginning, that you came to me to get you out of this thing? You see, if I let you get dependent on me it wouldn't really solve your problem. What I want to do is help you help yourself. This will strengthen you.

Pt. But if I can't help myself, what then?

Th. From what I see there isn't any reason why you can't get out of this thing—this self-sabotage. *(The patient responds with a dubious expression on his face and then quickly tries to change the subject.)*

In the conduct of psychotherapy, especially in its briefer forms, one may not have to deal with the underlying conflicts such as those above *as long as the patient is moving along and making progress. It is only when therapy is bogged down that sources of resistance must be uncovered.* These, as has been indicated, are usually rooted in the immature needs and defenses staged by dependent, masochistic, self-defacing promptings. At some point an explanation of where such promptings originated and how

they are now operating will have to be given the patient. This explanation may at first fall on deaf ears, but as the therapist consistently demonstrates their existence from the patient's reactions and patterns, the patient may eventually grasp their significance. The desire to make oneself dependent and the destructiveness of this impulse, the connection of suffering and symptoms with a pervasive desire for punishment, the masochistic need to appease a sadistic conscience that derives from a bad parental introject, the operation of a devalued self-image and the subversive gains that accrue from victimizing oneself, must be repeated at every opportunity, confronting the patient with questions as to why the patient needs to continue to sponsor such activities.

Sometimes a general outline of dynamics, such as will be detailed later (illustrated in Fig. 37-1) may be offered the patient with the object of either stirring up some anxiety for analysis or of providing the patient with an interpretation that fosters better self-understanding. Although some neurotic drives and defenses are probably typical in our culture of both "normal" and neurotic individuals, the specific modes of operation and the kinds of symptoms and maladjustments that exist are unique for each individual. Every person has a thumb, but patterns of thumbprints are all different. The therapist, employing a blueprint such as Figure 37-1 may try to fit each patient's problems into it and then choose for focus whatever aspects are most important at the moment. For example, a man may during a session complain of a severe headache and thereafter proceed to beat himself masochistically, blaming himself for being weak and ineffectual. The therapist should then search to see how this trend affiliates itself with guilt feelings and what immediate situation inspired such feelings. The therapist may discover that what is behind the guilt is anger in the patient at his wife for not living up to his expectations in executing her household duties. Further probing may reveal anger at the therapist for not doing more for the patient. Such transference manifestations may enable the therapist to make a connection with the patient's mother, toward whom there has existed since childhood a good deal of anger for her neglect and rejection. This will open up a discussion of the patient's excessive dependency needs and the inescapable hostility, low independence, and devalued self-esteem that dependency brings about. An association may be established between the patient's hostility turned inward and the

migraine headaches for which therapy was sought in the first place. The therapist should in this way take advantage of every opportunity to show the patient the interrelationship between the various drives, traits, and symptoms, keeping in mind that though a certain trend may encompass the patient's chief concern at the moment, it never occurs in isolation. It is related intimately to other intrapsychic forces even though the connection may not be immediately clear.

An individual can make a reasonable adjustment for a long time even with a vulnerable character structure. The patient's personality, defective as it may have been, still operates harmoniously; various balances and counterbalances maintaining the psychological equilibrium. Then because of the imposition of an external crisis situation or because of stresses associated with inner needs and external demands, anxiety, depression, phobias, and other symptoms appear. The patient may consider that adjustment prior to the presence of some precipitating factor was satisfactory if not ideal, with no awareness of how the tenuous personality interactions have been sponsoring various symptoms and ultimately had produced the patient's breakdown. The patient is very much like a man with back pain who credits his "sciatica" to one incident of lifting a weight that was too heavy, oblivious of the fact that for months or years he has, through faulty posture and lack of exercise, been accumulating weak and strained muscles.

Thus patients whose self-image is being sustained by a defense of perfectionism for as far back as they can remember will have to perform flawlessly even in tiny and most inconsequential areas of achievement. To perform less than perfectly is tantamount with failure and signals inferiority and a shattered identity. The merciless demands they keep making on themselves may be impossible to fulfill. At a certain point when unable to face up to demands in some truly important situation, the failure will act like a spark in an explosive mixture. The resulting symptoms that finally bring them into treatment are depression and insomnia. It will require little acumen for a therapist to spot the perfectionistic trends around which the patients fashion their existence. But to argue them out of the perfectionism and to counter the barrage of rationalizations evolved over a lifetime are difficult, if not impossible, tasks. We may, nevertheless, attempt to work with

cognitive therapy and select perfectionism as a focus, pointing out the distortions in logic that govern the patients' thinking process. Not all therapists have the skill and stamina to do this, nor is there yet sufficient data to testify to the efficacy of this approach in all cases.

What would seem indicated is to review with the patients the implications of perfectionism, its relationship to the defective self-image, the sources of self-devaluation in incomplete separation-individuation, the operations of masochism, and so forth. Obviously, the therapist must have evidence to justify these connections, but even though the therapist presents an outline to patients of possibilities and stimulates the patients to make connections for themselves the therapist may be able to penetrate some of the patients' defenses. In the first part of therapy, psychodynamic explanations usually have little corrective influence. They simply may stir up the patient's curiosity and perhaps mobilize some defensive resistance, which may become a productive focus. Giving the patients a general idea about personality development may be occasionally helpful, especially when insufficient time is available in therapy to pinpoint the precise pathology. Patients are usually enthusiastic at first at having received some clarification and they may even acknowledge that segments of the presented picture relate to themselves. They then seem to lose the significance of what has been revealed to them. In my experience, however, later on in follow-up many patients have brought up pertinent details and have confided that psychodynamic explanations stimulated productive thinking about themselves. (See also Chapters 39 and 44.)

Part III.
The Middle Phase of Treatment

Once the working relationship is consolidated, and patients accept a more active role of working on their problems, we enter the middle stage of treatment. This has as one of its objectives the revelation of what is behind the patients' symptoms and behavior. It embraces a more precise delineation of behavioral excesses and deficits as well as the internal and external reinforcing agencies that enervate them. The extent of such determination will depend on the goals of our therapeutic effort. In supportive therapy we may merely seek to identify and to bring patients to an awareness of discordant elements in their environment that activate their turmoil, so as to help us in their control. Here, an examination of factors that promote the situational entanglement and study of the effects on patients of their disturbance may be all that is attempted. In reeducative therapy there may be an exploration of the patients' more conscious interpersonal reactions, the ensuing difficulties that follow expression of their personality patterns, and the provocative individuals and situations that keep existing distortions alive. These therapeutic tasks are implemented by the conventional interviewing techniques.

In reconstructive approaches, the task is more ambitious since the level of exploration is on unconscious strata of mind. The symbolic extensions of unconscious conflicts are explored through a number of techniques that will presently be described. The contamination of rational behavior with derivatives of the unconscious is investigated and analyzed. There is also an inquiry into the genetic origin of the individual's conflicts, the determining childhood experiences that initiated and produced character distortions and maladaptive mechanisms of defense.

The underlying dynamics as they disclose themselves during the middle phase of therapy will be specific for the individual. While a great deal of variation exists in patterns of defense, it is possible to propose a few general propositions.

In the main, the individual who possesses an emotional problem is suffering from defective conditioning that cripples the capacities for adaptation. Conditioning is a universal process in learning. From birth on, the individual is constantly reacting to primary (unconditioned) stimuli that occur jointly with secondary (conditioned) stimuli. If this linkage continues for a period, the secondary stimulus, though adventitious and unrelated, is apt to evoke the same response as the primary stimulus. This association tends to become reinforced or to diminish and become extinct according to how consistent the two stimuli appear together. A generalization of the conditioning may occur, the individual responding to parts of the unconditioned stimulus. For instance, in learning any language there is a constant reinforcement of the conditioning of words (written or spoken) to objects and feelings until the word evokes the same responses as the objects and feelings. Attitudes and values likewise evolve from conditioning to rewards and punishments that are presented for specific kinds of behavior. Soon a host of external reinforcing situations, objects, and people accumulate that provoke various reactions. They may serve in this way as realistic sources of stress, promoting symptoms and defenses.

Symptoms and defenses are also the outcome of many conditioned inner reinforcers that affect the person's feelings of security, self-esteem, relationships with people, and capacity to express basic needs and demands. The primary sources of these inwoven mischief mongers are disorganizing life experiences that date back to the very earliest contacts of the child with parents and other important persons in the past. Distortions in values and attitudes engendered by unfortunate conditionings with parental agencies remain even in maturity, and the person usually reacts to life with archaic fears, frustrations, and hostilities, many of which singularly are little modified by adult experiences. It is as if the epoch of childhood creates the paradigms in adult life that reflect the very values and contain the same expectations of injury that the individual had as a child.

The consequence of disturbances in security feelings, self-esteem, and interpersonal relationships caused by unfortunate early conditionings is to make the individual

vulnerable to even average deprivations and vicissitudes. This is registered in terms of a failing life adaptation, when inner conflicts exert their pressure and external demands tax the coping capacities of the person. Earliest signs of adaptive disorganization are tension, anxiety, and the psychophysiologic components of anxiety. The latter symptoms, universal phenomena in neuroses, provoke the ego into marshalling all the defensive instrumentalities it has at its disposal to bring the individual to a psychic equilibrium. Anxiety and its attendant physiologic reactions are so destructive to the person that attempts to cope with it are always made.

Many symptoms the individual displays in response to the stimulus of anxiety serve to defend against the effects of this emotion. They defend also against the initiating conflicts themselves. Why different symptoms and syndromes are elaborated in different people to cope with essentially the same kinds of conflicts is a challenging question, the answer to which is not entirely clear.

The knowledge that symptoms arise out of failure of the individual in dynamic dealings with life, has, in recent years, tended to displace the emphasis in treatment from symptomatic relief to reconstructive betterment of relationships with other people. What a therapist hopes to effect in reconstructive therapy is a building of security in the person so that an individual no longer feels menaced by fears of the world. In addition, self-esteem must be enhanced to the point of self-confidence, assertiveness, and creative self-fulfillment. Each individual must gain self-respect without striving for perfectionism or superiority. Relationships with people must become harmonious and shorn of such impulses as dependency, detachment, and aggression. Finally, one must become capable of satisfying inner needs and demands without anxiety and in conformity with the standards of the group. Not every patient is capable of achieving the ideal goal in therapy of major personality rehabilitation; yet the therapist has a responsibility in promoting in each individual as extensive a growth in personality as is reasonably and practically possible.

Personality change is catalyzed by helping the patient in psychotherapy to arrive at an awareness of the operative forces within the self. This process is characterized by

progressive stages of self-understanding and steps of adaptive action, which, in the main, may be delineated as follows:

1. Elaboration by the patient of symptoms and complaints

2. Discussion of feelings associated with symptoms

3. Relation of feelings to dissatisfactions with the environment.

4. Recognition of repetitive patterns of behavior and appreciation of their responsibility for disturbed feelings

5. Awareness of dissatisfaction with behavior patterns, but realization of their compulsive persistence

6. Cognizance of the functional nature of behavior patterns

7. Exploration of preponderant patterns and the determination of their origin in early relationships

8. Disclosure of the archaic nature of the patient's disturbing life trends and mechanisms of defense

9. Challenging of early attitudes

10. Serious consideration of rights to a more productive life

11. Intense dissatisfaction with current patterns, insecurities, and devaluated self-esteem

12. Experimentation with new modes of behavior

13. Liberation from old values and types of action

14. Evolution of greater security, assertiveness, self-esteem, and a sense of mastery

15. Development of a different conception of oneself, of more constructive interpersonal relationships, and of greater capacities for the expression of personal needs

These stages of understanding and adaptive action are never pursued by the patient

in as rigidly sequential a manner as has been outlined. There is generally a shifting back and forth, and, as one pattern is discovered and explored, new discoveries are made that call for further elaboration.

The principle techniques by which the therapist helps the patient to the acquisition of self-understanding are (1) interview procedures, (2) free association, (3) dream analysis, and (4) the examination of attitudes toward the therapist, including transference.

39
Identifying Important Trends and Patterns: The Use of Therapeutic Interviewing

In all forms of psychotherapy, except Freudian psychoanalysis, the focused interview is the chief exploratory vehicle. From material obtained in the initial interview and during the early sessions the therapist will have some idea of the sources and dynamics of the patient's symptoms. Of these the patient may be fully conscious, partially conscious, or, more rarely, completely unconscious. If our goal in therapy is at least some personality reconstruction, underlying causes and dynamics are investigated through such techniques as maintaining the flow of verbalizations, directing their course through selective focusing, and devices like accenting, summarizing, restating, reflecting, establishing connections, and maintaining tension in the interview. It is imperative to become thoroughly conversant with the principles of interviewing that have been described in Chapter 19, "The Conduct of the Psychotherapeutic Interview." For without a good understanding of interviewing, the therapist will be handicapped in carrying the patient through the middle phases of therapy.

In attempting to identify important patterns during the interview, the therapist may listen carefully for a dominant theme that tinctures the patient's verbalizations. Sometimes unexpressed feelings are as significant or more significant than the verbalizations themselves. The patient's nonverbal behavior also reveals many important clues. Slips of speech, hesitations, blocks, evasions and changes in content may furthermore give warning of conflictive areas. The therapist must constantly be sensitized to evidences of conflict in the various concerns of the patient.

The following excerpt is an illustration of how insight may be gained through focused interviewing. The patient, an associate editor on a magazine, interested in music as a possible profession, brings up an incident in her work with an orchestra that arouses in her a destructive neurotic pattern.

Pt. I was getting along fine, but then things started to go wrong, *{pause)*

Th. Wrong? (*repeating the last word to focus on the source of the difficulty*]

Pt. Everything went bad. My head hurt and my stomach kicked up badly.

Th. How long did this go on? *[attempting to focus the patient's attention away from symptoms]*

Pt. It all started vaguely about 2 days ago. *(pause)*

Th. Anything happen at that time? *[probing for a cause]*

Pt. Nothing unusual … I've been menstruating and have a lot more pain than usual. I listened to a recording of our orchestra last Tuesday, and it sounded very bad, particularly in parts where I came in. [*The patient advances environmental happenings that may or may not be causative.]*

Th. How did this make you feel? *[focusing on feelings]*

Pt. Well, I'm disgusted. I wonder why they have to have a group of inexperienced people with us. It makes me feel no good, too. *[What comes to mind at this time is, first, that the patient is resentful and cannot adequately express her resentment and, second, that she is blaming and devaluating herself.]*

Th. This disgusts you. *[repeating the patient's expressed feeling]*

Pt. Yes, I'm furious at them, but it's impossible to say anything. *[This sounds like suppressed or repressed hostility.]*

Th. That must be very frustrating *[expressing sympathy with how the patient feels]*

Pt. Yes, it is. How can they expect to have a good orchestra if they include beginners? *[The patient apparently seeks approval here for her resentment.]*

Th. It does sound unreasonable, *[backing the patient up in her feeling]*

Pt. I am so mad that I feel like quitting. *(clenches fists)* *[Apparently my encouragement helped to mobilize this aggression.]*

Th. Mm hmm.

Pt. But I know I won't, *(pause)*

Th. You must get something out of wanting to stay in the orchestra in spite of how bad things are. *[inquiring about positive values in here present situation]*

Pt. I don't think anything is worth what I go through.

Th. Then you may have the temptation to give up your place in the orchestra in spite of any

possible good it does you.

Pt. But why should I be pushed out of a good thing? *[Apparently there are many positive values in her present situation.]*

Th. Yes, why should you? *[supporting the patient in her determination]*

Pt. (pause) You know, I ordinarily would get mad and then quit. I've done this about many things all my life—school, jobs, everything. I'd get mad and then blow everything up. It's awful. *[Patient recognizes a destructive pattern related to how she handles frustration and hostility. This insight should be of value to her.]*

Th. There must have been a reason why you did this, *[focusing her attention on causes]*

Pt. I'd get so mad, I'd be willing to blow everything up, including myself. I'm not going to let myself be maneuvered out of the orchestra though. I'm not going to be that silly.

Th. But your anger may be hard to control *[warning her of possibilities of repetition of her neurotic behavior]*

Pt. Yes, I know, but I won't let it—at least now I won't *[Her understanding of her resentment encourages more rational behavior.]*

The focus in interviewing may be on the patient's symptoms, feelings, environmental dissatisfactions, interpersonal relationships, past history, and slips of speech and on the therapist's intuitive understanding of the patient's problems.

FOCUSING ON SYMPTOMS

Concentration on symptoms is of primary concern in supportive and some reeducative approaches like behavior therapy. While some symptoms are surface manifestations of deeper problems, a careful exploration of their content and function and of the patient's attitudes toward them may reveal important facts about past conditionings, reinforcing situations and people, repudiated impulses, as well as defenses against the impulses.

Focusing on symptoms in reconstructive approaches is largely for the purpose of demonstrating their relationship to underlying feelings. Sexuality seems to be overweighted in our culture and many patients concentrate on their disturbed or inhibited sexual life when they come to therapy. Since sex may preoccupy them, they may

not be aware that this aspect of their functioning is only one dimension of their problem. This will be apparent in many of the interviews reproduced in this book. The therapist should at all times never be sidetracked by this focus and should attempt to place sexual and other symptoms into proper perspective. In order to do this, the patient's attention should be brought to undercurrent emotions whenever sexual and other symptoms are brought up. It is important also to explore the relationship of symptoms to definite life situations. If the therapist knows how to employ dreams, these may be used advantageously to establish the connections of symptoms with feelings and causal life situations.

A patient who had come to therapy because of depression following the rupture of a love affair started a session with the complaint of a skin symptom. Focusing on the symptom brought out the fact that it was a conversion phenomenon, resulting from certain conflicts of which the patient became aware during interviewing.

> *Pt.* Margaret was in my apartment no more than 2 hours when I noticed my arm itching. I took off my jacket. *[Margaret is the young woman with whom the patient is having an affair, after the violent rupture of a relationship with another young woman.)*
>
> *Th.* Where was the itch?
>
> *Pt.* On both arms, the round surface up here just below the elbow, like a band.
>
> *Th.* I see.
>
> *Pt.* It started in the left arm, and then it spread to this arm in the same place.
>
> *Th.* Exactly the same kind of band?
>
> *Pt.* Yes, and several hours after that I noticed a band about the size of 6 inches over the ankle on both sides. Almost like a wide bracelet.
>
> *Th.* Mm hmm.
>
> *Pt.* And immediately I thought, "Jesus Christ I'm itching." Funny I hadn't had it before. And Margaret said, "What are you so nervous about?" And then I started on her, "I don't know," I said, "I don't know what it is." *(pause)*
>
> *Th.* Now suppose you talk about the things that happened to you just before you got this itch, *[focusing on possible causes]*

Pt. Well, I was coming home from work and I decided to walk on Harriet's street where she lives. *[Harriet is the young woman with whom the patient was in love and who broke up the relationship.]* I passed Harriet's house and looked up and saw the light on and figured what's going on there. I'm itching like hell now. There must be a direct connection. This proves it. This itching is bad. I scratched so furiously I drew blood. So I said, "Jesus Christ that's stupid." So I put some salve on. Then I went to sleep with Margaret. I went to sleep, and I dreamed about Harriet. I dreamed I was back with her and I was suspicious as to what she wanted from me. She seemed to want to screw me, that is, get physically in me. I don't know if she was on my back, on the side, or what. She was bent forward in what I suppose was her driving position. I asked her why she was back, but she gave me no clear-cut answer except that she wanted "to get laid." Then I realized that she wanted to reduce me to impotence. I played along with her even though I didn't trust her. Then, in another room another girl came into sight. I thought I can lay this other dame. Do I owe Harriet anything? No. I don't trust her. I'll do as I want. I felt, the hell with her. *(pause)* That's all. *(pause)*

Th. I see. What are your ideas about that?

Pt. Well, you see, Harriet did make me impotent. That is, I got impotent with her. She kept comparing me with the other guys she screwed. She'd say, "Be a man and fuck me like the others did." It would make me furious. I'd compare myself with them, and ask her about them. She kept telling me that I didn't rate much when it came to fucking.

Th. What do you think this did to you?

Pt. I got so I couldn't function with her and I got impotent.

Th. And then she threw you out.

Pt. That goddamn bitch. I hate her. Margaret is such a better person. Considerate and kind, but … *(pause)*

Th. But … *(pause)*

Pt. I shouldn't feel so dissatisfied with her.

Th. But you do.

Pt. I must. I keep on thinking about Harriet. The other days when I walked by her house—I do that now a lot—I would look up at her room and feel relieved that the place was dark. Then I'd figure where else is she, and I'd say that she must be screwing in somebody else's apartment, not her own. But I'd push that out of my mind. This time when I saw the light, I felt very upset. I said to myself that she is half undressed or she's all undressed. She's in bed with a guy. He's undressing her or she's undressing him. I don't know who the guy is. He's probably a son of a bitch who doesn't look anything like me.

Th. What emotional effect did it have on you?

Pt. I thought to myself, it's amazing how little it concerns you: you have no reaction.

Th. It astonished you?

Pt. Where is the reaction there, I said. I'm going with Margaret. I've got a better girl. I thought I'd go home and make love to Margaret. So when I got home, there was Margaret, and then I got that goddamned itch.

Th. Mm hmm.

Pt. I kept thinking about what time this man with Harriet went home. Then I began to resent Margaret. I felt why can't Harriet be with me.

Th. In other words, Harriet still has more value to you than Margaret.

Pt. (scratching his arms) This itch is awful. I gradually moved into the position of asking Harriet to marry me. Every time I built up to the point she greeted me with complete silence.

Th. How do you feel about being with Margaret now?

Pt. I feel like I've got chains on.

Th. What kind of chains?

Pt. Tying me down, *(touches itching area of arm) (pause)* You know I just thought of something. I thought of chains in Egyptian times used to tie down slaves. You've seen pictures of them. I have seen pictures of them.

Th. What do the pictures look like?

Pt. Either there or here—bands of iron with the chain between them and anklets governing the size of the step. And, you know, the bands of irons on the arms and legs are like, in the same position as the areas of my itching!

Th. So the conclusion would be what?

Pt. That I'm wearing chains.

Th. And the scratching?

Pt. (excitedly) I want to tear them off.

Th. But these emotional chains you're wearing are what?

Pt. Jesus Christ, I feel a defiance. This thing is building up with Margaret. I was getting to think I was comfortable, but I resented the comfort. She's giving up her job, fluttering around, looking for this, looking for that. Basically she's here to stay because she wants to be with me. I feel as if I'm in chains with her. I don't want to marry her.

Th. So Margaret is your chain and you want to get rid of her. [*interpreting*]

Pt. But I know what is enslaving me. I don't want chains on me so I can go back to Harriet. But, shit, I don't want to go back to her; she's chains for me too. *[We thereafter discuss his masochistic*

FOCUSING ON FEELINGS

Feelings that are openly manifested or that lurk unexpressed behind verbalizations are extremely important aspects of the inner life of the person. Feelings cannot be isolated from intellectual and behavioral components, although anxiety may cause a dissociation. By constantly focusing on feelings and encouraging verbalization, a reunion of dissociated elements may be effectuated. Awareness of feelings and their meaning brings patients to an understanding of their relationships with people and to some of the basic sources of their symptoms.

Thus, patients may talk about their work situation. Sympathizing with their employer, they present an account of how difficult things must be for their employer. The responsibilities that confront the employer are so pressing that they would make anyone irritable and hard to approach. They feel sorry for their employer on this account, and they forgive the employer's rudeness. The therapist, legitimately suspecting that patients feel resentment they do not dare to express, or of which they are unaware, may decide to focus on latent hostility by saying, "Doesn't such behavior on the part of your employer irritate you?" or "I should imagine that your employer's attitudes would sometimes make you angry." This may liberate an acknowledgment of resentment and a more precise investigation of attitudes toward the employer and toward other authorities.

Other patients may be aware of strong sexual feelings in relation to a teacher. Such feelings preoccupy them a large part of the day. They have no idea of why the teacher has made so vivid an impression on them. The therapist, in order to help patients connect their feelings with attitudes toward the teacher, may say, "The teacher arouses certain feelings in you. Have you had similar feelings toward other people?" A description of previous situations in which sexual feelings were intense may reveal a succession of men or women with certain qualities. Asking patients what all of the men or women have in common may bring out the fact that they all resemble their older brother or sister of whom they were enamored as a child, and toward whom they had strong sexual feelings,

which made them feel guilty.

> During the treatment of a patient with a psychophysiologic intestinal disorder, a session was occupied listening to explosive outbursts directed by the patient at her children who were going through a recalcitrant, defiant stage in their development. She brought out several incidents in which one of her children demanded attention and she pushed him away. The patient berated herself for acting so heartlessly. As she spoke, I noticed what seemed to be a frightened expression on her face. Bringing this to her attention, she smiled with relief, and said, "You're right. I just realized that I am afraid, as if I expected you to beat me." She then revealed incidents where her father beat her for doing "wrong things."

In focusing on feelings, it is essential to help patients to a realization that many of their emotions are not rooted in reality, but rather they are derived from misconceptions about life, about people, and about themselves. The patients' attention may be directed toward a variety of aspects, such as the relationship of feelings to disturbing symptoms, the environmental situations that stir up untoward emotions, the repetitive patterns of behavior that provoke destructive feelings, and the relationship with the therapist.

In the following fragment focusing in the session on the patient's feelings of tension and discomfort helps to bring the patient to an awareness of how disappointed he is in his progress and how resentful he is toward me. He realizes that his resentment conflicts with the pattern of constant need for approval and that his inability to express resentment fosters his symptoms.

> *Pt.* I have a funny feeling of uneasiness that's been with me all day, all week, I mean.
>
> *Th.* Any clues to this feeling?
>
> *Pt.* No, just my feeling bad. Even yesterday I felt like throwing up.
>
> *Th.* When did this uneasiness get most uncomfortable?
>
> *Pt.* Just before coming here, *(pause)*
>
> *Th.* Just before coming here?
>
> *Pt.* I think I'm disappointed that I'm not better than I am. I've been coming here 2 months now. I feel I've accomplished nothing. I can't put it more bluntly.
>
> *Th.* Well, you have a right to feel disappointed if you expected an immediate cure. Sometimes, rarely, this happens, but usually it takes a period of time before a person learns about

patterns that stir up symptoms.

Pt. This whole week of complete tension made me think. But I could only think of my tension. I can't organize my thoughts. These thoughts are meaningless to me until I get so bad I have to force myself to think and try to solve my problem.

Th. Mm hmm *(pause)*

Pt. I feel insecure and inferior, and I need approval. Why do I need this approval? Because I have no security in myself. So I need somebody else's approval. So I don't act on my own motives. I try to be a smiling servant to everybody, to gain their good graces, to gain their approval. I lower myself to kiss everybody's behind to get their approval. Now why I haven't I got confidence in myself?

Th. That's a good question. If you need approval from the outside and have no confidence from within, there are reasons for it.

Pt. Why don't I have that self-security or self-approval?

Th. Well, what do *you* think?

Pt. I don't know, *(smiles)* But I do think you are helping me.

Th. But that isn't what you were just telling me.

Pt. Well … *(pause)*

Th. Could it be that you tell me this to get *my* approval—right now, I mean?

Pt. I know I told you I was disappointed in therapy. Maybe it doesn't make any difference what you think. I'm coming here and paying my hard-earned money and I have a right to say it.

Th. You have a right to say what you feel.

Pt. Maybe … wouldn't it be enough to cause tension for me to want to criticize you if I needed your approval, like I need everybody's approval? *[This sounds like insight.]*

Th. It might be.

Pt. So, if I get furious with you, that would be enough to make me feel that you wouldn't give me approval if I told you. And that could upset me like I was upset. But now that I've told you, I feel relieved and not upset any more.

FOCUSING ON ENVIRONMENTAL DISSATISFACTIONS

Environmental problems are suitable foci of attention; however, only rarely are reality circumstances entirely responsible for the patient's condition. Catastrophic life

happenings occasionally do occur in the form of accidents, inclemencies of nature, disasters of war, death of close relatives and friends, and financial and prestige losses. Operative also are pressures of desperate economic circumstances, unemployment, inimical work conditions, unhappy choice of occupation, bad housing, disturbing neighborhood, abnormal cultural standards and pressures, and exposure to destructive family members and mate. The *reactions* of the patient to the environment, however, are usually more important than the environmental distortions themselves.

Most persons project their insecurities, fears, guilt feelings, and hostilities onto their environment. The presence of disturbing life circumstances that seem to justify these attitudes and emotions may satisfy needs and expectations; their absence may create a void in life and perhaps incite one toward involvement in some situational difficulty. Thus, individuals who are intensely hostile may manipulate their environment in such a way that they can conveniently vent their hostility on it. They may entangle themselves in relationships with aggressive or domineering people or get engulfed in situations in which they are exploited. These conditions will tend to justify to themselves their own outbursts of hostility and to support their protestations that they are being misused. They will bitterly protest their plight, little mindful of the fact that they have created the very conditions of which they are so indignant. Indeed, where there are inadequate circumstances to warrant the deep hostility that they feel, they will experience depression, tension, anxiety, and various psycho-physiologic reactions. Environmental manipulation and other supportive efforts directed at the milieu rather than at the individual may fail utterly in their effectiveness here, or they may precipitate neurotic symptoms more incapacitating than those for which therapy was originally sought. Even in severe environmental distortions the personality of the patient must be taken into account as an important concern.

The following excerpt brings out how a patient gains an awareness of patterns of aggression through the consideration of her immediate life situation.

> *Pt.* My husband has been acting up constantly. Just doing mean things. I asked him if he would go out with me, and he said in a nasty way, "Don't intimidate me." Then he said, "Goodbye, you bitch." I had no desire to look at that bastard after that. Then I visited some old friends and

stayed out until 1 A.M. When I got home, he was waiting up for me. He screamed at me, "What the hell do you think you are doing." The nagging continued. He said, "A fine household I have." I told him to go the devil. He shook his finger at me. I pushed his hand away and told him to just stop that. I was going to hit him before he hit me. This marriage of mine is what's causing all my trouble, *(pause)*

Th. You must have felt very upset.

Pt. I was. He is so insulting all the time. I called him a son of a bitch, and then told him to go to hell and went to bed. I woke up 4 A.M. crying, and went over to him and woke him up and warned him. I said, "Why should you sleep when I can't." I shook him and told him I'd break his head open if he repeated it.

Th. You didn't want to let him get away with anything?

Pt. You're darned tootin'. And I won't. I won't with anyone. Anybody starts anything, and I finish it.

Th. What usually happens after you finish it?

Pt. That's just it. Nobody seems to understand. I make enemies.

Th. It is possible that any aggression toward you sets a process into motion where you explode a little too much? *[a tentative interpretation]*

Pt. I have to do what I do to protect myself.

Th. Mm hmm. *(pause)*

Pt. Maybe I *do* go to extremes though. *(pause)*

Th. Perhaps to protect yourself, you feel you have to go to extremes, *[more interpretation]*

Pt. But I do see that it can give people the impression that I'm an attacking bitch. I think I do go to extremes. Maybe I shouldn't explode the way I do. Maybe I cause some of my own troubles.

Th. Is this something you'd consider a pattern?

Pt. I can see that it's been with me many years. I used to be a timid thing, but my marriage made a change. I seem to have gone to the opposite extreme.

FOCUSING ON CURRENT INTERPERSONAL RELATIONS

Identification of basic patterns in relationships may be achieved through an examination of the patients' dealings with other people. The characterologic strivings of the patients in relation to authority, to compeers, and to themselves are, in addition to environmental happenings, a dominant theme in the interviews. Such strivings may

indicate why the patients' adjustment is being sabotaged. For example, they may anticipate criticism and attack from others. Accordingly, their life will be spent in fearful waiting, in detaching themselves from others, or in retaliatory counterattack. They may, in contemplating exploitation, assiduously avoid intimate contact with people and then act outraged at their isolation. They may feel forced to assume a submissive and ingratiating role and then burn inwardly at the indignation of needing to humiliate themselves in this way. They may be consumed by a power drive and want to domineer all persons with whom they have dealings. These aberrations will become evident as the patients talk about daily concerns and tribulations.

The relationship disturbances manifested by the patients will usually be vigorously defended by them, and they will attempt to justify such disturbance with rationalizations. They may even incite the individuals with whom they relate to provocations that precipitate the very reactions about which they complain. Repeated demonstrations are usually required before the patients recognize how they distort reality in line with their expectations.

It may be possible, therefore, by considering their immediate relationships with people, to bring the patients to an awareness of how their patterns influence their adjustment and maladjustment. Sooner or later they may express dissatisfaction with their patterns, but they will recognize the compulsive hold that such patterns have on them. They may realize, too, that their patterns serve a spurious and temporary function of enhancing their security and of bolstering their self-esteem.

The following excerpt illustrates how a consideration of current interpersonal relations may bring a patient to cognizance of important inner strivings. In the session the patient exhibits tension, and he relates it to a recent meeting with a woman who had attracted him. He becomes aware of ambivalent attitudes toward certain women.

> *Pt.* I just don't know what it is that upsets me, and I've been having lots of trouble.
>
> *Th.* Let's talk about it, and maybe we'll learn something about it.
>
> *Pt.* I don't know what it is. My wife is having trouble with the kids. She thinks I'm not sympathetic.

It's like I fear she'll attack or criticize me.

Th. Mm hmm.

Pt. And I met this woman and I found myself thinking about going with her. *(pause)* Having an affair, I mean.

Th. Mm hmm.

Pt. But I don't want to go out with her. *(pause)*

Th. Why?

Pt. I don't know. She's very attractive, but still … *(pause)*

Th. Anything to do with your wife and how she would feel?

Pt. Oh, no. It's more to do with her—the woman. I feel like irritating and teasing her.

Th. What does she mean to you?

Pt. I have a picture of her as a big wheel in the community. I think she is a person who likes to control things with men. I feel she doesn't want to be at home, wants to be a big wheel in the community.

Th. I see. *(pause)*

Pt. I'm a sucker for this kind of woman. Before I know it I'm up to my neck in trouble. I go for them, and then I can't get away. I feel like digging at this woman. Not that I'm mad at her personally, but she does something to me.

Th. The fact that you feel she's a big wheel in the community seems to have something to do with it. *[making a connection for the patient]*

Pt. I hate women who try to wear the pants. My first wife was like that. My mother was like that. Never home, always telling you what to do.

Th. But this type of woman seems to attract you.

Pt. Yes, that's the peculiar thing. I smell them out. At any party I make a beeline for certain women, and by gosh, there I am.

Th. What do you think this means?

Pt. Well, there's only one conclusion. I must be crazy about them and hate them too. I must want to suffer to get involved with them, but that's what I keep doing. *[This is the first inkling of awareness the patient had of this problem.]*

Th. It sounds like a vicious circle.

Pt. But I'm not going to call this woman I met (*laughs*) although I must admit the temptation is great.

Th. Well, that will at least give us an opportunity to investigate this attitude you have toward certain kinds of women.

FOCUSING ON PAST HISTORY

In supportive and reeducative therapy the past is relegated to a secondary position compared to events in the here and now. Yet inimical influences in early childhood, sometimes produced by improper handling by parents, sometimes by unfortunate experiences in relationship with other persons, can be catastrophic. Children whose experiences during early life are harmonious usually are able to evolve a system of security that permits them to regard the world as a bountiful place and to develop self-esteem that encourages assertiveness and self-confidence. They will be convinced of their capacities to love and to be loved. They will most probably possess character strivings that enable them to relate constructively to other persons and to express, through culturally condoned outlets, important needs. On the other hand, for those children who have been rejected, overprotected, or unduly intimidated, the world will constitute a place of menace. They will be devastated by fears and tensions. Their self-esteem will be warped to a point where they are overwhelmed by feelings of helplessness, by lack of assertiveness, and by loss of self-confidence. Relationships with people will be disturbed with the harboring of destructive attitudes toward others. Finally, inner strivings and demands will suffer repression in greater or lesser degree.

It usually will be discerned during interviewing that the patient projects onto others attitudes and impulses derived from relationships with important past personages. Thus, the individual may regard and treat certain people as rejecting mothers, punitive fathers, and jealous or hostile siblings, irrespective of the reality elements in the existing relationships. If early experiences with mother had conditioned the patient to expect that women are overprotecting, there is apt to be an automatic transfer of this attitude toward all women, or specifically toward those persons who symbolize in the patient's mind a mother image. As defensive gestures, one may observe in the relationships of the

individual toward others such attitudes as detachment, resentment, aggression, submissiveness, and masochism that have no affinity with the reality situation. Where the patient has been unfavorably conditioned by strong sibling rivalry in childhood, the response to people might be as if they were facsimiles of destructive brothers and sisters. The individual's social and work relationships will possess a pervasive competitive tinge that expresses itself in fears of being vanquished or in triumphing over others.

Other aspects of the past history are also important in understanding the life circumstances under which adjustment is most adept and maladjustment most apparent. Repetitive patterns will clearly be evident as one focuses on different epochs in the patient's past.

Through proper interviewing the patient may be brought to an awareness of trends and mechanisms of defense as they have manifested themselves in the past. The tracing of interpersonal patterns to their origins in childhood, their disclosure as archaic and destructive to reality functioning, will also enhance a challenging of early attitudes and a new conception of the self.

A patient with a personality problem of detachment, which had interfered with her capacity to establish a relationship with men, came to therapy because of a feeling that she would never get married because of her attitudes. Focusing on her past life brought out certain trends that were operating in the present.

> *Pt.* I feel that I have the capacity to feel, but I feel impersonal about everything. I've had this feeling as far back as I can think. With my father I was given the basic necessities of life—food, clothing—but aside from that there was nothing.

> *Th.* Nothing?

> *Pt.* One never dreamed of going close to him for anything. I remember when I was little I would run to him, but he would keep pushing me away. I felt it was wrong to need him. I felt awful when I was little, but then I felt all right. At school I had some friends, but I never felt close to them.

> *Th.* Did you ever feel warm and close to any person in your past?

> *Pt.* Yes, I had a music teacher. I felt he knew me and understood me. I felt that he was like God. But I hated him too. He seduced me. I couldn't resist him. I felt awful about the thing.

Th. Mm hmm.

Pt. I remember once my father came home with a box of candy. He handed it to me, and I was so happy I cried. Father asked me why I was crying and I didn't know.

Th. Do you know why now?

Pt. I believe that meant to me he preferred me. But he didn't. He said, "That's for your mother, bring it to her." I cried and cried and never got over it. I felt it was better not to expect anything.

Th. Not to expect *anything?*

Pt. From people I mean.

Th. Could that account for one of the reasons why you can't feel anything now? *[interpretation]*

Pt. You mean a feeling I might be disappointed. *(cries)* I do expect that all the time.

OBSERVATIONS OF SLIPS OF SPEECH

While slips of speech do not happen frequently, focusing on them when they do occur may reveal significant patterns. A young woman, in a defiant relationship with her father, showed a poor response to therapy during the first few months. During one session she exhibited a slip of speech that revealed rebellious attitudes toward any type of control.

Pt. I just don't know what I'm getting out of life right now.

Th. What are you getting out of coming *here* right now?

Pt. I come here to get well—that's my *blame, [slip of speech]*

Th. That's your *blame?*

Pt. Did I say that? I mean that's my *aim.*

Th. You said "blame." I wonder if you blame yourself.

Pt. (blushes) Maybe I'm ashamed of myself.

Th. Ashamed of coming here?

Pt. I just think I don't want to get well to annoy you.

Th. To annoy me?

Pt. You know that I'm capable of doing anything, and I slop around so.

Th. Maybe you are slopping around for my benefit, *(smiles)*

Pt. (blushes) I don't want you to get too controlling. I feel if you would only leave me alone.

Th. You feel I control you?

Pt. Yes, I do.

Th. How?

Pt. Not so much control as I need to do things for myself. I don't want you to interfere.

Th. Am I interfering?

Pt. This is what's funny. You don't, but I think I do feel you do. I don't like anybody controlling me.

Th. But why do you come here then if I do these terrible things to you?

Pt. I look on you as my bridge to health. I don't want to be this way. I don't like to slop around. I can see this is something I do all the time. Even good things I throw away because the goodness spells danger in my standing alone.

Th. So that your "blame" in coming here is in not wanting to do what part of you wants, which is health? *[interpreting the slip of speech]*

Pt. I'm being a horror by fighting everybody. I know. Why do I act so rebellious?

Th. That's a good question. Let's start investigating that.

USE OF INTUITION

Sometimes therapists have to depend on hunches and intuition in perceiving what is going on in the patient. By self-observation therapists may recognize certain emotions in themselves that are evoked by what the patient is saying or not saying (countertransference). They may use this intuitive feeling in various ways, as by questioning, reflecting feeling, focusing, and interpreting. A sensitive therapist with a great deal of experience may be able to perceive nuances through this use of intuition that escape the usual observational methods. *Intuition* is probably a misnomer, for the skill alluded to does not just automatically happen; it is acquired by a sensitive and astute therapist with good clinical judgment who has had extensive clinical experience. A

seasoned therapist is best capable of utilizing countertransferential feelings constructively. These are especially important indicators of what is going on unconsciously in the patient, being manifestations of projections from the patient that are subtly being communicated to the therapist.

40
Identifying Important Trends and Patterns: The Use of Free Association

Free association is rarely employed in psychotherapy, except in some forms of reconstructive therapy especially classical psychoanalysis in which it may constitute the primary kind of communication. The use of the couch position, the extreme passivity of the therapist, and the removal of the therapist from the line of vision of the patient reduce the influence of reality to a minimum. This encourages internally inspired stimuli. As a result, thought images reflect unconscious dynamic conflicts and impulses that come to the surface in a more or less direct form. The therapist listens to these with what Freud referred to as an "evenly-hovering attention," without selection of material. The therapist sensitizes himself or herself to what is behind the verbalizations and to the appearance of unconscious derivatives.

Free association also encourages transference reactions, grist for the psychoanalytic mill. Patients must be trained to associate freely. Verbalization of thoughts without restraint is often very difficult, because obscene ideas, distressing recollections, and offensive notions concerning the therapist may press for expression. As a defensive gesture, patients may exhibit blocks in their stream of thought, or they may try to protect themselves by going off into reverie. Impulses and strivings even at the periphery of awareness may be so repulsive that the person may not dare to permit himself or herself to think of them.

Some resistances to free association are relatively superficial. Patients may believe that the therapist considers their fears and fantasies absurd because they, themselves, consider them ridiculous. They may want to analyze their impulses and actions beforehand, since they anticipate censure, or they may feel that the therapist will think more of them if they analyze their problems without help. There may be a conscious need to maintain control, with resistance extended toward the revelation of significant material.

An intense fear of failure may foster an inability to utter what comes to mind.

By far the majority of resistances to free association are unconscious in nature. Patients may want to cooperate, but whenever they attempt to verbalize fantasies and thought images, they experience, to their consternation, anxiety that blocks their efforts. They may not even be aware of anxiety because memory of the traumatic material is so fleeting that it never actually occupies the field of attention. In some cases the character structure acts in resistance to free association. The individual's pattern of life, for instance, may be so stereotyped that little or nothing spontaneous is allowed to intrude itself. Fear of expressing hostile or erotic impulses may prevent letting oneself go, or that exposing one's thoughts will reveal one's ineptness or contemptibility. On this basis, one may exhibit a mental or vocal inertia that can develop into mutism.

The following example of free association demonstrates how a 38-year-old female patient with a phobic disorder gains an understanding of certain unconscious conflicts.

Pt. So I started walking, and walking, and decided to go behind the museum and walk through Central Park. So I walked and went through a back field and felt very excited and wonderful. I saw a park bench next to a clump of bushes and sat down. There was a rustle behind me, and I got frightened. I thought of men concealing themselves in the bushes. I thought of the sex perverts I read about in Central Park. I wondered if there was someone behind me exposing himself. The idea is repulsive, but exciting too. I think of father now and feel excited. I think of an erect penis. This is connected with my father. There is something about this pushing in my mind. I don't know what it is, like on the border of my memory, *(pause)*

Th. Mm hmm. *(pause)* On the border of your memory?

Pt. (breathes rapidly and seems to be under great tension) As a little girl, I slept with my father. I get a funny feeling. I get a funny feeling over my skin, tingly-like. It's a strange feeling, like a blindness, like not seeing something. My mind blurs and spreads over anything I look at. I've had this feeling off and on since I walked in the park. My mind seems to blank off like I can't think or absorb anything. *[This sounds like a manifestation of repression, with inhibition of intellectual functioning, perhaps a way of coping with the anxiety produced by a return of the repressed.]*

Th. The blurring of your mind may be a way of pushing something out you don't want there. *[interpreting her symptoms as resistance]*

Pt. I just thought of something. When father died, he was nude. I look at him, but I couldn't see anything, I couldn't think clearly. I was brought up not to be aware of the difference between a man and a woman. I feared my father, and yet I loved him. I slept with him when I was very little, on Saturdays and Sundays. A wonderful sense of warmth and security.

There was nothing warmer or more secure. A lot of pleasure. I tingle all over now. It was a wonderful holiday when I was allowed to sleep with father. I can't seem to remember anything now. There's a blur in my mind. I feel tense and afraid.

Th. That blur contaminates your life. You are afraid of something or afraid of remembering something, *[focusing on her resistance]*

Pt. Yes, yes, but I can't. How can I? How can I?

Th. What comes to your mind?

Pt. Sunday I got stomach pains. I was depressed and frightened. I started crying. I wanted to hold onto mother. What is the use of becoming aware of needs if you can't satisfy them. I had a dream that night. A group of army officers in my sister's room. I felt jealous. They weren't interested in me. Then I was on the water. One man was walking on water with no legs. He walked confidently. I asked him where his legs were, and he said that when he had legs, he felt strong and masculine. Then I see flowers and I feel lost. Then I am on a ruined street. I see an old horse, emaciated, waiting to be slaughtered. I'm horrified, sick, upset. I have flowers, but everybody criticizes them. I felt they weren't good. And that's all.

Th. What do you associate to the dream?

Pt. I felt the officers kissed my sister and mother and not me. I feel father give my sister and mother everything and not me. I wanted to look into the room where the officers were with my sister, but my mother wouldn't let me. I was mad. I remember a part of the dream where I saw condoms in a box. I felt my sister could have it and not I. I feel deprived and helpless, like a mutilated person. That must be me walking on the water. I walk, but like a cripple. I want to be strong and not weak. Men are strong. My father wouldn't let me grow up. My sister has a husband and I don't have one. She has everything. I have nothing. Not anything that is worthwhile. What I have is not much. I always wanted to be strong. I used to fantasy being a boy and having a penis. I suppose the flowers in the dream are my femininity. I put little value on myself. I realize now how bitter I feel toward father for not devoting himself to me. [*The patient goes on to correlate her incestuous wishes, her castration fears, and her penis envy.*]

Free association, despite its serious limitations (Marmor, 1974), is one avenue to unconscious sources of problems that may be essential in the more formal analytic procedures.

Identifying Important Trends and Patterns: The Use of Dreams and Fantasies

In all forms of psychotherapy dreams give the therapist important clues—not only about dynamics, but also about the therapeutic process itself. The use that is made of dreams will depend largely on the skills of the therapist. In supportive therapy dreams help the therapist perceive more accurately the inner responses of the patient; however, the dream material itself is not usually discussed. In reeducative therapy therapists who are adequately trained may utilize dreams with the object of detecting resistance. In reconstructive approaches dream analysis is constantly employed and is considered indispensable for the proper implementation of therapy.

Properly utilized, dreams illuminate the existing dynamics of emotional illness. They reveal conflicts, coping mechanisms, defenses, and character traits. Most importantly, they reflect what is going on and the patient's responses to the therapeutic process. Thus, where therapy is not proceeding well, dreams may reveal more than any other form of communication what resistances are obstructing progress. Even if the therapist does not laboriously work out the meaning with the patient, as in supportive and reeducative therapy, dreams may still provide guidelines for circumventing roadblocks to the most effective use of techniques.

What are dreams? We may conceive of them as images or fantasies that are an intrinsic part of normal sleep. We know from human experiments that dream deprivation (interfering with dreaming by awakening the subject when there are physiological—REMS [rapid eye movements]—or electroencephalographic evidences of beginning to dream) can produce personality aberrations. We have learned a great deal about dreams from contemporary dream research. The REM periods during sleep that are accompanied by dreaming have been found to be associated with activity in the limbic system, the primitive portion of the brain associated with the emotional life of the individual. This

lends emphasis to the theory that the dream is a regressive phenomenon. However, we are merely talking here of the neurophysiological activity that sponsors the formation of dream images, not of their specific content or significance, which may involve other dimensions than regressive emotional ones.

Relaxation of ego controls liberates needs and impulses that, lacking opportunities for motor release, find access in sensory discharge. The content of the dream draws from past impulses, memories, and experiences as far back as early childhood. The conversion of repudiated drives and desires into dream images sets into motion oppositional defenses and prohibitions that may appear in the dream in a direct or masked way. Immediate experiences and current conflicts participate in the structure of the dream. It is likely that a happening in daily life that the individual interprets as significant serves to stir up important needs, frustrations, memories, and drives from the past. The latter, constantly dormant, invest certain immediate experiences with special meaning, alerting the individual to signals that in other persons would go unnoticed.

Some years ago, I initiated a group of experiments in the hypnotic production of dreams. Dreams under hypnosis range from fleeting fantasy-like productions in light trance states to, in deeper stages of hypnosis, highly distorted symbolizations akin to regular dreaming during sleep. I found that hypnotic dreams could easily be triggered by immediate stimuli and that from the content of the dream one could not always identify the specific provocative stimuli that produced the dreams. Thus bringing an open bottle of perfume under the nose of a person in a trance, with no verbal suggestions to influence associations, would in some individuals inspire a dream that revived memories of previous experiences. At different times the same stimulus acted to provoke different kinds of dream content. For example, in one subject the perfume initially touched off a dream of being scolded by a maternal-like figure, the subject crouching in guilt. No other dreams or fantasies were recalled. On rehypnosis the subject was asked to redream the same dream and to reveal it in the trance. She brought up a pleasurable sexual dream, which was followed by a second punitive dream identical to the one previously described during the waking state. Apparently the subject had repressed the initial part in the first

trance, denying the content and reprocessing it by elaborating the punishment scene. The punitive dream might be considered equivalent to the manifest content, those manifestations acceptable to the patient. The repressed portion could be regarded as the latent content that the patient could not accept. On another occasion the perfume stimulus created a dream of wandering through a botanical garden.

The mood of a dream also fashions the dream content. An upset patient during hypnosis utilized the sound of a bell that I rang to elaborate a dream of fire and fire engines with reactions of anxiety. At another session, during a quiescent period of this patient's therapy, the same sound produced a dream of worshipping in a church. A disturbed female patient at the beginning of therapy interpreted my touching her hand during hypnosis adversely by dreaming of a man choking her. Later in therapy the same stimulus produced a dream in which her father was embracing her tenderly.

The dream content is additionally subject to changes of attitude on the part of the dreamer. For example, a patient on being asked to bring in dreams responded with the following written comments to this suggestion:

> The doctor requests that I dream. He is interested in helping me, so I better dream. In dreaming I am pleasing his authority, so why should I dream just because he asks me to. He is trying to force me to do what *he* wants. But I want to do what *I* want to do. I may not want to dream. But if I don't bring in a dream, the doctor will be displeased. Should I defy him or should I please him? What will happen if I don't dream? What does he want me to tell him? If I dream and confirm what he has said about me, he will like me. If I dream opposing his ideas about me, he will not like me or he will punish me. If I don't dream or I dream something that opposes his ideas, this will make me feel strong and superior. I do want to find out about myself so I can get well, since my therapist tells me this is how I can help him help me. This is why I should dream. But I am guilty about some things and afraid of some things, and I am afraid of what I will find out about myself if I dream. So maybe I better not dream. Maybe I'll find out something about myself I don't like. It is normal to dream, and I want to be normal. But if I do dream, I have a better chance of getting well, but getting well will throw more responsibility on my shoulders. I'll have to be more independent, take responsibility. Maybe I better not get well so fast. Therefore, I shouldn't dream. Or maybe if I do dream, I can mention only those things that please him and that don't scare me and don't make me get well too fast.

Not all patients are so obsessively stimulated by a casual suggestion. But in all patients the act of dreaming does involve varying motivations that are incorporated in the

dream work and fused into a complex kind of symbolism, distorting, repressing, displacing, and otherwise disguising the content. What may come through is a compromise of part forgetting and part remembering, of primary and secondary process thinking, of present and past, of impulse and defense.

THE STRUCTURE OF DREAMS

Dreaming is, according to F. Snyder (1965), a distinctive physiological state related to but different from sleep or waking. It is associated, in the majority of dreamers, with a phenomenon discovered by Aserinsky and Kleitman (1953, 1955) of REMS. A basic and unitary biological process, REMS occur ordinarily in the midst of sleep and are characterized by unique electroencephalographic patterns. Since REMS are found in subhuman species, it is postulated that this aspect of the sleep phase, and perhaps the dreaming experiences affiliated with it, plays a prominent role in all mammalian life. Dreams occur occasionally also during non-REM sleep, from the closing (stage I) to the deep (stage IV) states. Even nightmares can appear in stage IV (Fisher, C, 1970).

The exact function of dreaming, however, is not fully known. Is it a homeostatic device to keep the nervous system in balance? Does it serve an anxiety-binding function? Does it have a synthesizing and restorative effect preserving the emotional balance? Since dreams are an intrinsic part of normal sleep (Dement & Kleitman, 1957; Kleitman, 1960), their functional utility in the psychic economy may be assumed. This is particularly credible in view of the experimental evidence that deprivation of REM sleep is followed by definite personality aberrations (Dement, 1960, 1966). Moreover, if REM sleep is blocked, it is made up "in amounts distinctly related to the amount of deprivation."

Dreaming as a safety value for the discharge of instinctual pressures has been hypothesized for many years by psychoanalysts. As far back as the turn of the century, S. Freud pointed out that the prime function of dreams was to safeguard sleep by fostering solution in fantasy of powerful needs, fears, and conflicts that were too dangerous or repulsive for resolution in reality. Dreams apparently helped in the psychic mastery of seemingly insoluble situations, providing for a discharge of tension, a propitiation of deep

wishes and demands, and a fantastical working through to a conclusion of destructive experiences that defied the coping capacities of the individual in the waking state. The wish-fulfilling drives represented in dreams were compromised by the demands of the repressing forces. What the dreamer then tended to satisfy was not the raw wish, but a compromise made necessary by the repressing elements. An important effect of dreams was to discharge the emotion that was associated with deep conflicts in the personality. "Dreaming has taken on the task of bringing back under control of the preconscious, the excitation in the unconscious which has been left free; in doing so, it discharges the unconscious excitation, serves it as a safety valve and at the same time preserves the sleep of the preconscious in return for a small expenditure of waking activity."

Ella F. Sharpe (1931), expounding Freud's ideas, considered dream interpretation the cornerstone of psychoanalytic technique. Dreams, she said, are sensitive indicators of the individual's unconscious and offer a means of exploring the dreamer's current conflicts through the elaboration of preconscious thoughts. The latent content of dreams is arrived at through free association. "Dreams may prove of value apart from or in addition to the significance of the latent content. They may be used as a means of unconsciously placating the analyst, as symbolic of power, of control over faecal product, as proof of control over the analyst. The dream may represent a love gift." T. M. French (1952) and French and Fromm (1964) stated that, in addition, dreams, reveal old conflicts, reflect hope and introduce new solutions.

Classical ideas about dreams revolve around the contention that with the shutting out of sensory receptors and the progressive cortical inhibition induced by sleep, a number of important changes occur in the operative psychic processes. These changes, reflecting themselves in dreams, consist of the following:

1. Visual images rather than words are employed to represent concepts.

2. The mind becomes contaminated with an archaic, pre-logical kind of ideation that utilizes perseverations and stereotypes. There is a replacement of abstract conceptual for concrete thinking and an abandonment of accepted rules of time and space.

3. Certain distortions prevail in dreams, probably conditioned, first, by a need to evade the psychic censorship that continues to operate in sleep, though to a lesser degree than in the waking state, and, second, by a primitive type of thinking that seems to be released by inhibition of the higher cortical centers. Inacceptable and repudiated aspects of the personality are, through distortions, made acceptable to the dreamer's ego.

4. Among the mechanisms serving the interests of distortion are symbolization, displacement, condensation, representation by multiples and opposites, secondary elaboration, and substitution for people of emotionally equated objects.

5. Symbolic representations are unique for the person, although there is some universality of symbols. Because primitive processes permeate the thinking process in sleep, there is a tendency toward a universal language in dreams. The similarity of experiences of the average person within a certain culture also makes for some unity of symbols.

Not long after Freud published his revolutionary discoveries about dreams and dreaming, defections from Freudian formulations began to appear. Rejecting the concept of wish fulfillment as the prime determinant of the dream, Jung (1960) approached dreams from the phenomenological level. Dreams were not, he claimed, disguised symbolizations of irrational childish impulses. Rather they were experiences in self-confrontation; their symbols were explicit metaphorical referents. Dreams were compensatory and rectifying rather than irrational "whereby those thoughts, inclinations and tendencies which in conscious life are too little valued, come spontaneously into action during the sleeping state when the conscious process is to a large extent eliminated." Jung ascribed to each dream image a special significance of its own: "from the final standpoint the symbol in the dream has more the value of a parable: it does not conceal, it teaches." It was a spontaneous self-portrayal in symbolic terms.

Adler also veered away from Freud's explanation of the dream as a symbolic vehicle for wish fulfillment. Rather, he declared, the dream was the key to the understanding of an individual's life styles and the choices available to that person in social situations.

The adaptive and problem-solving functions of the dream have fashioned its uses by

neo-Freudians. Instead of being the royal road to the unconscious, it is regarded as an attempt at solution of conflicting needs, an expression of unified personality structure (Horney, 1950). The neo-Freudian viewpoint is developed in Walter Bonime's book (1962), *The Clinical Use of Dreams.* Bonime contends that since the character structure evolves through interpersonal interaction, its manifestations in dream symbolism have a specific meaning for each individual in terms of that person's unique life experience. "Human emotions have conceptual and communicative implications which arise out of social interaction" and their identification and evaluation through dreams and other communications constitute an important focus of the therapeutic work. The dream must be related to the characterological and social realities of the patient's life. In the context of self-confrontation, the dream registers the interplay between genuine awareness and neurotic techniques of avoidance. Rational and irrational can be split apart by applying the metaphor of the dream to the concrete life situation implicated in the dream. The dream yields clues to how a patient is coping with a particular problem at the moment.

Classifying dreams into categories of action, individuals, surroundings, and feeling, Bonime puts emphasis on an interpretive hypothesis in which patient and therapist make a collaborative effort at meaning, rather than the therapist giving a pointed interpretation to the patient. The dream, consequently, becomes a medium of relationship between patient and therapist. In this interaction transference is regarded as an obscuring rather than illuminating concept toward understanding the total characterological contours of the individual. "The clinical problem is to investigate the kind of personality the patient has today, to seek out precisely what he is experiencing in reaching to the analyst and to discover the elements of the immediate situation which are engendering the irrational" feeling.

Contemporary dream research suggests dreams as products of neurophysiologic-biologic processes rather than unique responses to specific psychological-experiential factors (Trosman, 1963). What initiates the dream is physiology, not conflict; however, physiologically induced alterations in the state of the psyche during the night result in shifts in emotional equilibrium. At a critical point in this imbalance the dream begins and

operates to reestablish homeostasis. If anxiety is neutralized in this process, sleep continues; if too much anxiety is released, and it cannot be handled in the dream work, a nightmare may result with possible awakening. Unconscious wishes then ride on the back of neurophysiological-biochemical mechanisms, their representational forms being conditioned by the dream work.

THE CONTENT OF DREAMS

A dream is a mosaic of diffuse symbolic conceptualizations, recruited from recent and remote memories and fashioned by current feelings, attitudes, motivations, and values of the individual. Each dream is a fragment of the total life experience, distorted in accordance with the regressive thinking process that prevails in sleep and shaped by the immediate psychological needs of the person. It is doubtful if the function of the dream is to preserve sleep; rather it appears to be a processing of the day's experiential residues with attempts at problem solving.

In examining any dream, two kinds of content are apparent. The first, the *manifest dream content,* is an overlay of situations and events that mask more fundamental latent meanings. The manifest content is constructed out of events in the recent past, usually events of the previous day, blended with remembered situations in the distant past. The second, the *latent dream content,* which is determined by decoding the dream, embraces some or all of the following:

1. Early memories or experiences, perhaps long forgotten, that have made a significant imprint on the person

2. Attitudes and fantasies in relation to parental agencies and siblings

3. Defenses that were elaborated against early experiences, conditionings, and fantasies

4. Emotionally important immediate life experiences

5. Current wishes and demands in open or disguised form as well as defenses against these

6. Interpersonal strivings and attitudes

7. Unconscious repudiated impulses and needs

8. Nascent conflicts that agitate the person and create tensions and anxieties

9. Patterns of reaction and mechanisms of defense habitually utilized by the person to resolve troublesome conflicts

10. Latent character strivings and latent mechanisms of defense

11. Representation of different aspects of the self, as well as disparate interpersonal drives, through such symbols as multiple characters

12. Attitudes toward therapy, including resistances to the various phases of treatment, and defensive reactions that are marshalled by interpretations

13. Attitudes toward the therapist including transference manifestations

THE THERAPEUTIC USE OF DREAMS

There is a difference between decoding a dream as part of a scientific endeavor and utilizing it as a therapeutic implement, which is an artistic, intuitive task. The ideal approach to dreams is a collaborative working together during which the therapist studies the interaction between the patient and himself or herself and utilizes the dream as one form of communication both to understand the needs, conflicts, and defenses operating in the patient as well as to facilitate the therapeutic interpersonal relationship. Before this ideal is reached, the patient will require help toward being motivated to remember, to report, and to examine dreams critically. The patient will need education regarding the conflict-solving function of dreams. The therapist may, therefore at the start have to be quite active in showing the patient how one goes about working with dreams and in explaining how they lend themselves toward exploring distortions in the relationship of the patient with other human beings, including the therapist. The patient not only will learn that the dream is a repository of archaic attitudes but also will discover that it points out potential avenues of growth. As soon as the significance of dreams is grasped, the patient will be able to explore them with minimal activity on the part of the therapist.

In requesting the patient to report dreams, one may give an explanation such as in the following excerpt:

Th. I should like to have you try to remember your dreams and bring them to me.

Pt. I never dream. Are dreams important?

Th. Dreams are important because when the mind is asleep, problems that bother it are brought up more openly. In the waking state a person pushes those problems away.

Pt. I suppose I dream, but I can't remember my dreams.

Th. All people dream, but many people don't remember their dreams. If you find it hard to remember your dreams, keep a pad of paper and a pencil at the head of your bed and jot down any dream fragments you remember the minute you get up. Otherwise they are likely to slip out of your mind. If you wake up in the middle of the night and have had a dream, take the time out to write it down.

Simple suggestions along these lines often induce dreaming. Should the patient persist in being unable to remember dreams, the therapist may remark, "I wonder why it is that you have no dreams. It's possible that certain things are bothering you so much that you just don't remember what you dream." Mention of possible resistance sometimes promotes enough tension in the patient to force a breakthrough of a dream. Some therapists attempt to stimulate their dreamless patients through hypnosis during which it is suggested that the patient be able to recall important dreams. Fantasies and dreams may also be suggested during the trance state itself and discussed if desired during or after the hypnotic session.

It is, however, generally unnecessary to employ adventitious methods to promote dreaming, for the patient will readily relate dreams once told that the discussion of dream material is helpful in therapy. If the patient refrains from mentioning dreams spontaneously, the therapist may ask at each session whether there are any dreams to report.

The first dream after therapy has started is frequently of great moment, sometimes containing a cross section of the patient's problem. It may require many months before the patient and the therapist will appreciate the full importance of the material portrayed

in the dream.

During the third therapeutic session a female patient presented her first dream:

> My husband's family took suitcases to the station in a streetcar. I thought this was grubby.

> Then I dreamed of an old woman who invited me to eat roast lamb. It didn't seem good, and I wouldn't eat more. I said it was spoiled, and if you kill and eat lamb that's led a lonely life, that makes you sad. And then—this is the horrible part—she prepared to kill another lamb. She got it partly skinned and the skin was up over its head, but it was alive. It kept looking at me for protection, linking its head in my arm and pulling me, as if to say, 'Please get me out of this,' And I thought, 'Oh god, I wish I could help this poor creature, but the only way to help it is to kill it.' But I didn't want to tell the lamb that. And I couldn't kill the lamb myself.

> Then I dreamed I was on a cloud, high up: but it wasn't a cloud, it was terra firma. I was on the edge and with me on the earth-cloud was a young man. I didn't know what he looked like or who he was. I kept slipping off the cloud with a dreadful fear of falling off. He couldn't support me and I was panicky.

> Then I dreamed I was in bed with my husband, Dick. A sex dream. We just had an affair. He got up, but I stayed in bed and hid back under the bed covers. He came back with his penis erect. I wanted another affair, but he started horseplaying like a frisky kid.

Associations to the dream were barren. Even mention of the similarity between "kid" and "lamb" brought little response. The patient's feelings about her husband were hesitantly expressed, but they were on the positive side. It was many months before the patient realized her ambivalent attitudes toward her husband, her pity for him as a "poor lamb" she felt she was destroying, and her murderous rage, mobilized shortly after her marriage, because her husband and his family were "grubby" people. She believed that she had demeaned herself by a mismated alliance. Appreciating that she had been "up in the clouds" about her marriage, she realized that she was very much dissatisfied with the sexual aspects of her relationship. Her hostility had been self-directed and had expressed itself in depression and psychosomatic symptoms for which she sought psychotherapy. Her responses to her husband, positive and negative, were shown to be part of a larger pattern in her relationships with men that went back to her relationship as a child with her father. Her dream brought out many aspects of her problem, but her ego needed strengthening in therapy before she could accept the full implications of the dream.

THE TECHNIQUE OF DREAM INTERPRETATION

Once the patient has presented a dream to the therapist, it may be handled in a number of ways. Some therapists ask the patient to associate to the different objects, people, and incidents in the dream. Others pick out a general theme from the content and then present this to the patient as a focus on which to concentrate. Still others formulate their impressions of the dream for the patient's benefit. Finally, there are therapists who do not direct attention to the dream or ask for associations; they merely listen, attempting to connect preceding statements and those that follow the dream in the hope of identifying the initiating precipitants of the dream.

Because the dream embodies so much material, therapists generally select aspects for discussion that accord with what they are trying to emphasize at a specific session: inculcation of insight, confirmation of a hypothesis, probing of past traumatic events and memories, defensive operations, transference manifestations, resistances to the therapist and to the techniques, fears of utilizing insight in the direction of change, and so forth. Sometimes a therapist will merely listen to a dream for his or her own information: at other times interpretations are given the patient. In advance of this the patient is asked for associations to a dream and for formulation of impressions about it. Many patients rapidly become skilled at understanding the meaning of their dreams. To facilitate associations, some therapists summarize the dream events and ask the patient specific questions in relation to people and incidents in the dream. Dreaming about different people is occasionally a way of representing different aspects of oneself. The therapist, if the meaning of the dream is not clear, may ask about the setting of the dream. Does the patient recognize it? Is it in the past or present? Does it have any significance for the patient? Do the characters in the dream have any meaning for or relationship to the dreamer? Do any of the characters represent the patient's parents, or the therapist, or oneself? Are any underlying wishes or needs apparent? What personality traits are revealed in the characters? What mechanisms of defense are displayed—flight, aggression, masochism, hypochondriacal preoccupation? What conflicts are apparent? What is the movement in and the outcome of the dream incidents?

Therapists interpret dreams in line with their theoretical persuasions, some treating a dream like a Rorschach, projecting into it their own special fantasies. While this may be effective for highly skilled, experienced, and intuitive professionals, it is better for most therapists to work out the meaning together with the patient. It is a poor tactic to interpret dogmatically the latent content of the initial dreams revealed by a patient. First, the therapist does not know enough about the patient and the operative defenses. Second, to penetrate into the unconscious prematurely will merely promote greater repression of and distortion in later dreams as a way of avoiding anxiety. One may, however, productively search for current reality reactions (e.g., resistances to the therapist or to the techniques; fears, or misinterpretations the patient may harbor about therapy) or for bizarre hopes and expectations that could result in a defeat of the therapeutic attempt. Or character drives may be explored advantageously as they exhibit themselves in the dream, provided that the patient is already aware of these.

Resistance is apt to occur as the treatment process proceeds. It may appear in relation to the setting up of the working relationship at the start of treatment, to the exploration of the dynamics of the inherent neurotic process, to the putting into action of insight, and, finally, to the termination of therapy. Manifestations of resistance may first appear in dream structure. The dream provides a great opportunity to deal with it before it becomes an irreparable obstacle to treatment. Of confounding concern, however, is the employment of dreaming itself as a form of resistance as the patient becomes aware of the importance of dreams. The patient may thus use dreaming as an outlet to frustrate or impede the therapist. The patient here may dream incessantly and try to flood the therapeutic hour with an avalanche of dreams, or may unconsciously elaborate the symbolism of the dream as a way to confuse the therapist and to divert from central issues. Some patients bring in pages of written dreams, which may overwhelm the therapist, and this may be one way of avoiding dealing with reality problems. These resistances should be interpreted.

Of vital importance are the revelations in dreams of transference in which impulses, experiences, and defenses in relationship to important past personages are revived

through the agency of the therapist. A wealth of information can be exposed in such dreams, and opportunities are afforded the patient and therapist for understanding of how early attitudes and patterns disturb the patient's present existence. This provides a means to work through transference distortions. In the process of interpreting transference, one must always search for reality provocations that are initiated by the therapist personally. The way transference in dreams is handled will depend on when it appears and its function as resistance. A demand for infantile gratification in terms of complete givingness, lovingness, and understandingness, an expectation of hurt and condemnation for the revelation or expression of impulses of which the patient is ashamed, can serve as blocks to therapeutic progress. Such demands and expectations will require careful interpretation. On the other hand, a delving into genetic foci, into important early formative experiences, if employed at all, may require tact and great patience. Premature or too forceful interpretations may do more harm than good.

One of the ways that the dream can help the therapeutic process is by revealing signals of anxiety before it becomes too intense and interferes with therapy. Where the dream brings out anxiety in relation to important incidents, past or present, it may be possible to help the patient endure it enough to avoid the upsurge of too great resistance.

Often the dream will reveal the nascent drives that marshall anxiety. These may be imbedded in a pregenital fusion of sexuality and aggression. Their emergence in symptoms and in acting-out tendencies may be responsible for the patient's current difficulties as well as for a pervasive inhibition of function and other ego defenses. The studied interpretation of dream elements will do much toward clarifying the punishing and masochistic reprisals of the superego. By ferreting out projective, denial, isolating, and repressive defenses, as they come out in the dream work, one may occasionally liberate early memories that concern themselves with the fantasies or actual experiences associated with the patient's sadistic and masochistic maneuvers. Obviously, the interpretations preferred must take into account the patient's readiness for change and the intensity of anxiety. Above all, the manner of interpretation serves as an important factor in helping or retarding the patient in accepting and integrating the significance of

the dreams.

Techniques of dream interpretation in the early phases of therapy may advantageously concern themselves with teaching the patient how one may approach one's dreams. They include:

1. Summarizing for the patient the basic trends in the dream

2. Asking the patient for spontaneous associations

3. Making a tentative, unverbalized formulation of the dynamics

4. Encouraging further associations through focusing

Summarizing for the Patient the Basic Trends in the Dream

Although the routine of summarizing is not absolutely necessary, it may conveniently be employed at the beginning stage of working with a dream especially where the patient does not spontaneously associate to it. To illustrate this and other routines in dream interpretation, we may consider the following dream of a depressed woman with whom I was employing dynamic psychotherapy:

> A person—I don't know who it is—wants to kill me and my child. The room I'm in has a double dormer window, but the furniture is modern. I can't get out. I try to escape and can't. Then the next part is that I am somewhere with two men. One man wants me, but I don't like him and feel contempt for him. I like the other person, but he doesn't want me. I say to him, "I'm sick and going to die in 2 weeks." He reassures me and tells me he loves me and everything is sad and beautiful.

In summarizing the trends in the dream, the therapist may remark:

> Now here is a dream that takes place in a room. A person is there who threatens to kill you and your child. You try to escape and can't. Then you are with two men. One you like, and one you don't. The one you like doesn't want you. You say you are sick and going to die. Then he tells you he loves you, and everything is sad and beautiful.

Asking the Patient for Spontaneous Associations

Following the summarizing of the dream, or if summarizing is not employed as a

routine, the patient may be asked to associate to the dream immediately after it has been reported. The following excerpt of the session with the patient whose dream was just described is illustrative:

> *Th.* What are your associations to the incidents and people in the dream?
>
> *Pt.* I don't know who the person is, but it's a man, like an ogre. I was frightened of him. He was making frightening gestures to us. *(pause)*
>
> *Th.* What about the room?
>
> *Pt.* There is something familiar about it. It's like the room I had when I was a girl. This was in North Carolina. The room I shared with my sister. It had a dormer window like the one in my dream. I'm sure this was the room.
>
> *Th.* What about the furniture?
>
> *Pt.* We had this curly maple old American furniture. But the furniture in my dream was modern, like *(looks around the room)* in your office, *(pause)*
>
> *Th.* What about the rest of the dream?
>
> *Pt.* Yes, this man who didn't like me was a very desirable man, the kind I feel so embarrassed with and uncomfortable. And the last part gives me a quiet, wonderful feeling as if everything is going to be all right.

Tentative Unverbalized Formulation of Dynamics

On the basis of what knowledge has already been gained of (1) the patient's problem, history, current life situation, and dream symbols employed in the past, (2) the patient's associations to the present dreams, (3) what is happening immediately in the therapeutic situation, and (4) the therapist's intuitive feelings, the therapist will be able to develop some tentative formulations of the existing dynamics—these *are not to be conveyed to the patient*. They are concocted in full recognition of the fact that they may later have to be radically revised.

In organizing the material of the dream for purposes of this formulation, it is often helpful to employ a certain framework that considers the setting of the dream, the characters, the underlying wish, the revealed personality traits, the apparent mechanisms of defense, the ostensible conflicts, the movement, the outcome, and resistance and

transference phenomena.

The Selling of the Dream

One may ask oneself a number of questions concerning the patient's dream's setting. For example, What is the locale of the dream—outdoors, indoors, a changing setting? Does the patient recognize the locale? Does the locale have any special significance for the patient? Is there an indication as to the temporal setting—past, present, or both?

In the dream we are using as an example, the setting seems, according to the associations of the patient, to be a fusion of the past (the room shared with her sister as a child) and the present (the therapist's office). One may speculate that the patient is talking about a situation or about feelings that are equally applicable to the past and to the present or that, originating in the past, are being projected in the present.

The Characters in the Dream

Who are the characters in the dream? Are they identifiable people; do they resemble in appearance or behavior people the patient knows or has known in the past? What is the relation of the patient to the characters in the dream? How does the patient feel about the various characters? Are they possibly parental or sibling representatives? Are the characters in the dream representative of various aspects of the patient? Are any of the characters symbols for the therapist?

Referring to the dream that we are considering, the characters are the patient, her child, a hostile unidentified man, a man who likes her whom she rejects, and a man whom she likes but who rejects her. From her past history there is a suggestion that the hostile man in the dream is representative of her father, whom she considered a person one could never approach closely enough to know. She remembered him as one who was disposed to hostile outbursts. There is a possibility also that the man may be representative of the therapist (transference), since the patient had for several weeks manifested resistance in therapy and had on several occasions mentioned that I seemed distant from her and that it

was hard to get to know me. The other two men are probably representations of a dualistic attitude she displays toward men. In response to those men who express a liking for her, she exhibits coldness and contempt. On the other hand, she manifests a keen interest in men who are not approachable.

The Underlying Wish or Need

A search will usually reveal one or more deep wishes or hidden demands as the base of the dream. These may consist of early repudiated impulses and strivings, or of later wishes, or of current demands. Sometimes the wish is an extremely concealed one that is hard to detect in the dream content. At other times it is very clearly defined.

In the dream under discussion the wish is perhaps to win the love and approval of a rejecting, aloof man, in this way breaking down the barrier to a warm relationship with a father figure. There is a desire to be accepted for herself and to be the preferred one in any competitive struggle (originally with her sister or mother?).

Personality Traits as Disclosed in the Dream

What personality traits are divulged in the dream? What is the nature of the patient's relationship with other persons in the dream? What are the patient's feelings about himself or herself? What are the patient's attitudes toward authority? Toward subordinate persons?

In the dream that we are reviewing the patient shows great fear in relation to a hostile male figure, contempt toward a person who likes her, and feelings of rejection when she approaches someone she admires. These tendencies are actually substantiated by studying her real life adjustment. They explain why it is difficult for her to relate well with people. Strong people are overvalued; she fears their hostility and rejection, and she tends to detach herself from them. Toward weaker people she feels contempt and hostility, and she removes herself from their presence out of fear of being exploited. On those who avoid or reject her she places special values.

What are the mechanisms of defense that are exhibited in the dream? How do these compare with the defense mechanisms the patient habitually employs in life? Are there any evidences of anachronistic defense mechanisms that issue out of early life experiences and impulses?

In our patient's dream the defense mechanisms suggested are those of (1) flight from hostility or from a hostile authoritative person, (2) disdainful and perhaps aggressive attitudes toward individuals who are fond of her, and (3) masochism and hypochondriasis in relation to rejecting personages, the latter tendencies perhaps serving as means of winning sympathy and love. These mechanisms are essentially those that the patient exhibits in her reality adjustment.

Conflicts Expressed in the Dream

What conflicts are manifested in the dream? Do these result from clashes with or stress from special situations? Are these a consequence of incompatible relationships with people or contradictions of various character traits? Are there evidences of deep inner wishes and needs that come into opposition with moral prohibitions?

Returning to our patient's dream, we find a number of conflicts that suggest themselves. The attitudes of flight, contempt, admiration, and masochism are mutually contradictory. Her relationships with people are fertile sources of conflict since she constantly anticipates attack or she may desire to attack others. Her need for a close relationship conflicts with a fear of being hurt or of hurting. There are hints of an Oedipal conflict.

The Movement and Outcome of the Dream

What is the drama enacted in the dream? What emotions are associated with the actions? Does the dream reveal any important early memories or situations? Does it reflect emotionally significant immediate experiences? What is the outcome of the dream?

In our patient's dream the drama is, first, a fear of being destroyed and helplessness in escaping destruction. The emotion here is terror. The outcome of this episode is not defined. Second, the patient plays a rejecting role with a man who seeks her companionship, and she is rejected by someone she likes who does not want her. Her protestation that she is sick and about to die incites the man to profess love for her, and she feels emotions of contentment, but also sadness. The outcome, though satisfactory to her, is actually a neurotic masochistic solution to her feelings of being unloved and unworthy in a relationship with a "superior" man.

Resistance and Transference Manifestations

What manifestations in the dream are reactions to therapy and the therapist? Are there any evidences of fear, antagonism, detachment, or sexual interest in relation to the therapist? Are there any responses that seem oppositional to the therapeutic effort?

The fact that our patient associates the furniture in the room in which she is trapped with the furniture in my office suggests a transference situation. She perhaps feels trapped by therapy as she was trapped in an untenable relationship with her father in the past. She may fear attack from me as she feared attack from her father. It is possible that she exhibits resistance to therapy in the form of fear or helplessness. There is a possibility also that the last part of the dream reflects an impulse to win my affection by displays of illness and depression. Actually, the patient started the session by complaining that she felt physically ill. Emotionally she appeared listless and depressed.

Encouraging Further Associations by Focusing

Once we have come to certain tentative conclusions about the dream, we may want to direct the patient's associations toward certain parts of the dream in order to validate our own formulations and to help inculcate insight in the patient. The process of focusing will depend in part on the dream material and in part on the specific phase of therapy in which we are engaged.

Because the dream is so highly condensed a production, it is possible to extract from it material that will fit in with the objectives of our immediate therapeutic effort. Thus, if we are in the opening phases of therapy, our chief goal is to establish a working relationship. An attempt is made to discover in the dream evidences of resistance to a working relationship, defective motivation for therapy, and transference blocks to the full acceptance of the treatment situation. For example, were the dream that we are studying presented during the first therapeutic phase, we might perhaps consider the patient's fear of the man in the dream and her terror of being trapped as symbols of a fear of therapy and of me. We may speculate from this that she would, during therapy, try to get me to express my liking for her so that she could reject me; or, that, convinced of my aloofness, she would employ a masochistic reaction in order to get me to profess my fondness for her. With these factors in mind, we would try to focus her attention on her feelings toward me, in order to work through her resistances to a working relationship.

Were the patient in the exploratory phase of therapy, we would utilize her dreams as a means of investigating the dynamics of her disorder. Thus we would focus on, and attempt to demonstrate, provocative elements in her immediate environment that activated basic conflicts. Actually, the patient was in this treatment phase. An excerpt from the interview follows:

> *Th.* Perhaps, if you tell me about any special things that happened to you the day before, or a few days before the dream, we may learn something important. *[Events of the day before, which had an emotional impact on the patient, consciously or unconsciously, may have detonated the tensions revealed by the dream. Focusing the patient's attention on possible stimuli may enable her to make certain connections.]*

> *Pt.* There were several things that happened. I got a letter from Sally (*her sister).* She rarely, if ever, writes. Since my divorce, I don't think I have gotten more than three letters from her. She told me about how wonderfully she and John (*her sister's husband)* were getting on, and how well her two children were doing in school. I felt she was needling me, blaming me for making a mess of my life. *[The resentment evoked by her sister's letter may have touched off early competitive feelings. I decide to explore these.]*

> *Th.* How did you get along with your sister before?

> *Pt.* As I told you, we hated each other when we were little. My father told me I used to admire her when I was a tot. She was 3 years older and I tried to do everything she did. The only thing I remember is fighting with her. She considered herself wonderful and would tell on me. I'd get spanked plenty, [*Is it possible that unresolved sibling rivalry still continues?]*

Th. How did your father feel about her?

Pt. After mother died, she was the favorite. She used to do everything with dad. I used to get the spankings. They told me I had an awful temper. That amuses me because I'm such a Casper Milquetoast now. *(pause)*

Th. How do you feel about your sister's taking your father away? *[This is a very provocative question and is actually intended as an interpretation.]*

Pt. I guess I accepted it. There was nothing else I could do. *[The patient is probably unaware of her deep resentment about being rejected and of her intense desire for a good relationship with her father.]*

Th. But it would seem natural to resent such a situation, *[more interpretation tentatively given]*

Pt. Well, it was a bad situation all around. And I was difficult, I suppose. There were times when dad was very sweet though. When I was sick for instance. *[Could this be a genetic determinant of the masochistic impulse ? Her present tendencies toward depression and psychosomatic illness may be a result of a pattern of sickness that in her childhood invoked her father's attention. This is the mechanism that seems so clearly portrayed in the dream.]*

Th. This must have made sickness a premium for you? *[I am attempting here to get her to think about this mechanism.]*

Pt. (*laughs*) I was a sick child they tell me. Even now I don't feel good. I don't think I ever felt like I was all together.

Th. There may *still* be dividends that you get out of your being sick or feeling sick, *[a tentative interpretation of her hypochondriac pattern]*

Pt. (pause) Say … well, I wonder. Do you think I make myself sick so people can feel sorry for me? *[This sounds like emerging insight.]*

Th. There is *some* reason why you feel sick.

Pt. I did feel like hell yesterday and today. My back is killing me. I dosed myself up with aspirin, *[deviates into talking about her symptoms]*

Th. (interrupting) Now let's look into this thing. If you got dividends of love and attention from your dad by being sick, this could have started off a pattern. Do you have any idea whether you got sick with people you want attention from?

Pt. All I know is that I make a nuisance of myself with people. I guess I make them sick. *[The patient is resisting here.]*

Th. Well, now the dream brings out the fact that you tell the man who is hard to get that you are sick and going to die, and then he tells you he likes you, and everything is sad and beautiful. That sounds like the same thing, doesn't it?

Pt. (excitedly) Yes, I see. The night before the dream I went to a party. There was this very attractive man there who was taken over by another girl. I tried to engage his interest. He was polite, but I didn't get too far.

Th. Mm hmm.

Pt. The nice men are always in demand and married, or something.

Th. Sounds like nobody takes any interest in you.

Pt. The men who are attracted, I feel there is, I know they are castoffs. They are either people who want a mother or are married and want an affair. And that's not for me.

Th. Maybe you undervalue people who like you. *[This is more tentative interpretation.]*

Pt. I don't know, but I must attract the wrong people. *[The patient is apparently not ready for the interpretation.]*

Th. You know, the dream seems to bring out your pattern of disinterest in men who want you, and hopelessness with men you want.

Pt. Yes, it does, *(pause)*

Th. But what do you do in the dream to get the person to tell you he loves you? *[attempting to stimulate thinking about her pattern]*

Pt. (laughs) I tell him I'm sick and going to die.

Th. Like you did with *whom* before, as far back as childhood? *[more questioning to promote thinking]*

Pt. With father, of course.

Th. It sounds as if you are using this pattern constantly, whenever you are up against a situation where you feel you are second best. It's like you are still living with a sister your father prefers, and you have to use drastic measures to win out. *[interpreting her pattern]*

Pt. It's true; that's what I must be doing. In everything I feel hopeless, in everything, *(cries)*

Th. But is it *really* hopeless or do you *feel* it's inevitably hopeless because this has been the pattern of your life?

Pt. Just look at how my sister is, and look at me.

Th. You are still pitting yourself against your sister. Let's take the letter she wrote you, which seems to have stirred up the dream and the old conflict of being preferred or not. Now you read into it something she may not at all have intended.

Pt. Of course, that's possible.

Th. Or take your feeling about me. If the pattern we talked about is there, it may come up with me too. Have you felt that I didn't like you or didn't pay attention to you? *[probing for possible transference reactions]*

Pt. I have felt you were distracted and not interested in what I was saying.

Th. Perhaps I did something that gave you that impression?

Pt. Well, you changed my appointment last week.

Th. What did you think that meant?

Pt. Nothing, I suppose, but (*laughs*) I'll tell you what I thought about.

Th. Yes.

Pt. I thought you were seeing somebody in my place, more important or attractive.

Th. Like your sister? *[accenting the transference element and the possible misinterpretation]*

Pt. (laughs loudly) I suppose so. It seems like I keep doing the same thing all over.

Were the patient in a phase of translating insight into action, the focus would be on resistances to activity, normality, and the abandoning of primary and secondary neurotic gains. The dream material would be utilized in such a way that any possible resistances or defenses against utilizing insight constructively would be accented in order to expedite the therapeutic process. If the patient, finally, were in the terminal phase of treatment, the dream would be searched for evidences of resistance to termination or for refusal to yield her dependency and to exercise assertiveness. In this way the greatest good would be derived from the interview.

DEALING WITH RESISTANCE

An insidious form of resistance is forgetting dreams. This, often a maneuver to keep the therapist at bay in order to avoid anxiety and to retain the secondary gains of the neurosis, may remove dreams as a form of communicative interaction. Focusing on the possible reasons for not dreaming may enable patients to recover their dreams. Sometimes as mentioned before, hypnosis helps to break through the dreaming block. Another resistance is that of bringing in reams of written dream material and filling the

session with intellectual recitations about possible meanings. Enjoining patients *not* to focus on dreams serves to bypass this defense. A third resistance is disavowing the significance of dreams, and of the characterizations and actions that are taking place. Here the therapist may point out that what the patients have presented is *their* dreams, that they had a free choice of portraying what they felt, and that they selected their own script and characters. Repudiating their own creations is a means of trying not to take themselves seriously to avoid anxiety or to retain the pleasures of their neurosis.

FANTASIES

Fantasies or daydreams are almost as important as night dreams in reflecting deeper mental trends. While fantasies are influenced more by conscious ideational processes, they follow many of the laws of dreams. They may be handled in a manner similar to that in working with dreams. Of particular importance are masturbatory fantasies, which embrace some of the most disturbing conflicts of the person. The individual's emotional reactions to fantasies may be as significant as their content and should, therefore, always be taken into account.

ILLUSTRATIVE CASES

Example 1

A patient with an anxiety reaction came to therapy partly because of distressing symptoms and partly because of a realization that she was unable to get along with people, particularly with those in authority. She felt great envy toward persons who possessed more material things than she had, or who knew more than she knew, or who happened to be in any kind of superior position. She feared expressing her hostility and, in defense, adopted a compulsive ingratiating attitude. Her relationships with men were characterized by an initial period of temporary enthusiasm and passionate involvement, followed by disillusionment, resentment, and an inevitable rupture of the friendship. During the thirty-sixth session, she presented the following dream.

> I am in a field, but instead of there being grass, the earth is blanketed in a cloth cover with a peculiar design. I see an animal in the distance coming toward me. I don't know if it is a cow or a bull. I somehow have the power to make it either, by looking at it a certain way. I make it a bull and run away as it charges me.

> Then I see myself in a room. A woman is about to leave two little children. They are good children and I feel angry that they are left alone.

In her spontaneous associations the blanketed earth resembled the cover of the couch in my office. During her last visit, as she entered the waiting room, she ran into my wife who was on the way out. She had a transient fantasy then that my wife was abandoning my two children in protest over my working constantly and, therefore, having no time to devote to my family. Associating to the animal in the dream, the patient described a recurrent fantasy of being caught some day on a field by a bull who charged her while she was completely helpless.

A tentative unverbalized formulation on the basis of what I had learned about her in therapy was that she related in two distinct ways to people. First, she would idolize any person whom she could identify as a powerful authority. She needed to convince herself, however, of the omniscience of this authority. Any flaws or weaknesses that she detected in personages whom she endowed with superior virtues resulted in her losing respect for them and rejecting their friendship. Second, she would, in association with a weaker person, assume command and insist on the person's complete submission to her When this happened, she would develop contempt for the individual's weakness and then feel repulsed by any contact with the person.

In her relationship with me the first pattern had prevailed. I was elevated to the position of the invincible authority who knew all and could do no wrong. From time to time I challenged this attitude, attempting to show her that her notions were based on a need for a power figure. While she accepted this idea intellectually, emotionally she clung to the feeling that I was a kind of demigod, possessed of varied virtues, including superb judgment and exquisite intelligence.

Several days prior to the dream we had, during a session, discussed her relationship with her fiancé, which had followed along the lines of her typical pattern and now was in

the final stages of disintegration. I had given her several strong interpretations, her response to which was that I was criticizing her. I had a feeling that she resented my intimation that discharging her fiancé might not be the best solution for her present plight.

Focusing on her present dream, I suggested that the blanketed earth on which she stood in the dream and which resembled my couch cover was probably a symbol of the therapeutic situation. Her emotion in the dream might then relate to therapy or to me. This remark sponsored associations to the effect that she had been angered by my comments of the previous session. She confessed that as she left the office, she had begun, for the first time, to doubt my competence.

The meaning of the dream then became more apparent. She viewed me, first as a cow, tearing me down as an incompetent, weak person over whom she could ride roughshod. Second, she regarded me as a "superior" ferocious bull who could hurt her. In this way she symbolized her conflict between wanting to tear me down, as she had torn down all other authorities, or making me even more invincible, and hence potentially dangerous. She chose the latter in the dream. Envisaging escape from therapy, she rationalized her contemplated move with the idea that, in providing me with more leisure, I could devote myself to my wife. This would prevent my wife from leaving my children, who did not deserve a broken home. The last part of the dream was a partial expression of this notion. The interpretation of the dream helped the patient to realize that she was expressing in her dream structure a symbolized version of many of her basic life patterns. This insight proved of great value in promoting progress in therapy.

Example 2

Sometimes spontaneous associations to a dream help the patient gain awareness of inner conflict with dramatic force. In the following excerpt a male patient achieves insight into fleeting homosexual impulses:

> *Pt.* I dreamt my father was quite ill and I was taking care of him. I don't know what was the matter with him, but he was ill. I guess my sisters were around there somewhere, but I seemed to be feeding him and giving him his medicine. And there's one thing that sticks in my mind—a view of a spoon, an ordinary tablespoon, leaning up against something—in jelly or

something along that line, something gelatinous. And I thought I was sort of half awake and I thought: "Well, Jesus Christ what am I doing— what can I say to that dream? It means that I am being my mother; I'm carrying out the functions of my mother, taking care of my father." And this is what I know it means: I have a desire or fear of being homosexual. I'm taking my mother's place. It hit me hard between the eyes, and I almost fainted. And the next night I dreamt about a hasp, kind of lock—you know, the kind where the hasp drops over a part when you drop a padlock into it. And I thought there was something about the hasp, and I thought I'm on the outside of it; somebody is on the other side and can't get in, and I can't get over there. It could be turned around the other way. I could be over there, couldn't get in, and *he* could be here and not get out. It was not in any way a menace or anything like that, but it was that I'm here, and the presence of this hasp keeps *him* out and keeps *me* in. I can't get to him, and he can't get to me. It's possible that you can turn it around, and the same thing would be true. In other words, it's an equation, *(pause)*

Th. What are your associations to this dream?

Pt. That is, if I were on the other side, the hasp would prevent me from getting inside. He would be inside, and he would be prevented from getting outside. I just remembered that I had another dream. I dreamed about a man I worked for about the time I got married the second time. I had worked for him once before. He was very fond of me, and I of him. Now I suspect there was a funny component in that relationship. He was, himself, in analysis. We had a lot in common for artistic reasons, philosophic and political reasons. However, in the end he turned out to be a heel. In spite of this guy's glowing promises, and so and so on, I hadn't been married a month before I was fired. It wasn't his fault; he was just going broke. But the slob didn't even buy me a drink when I got married. This was a pal, wept on my shoulder when his wife left him, and I used to go up there to spend all the evenings with him. When he was very bad, I'd stay over, you know, that kind of thing. He was going through what I went through with Anna, only I didn't know it then. You know I'd get flashes —now I know what they mean—that maybe he and I would be better off without women.

Example 3

The following portion of a session with a man suffering from impotence illustrates the value of focusing associations to a dream for the purpose of inculcating insight:

Pt. I have sort of a feeling of frustration at the business of looking around for an appropriate woman. This is partly the result of the fact that it's such a time-consuming operation and rather unrewarding unless one actually, until one actually, finds the appropriate person. And there is, there was one such futile evening which I spent yesterday. I suppose you may say that this is in the nature of resistance, but it generates feelings of how much more profitably I could have spent my evening yesterday had I not had to waste it looking for some woman. *(pause)*

Th. Some woman?

Pt. Yes, some girl I had never met before. She was a close friend of other close friends of mine. I called her up, you see. I had a fairly elaborate description of her. But the situation produced was that it was not something I could pursue very far because I was not substantially

interested in her. I suppose I had a strong negative reaction, that I felt that she was tightly absorbed in her family, which produced a negative reaction. *[This reaction is typical of the patient's responses whenever he attempts to relate to a woman. He finds some objective reason to justify his apathy and disgust. He is not aware of more fundamental fears and conflicts that condition his desires for flight.*]

Th. Could there possibly be more basic reasons why you found her unattractive? *[attempting to focus his attention on deeper conflicts]*

Pt. Well, I keep thinking that what I want from a woman is to find her substantially attractive, but more than just a sexual relationship. It is one in which there is substantial frankness. She should have a substantial intellectual capacity. Since those don't abound in very large numbers, that reduces the field very much, uh uh, especially if you, uh, introduce the factor that there is some sort of automatic resistance which would, in any case, reduce the attractiveness of most women on the sexual level. *[The patient dodges my question, but he does bring in the factor of his sexual resistance.]*

Th. Well, what about that automatic resistance? *[another attempt to focus on his conflict]*

Pt. Why, there is this impotence problem I came to you for, which is still with me. This substantially reduces my effectiveness with women.

Th. It doesn't seem to have made you unpopular. After all, there are many women after you, in spite of the impotence.

Pt. I suppose so. *(laughs)*

Th. I wonder if all of the specifications that you have for an ideal woman, and the lack of feeling for women, may not be indicative of certain fears? *[focusing still on basic conflicts]*

Pt. I suppose they must be.

Th. Like what, for instance? Do you have any ideas or feeling about this?

Pt. Frankly, no. Except that there is this lack of enthusiasm, *(pause)*

Th. What about dreams; have you had any since our last visit?

Pt. Yes, quite a few. On Tuesday night I dreamed I was in some sort of a revolutionary turmoil, and some dictator had his arm torn off. Then I became the dictator, and my arm is attached. As I proceed somewhere, each time someone touches my arm, I feel it's going to be torn off. This is followed by a dream in which I and a girl are going somewhere, and running to catch a bus, and my hand begins to bleed. I'm becoming covered with blood, and she says, "Look what's happening." I say, "It doesn't matter; let's get there in a hurry." Then I exclude from an appointment I had arranged with people, this girl.

Th. Exclude her?

Pt. Yes, she was excluded in some way.

Th. By whom?

Pt. By me.

Th. Mm hmm.

Pt. I was in considerable turmoil. And then I dreamed of my cousin, my young cousin at school. He reports that a number of children at school have succumbed to some epidemic, to some disease. Following this, I help him conceal a knife that he's to use illegally in fights with other boys, and I instruct him how to use it. Then I walk along a dark street alone and see adults discussing something. Then these adults transform into a group of children. I walk along in imminent fear of attack. I pass a boy with a large hound. At first the dog appears planning to attack me, and he does, and the dog jumps on me and seizes me by the arm, and, oh, I had a painful sensation in my arm. *(pause)*

Th. Is that all?

Pt. Yes.

Th. What do you make of it, the dreams, I mean?

Pt. I suppose I am upset and afraid. I must be the dictator whose arm is hurt.

Th. Yes, as if you are in jeopardy of being attacked as a dictator and physically hurt.

Pt. Yes.

Th. What about being a dictator?

Pt. That's what some girls call me, when they fall in love with me and get angry. This dream followed this date with the girl.

Th. I see. Perhaps your feelings about this girl touched off the dreams. It's significant that in the dream you are running with the girl to catch a bus and your arm is bleeding.

Pt. Yes, we are going somewhere, and I want to get there in a hurry.

Th. Where do you think you want to go in a hurry?

Pt. *(pause)* To get sex I suppose. I am in a rush to get this thing settled.

Th. But perhaps this dream tells us why it's difficult to get things done in a hurry. After all, your arm is mutilated. Could it be that in rushing into sex you feel you might be mutilated in some way?

Pt. *(emotionally*) There must be something that scares me. I feel anxious as I talk now.

Th. In what way could you be mutilated? Who would mutilate you and why?

Pt. I don't know. In the dream I help my cousin fight off an attack. This must be an aspect of me. Then I am attacked by a boy and dog who jumps me.

Th. And you get a painful sensation in your arm. The arm that bled in the other part of the dream?

Pt. Yes.

Th. But what about the part of the dream where you exclude her?

Pt. I don't know.

Th. Why should she be excluded?

Pt. I might want to exclude her, I suppose, from myself.

Th. That's what you actually did in your feelings toward her during the date.

Pt. Yes.

Th. And is what you do with other women?

Pt. I suppose so.

Th. Is it possible that you exclude her because of feelings, indicated by the dream, of fear, of bloody mutilation?

Pt. If I were to expect attack from this source, I can see that.

Th. One way to escape attack is to give up the sex object, remove yourself from her, become impotent and apathetic, *[interpretation]*

Pt. I just remembered. I had a dream the day before I saw the girl.

Th. Mm hmm.

Pt. A series of two dreams, not entirely clear. There's a small girl who demonstrates strong friendship feelings toward me and offers something valuable which, in the dream, is a source of energy which she tells me to take from a series of intangible columns of materials. Later in the dream a small girl is very friendly to me. However, she transforms into a small boy who then picks up my pack of cigarettes and throws it out of the window, despite my protests. Then I'm with a police officer, and he hides a pearl necklace in the files. I'm interested in it, but tell him I'm not, and I just want to go to some town. I go to the railway station, check my suitcase, and enter the train car. Then some woman rushes out with a suitcase that looks like mine. I follow her, but we investigate and find the suitcase is hers. I return to the car and find my suitcase. The contents are all female articles, and I think to myself it will be difficult to prove that this is my suitcase, *(pause)* And that's all.

Th. I see. What do you think of that?

Pt. (*laughs*) Well, I suppose my impending date got me to dream of this girl. I think of this treasure, the pearl necklace.

Th. The treasure being hidden by a police officer?

Pt. Yes, keeping it from me.

Th. What is the most previous treasure you can think of?

Pt. What I want here. To have sex with a woman. Sex must be locked away from me, if we are to believe the dream, by some authority.

Th. Mm hmm.

Pt. The recognition of that by the woman— the suitcase—is rather puzzling. It apparently involves some uncertainty in my, uh, virility and masculine qualities, as much as the woman had the same suitcase as I.

Th. As if she's a counterpart of you, as if you don't know your identity—male or female. *[interpretation]*

Pt. Yes, I can see something now; it occurs to me that the arm in the dreams is a symbol of my genitals.

Th. Mm hmm.

Pt. And the dictator, being in the position of dominance like a male, can leave his genitals hurt and not be a man. If I try to be a man, I may be hurt—my superiority and power torn off so to speak.

Th. And sexually mutilated.

Pt. Yes, undoubtedly.

Th. And in a sexual role with a woman?

Pt. I'll be sexually hurt, hurt.

Th. Now, if it's true that you could be hurt for trying to be a man, what defense would you use?

Pt. To get away, run away, or to be a woman and not have to face it.

Th. What about fighting back?

Pt. Yes, yes. The aggression. Like in the dream, the attacking with a knife.

Th. Your dreams seem to bring out mechanisms of why you act the way you do.

Pt. I can definitely see that, but it's so peculiar. I know it's true. I feel it. But it's so strange.

Th. It would explain your coldness with women, the impotence. If you expect to be castrated, that's no fun.

Pt. (*laughs*) Gosh, uh, yeah, uh, I had one reaction of this sort, which I became conscious of, and that is that in playing with my girl friend, the old one, she accidentally hurt me very slightly around the genital region, but it was very slight. And, nonetheless, it, for a while, caused a complete disappearance of sexual desire.

Th. When did this happen?

Pt. A number of days ago.

Th. Before or after the dream?

Pt. Before.

Example 4

The fragment of a session that follows is an illustration of the active working out by a patient of an anxiety attack with psychosomatic symptoms through an analysis of her dreams:

Pt. After I left you the last time I felt good, but it didn't last. The next day I awoke and felt tense and bad all over, physically sick. I wanted to go to my desk and do that work; I could have made myself do it. So I gave myself the only therapeutic treatment I know of. I just went to bed. I stayed there all afternoon.

Th. Did you feel better?

Pt. I still felt awful when Mark got home last night. Janet, my friend, came in about 4 o'clock, and I had had nothing to eat all day, you see.

Th. Mm hmm.

Pt. Well, I started to figure out things in bed, and I apparently figured out some things because I had some good results. I didn't order groceries. I didn't do a goddamned thing. But I did get up, and we ordered Chinese food in, last night; and I did get up and fix that and ate dinner. First meal in almost 24 hours.

Th. What have you figured out?

Pt. This morning when I awakened, I felt fine. When I say fine, I mean as fine as I can feel. And I've been doing everything in perfectly normal order all day. Almost called you yesterday; then I thought no. It's absolutely ridiculous; this thing is my own doing. I might as well try to figure it out myself.

Th. Did you?

Pt. No, I don't think I have completely, but I think I worked some of it out though.

Th. Well, let's talk about it.

Pt. Well, would you rather hear some dreams first or second?

Th. Whichever you want.

Pt. There was one damn dream that was important that I forgot. All these things happened one on top of the other. For instance, when I went to bed yesterday at 12 o'clock, with the exception of phone call interruptions, which I talked perfectly normally on, I'd go right back to sleep. When things get too tough, I can go to sleep. That's what I did yesterday. Things got too rough to stand it, so I went to sleep, but all that time I had one dream, after the other dream, after the other dream; and the night before, that would be Sunday night, I had a dream about you. It seemed that you must have been visiting me, or else you had taken over my production, I don't know. But anyway it was a big house, and we were in one small room of it with a table between us, a regular interview setup like this. There was a table between us, and on one side was a sort of a rack where equipment could be put. And, although I never saw this in my dream, I knew that in the other room, it was a large room, you were helping me prepare a product and you were in charge. And you had something to do with that. Then that room opened off onto several other rooms which we never got into; we were still in this one room. And every so often we could hear the clatter of the girls who were also making the product. Finally, at about 4 o'clock, quitting time, these girls came in, a couple of them, and rolled this piece of equipment thing used in the product and put it in this rack right next to us. And at that time you were telling me that you didn't think my behavior was very good, that you did not like me to call you by your first name, that you felt that until our relationship was established on a firmer foundation, that I should at least give you the courtesy of calling you by your second name. And about that time I was feeling sort of slapped down about it, Mrs. Wolberg came through. It seemed that she kept the books, and she said to me, "Well, besides that, you won't have much more credit up here." Then yesterday afternoon I dreamed of a marriage. Elsa Maxwell handled all the arrangements for the thing, and so forth. And someone else was going to be the overseer and the participant in the affair to replace me. And I saw all this very clearly, the arrangements and the publicity and the beautiful church and the gown; and I felt very much left out of it, and very resentful of the other woman. That's when I awoke and realized it was nothing but a dream. I guess they're all anxiety dreams, but that was a dream that showed to me at least what my feeling was.

Th. Which was?

Pt. That I feel very rejected by you and left out of things. (*laughs*)

Th. You feel rejected by me?

Pt. Then I dreamed of a room full of little girls, blondes and brunettes of different ages, but all within say, 3 to 6 years old. Going into this room was like going on the boat that goes to Catalina where they have all these benches. You know what excursion boats are like. That's what the room looked like. The benches were all full of these little girls. I went in with these attendants, and I was told to pick out the child that I thought I should have had. The phone rang and I never got to picking her out, and that was that.

Th. What do you think this all means?

Pt. This morning after I awakened I tried to piece this stuff together with what little I know about it. I usually think, well, what's my day going to be, the first thing when I wake up in the morning. How soon do I have to get up? How soon do I have to dress? Who do I have to phone? And so forth and so on. This morning I thought: "What is my day today and what is going to be pleasant in it." And the first thing I thought of being pleasant this morning was to come up here! And I had to have my hair done, and I had a certain amount of desk work to do, which to me isn't particularly pleasant or unpleasant. It's something that has to be done, and that's that. It never bothers me too much, but neither do I look forward to it. But I looked forward to coming up here.

Th. It's interesting in the dreams you put me in a certain role with you.

Pt. As if I want to be in Mrs. Wolberg's place.

Th. Do you?

Pt. Yeah, and very much so. (*laughs*) I'd like to have you take me over, I guess.

Th. So that here you're shoved out, and it's almost as if you tentatively have a place and don't have a place. You just don't know. As long as you pay your bills, you have a place. If you don't, god knows what will happen to you. You may be thrown out on your ear. The role that you play with me is not defined. The corollary of that is that you may want me to play a masterful role with you. *[interpretation]*

Pt. And yet I'm the very person that fights against any authority.

Th. That's the annoying part of it. You may not want an authority, but when it isn't there, you may feel insecure, *[giving her more interpretation]*

Pt. I think ... I know you're absolutely right. Because right after our last session, I said, "Goddamn it, why doesn't he do more for me." Then I started getting angry at your wife. I felt like killing her. That made me laugh, because after all, I'm not 20. Why should I feel this way about you? But I do, and I know damn well that your not telling me what to do, and your not letting me figuratively move in with you, bothers me like hell. I know it's silly, but that's how I felt. And it made me feel guilty.

Th. And crowding these things out of your mind must have brought on some reactions.

Pt. It made me sick, I know it did ... *(pause)* It's so silly. (*laughs*) I feel better now.

Perhaps the most important use of dreams in therapy is toward recognizing the signals that they emit pointing to the beginning development of a negative transference reaction that, if unheeded, may expand to block or destroy progress in therapy. Where a therapist does not encourage the patient to report all dreams, the patient may forget or

repress them, and the only sign the therapist may notice that things are not going well is that the patient's symptoms return or get worse, that disturbing acting-out behavior appears, or, worse, that the patient simply drops out of therapy. Where dreams are regularly reported, the therapist will have available a sensitive barometer that indicates the oncoming of an emotional storm. A patient in the middle stages of therapy began coming late for appointments. Only upon urging did she report the following dream:

> *Pt.* I was asleep on a desk or table in your office. I was lying on my side with my knees bent. You walked over to me. You were a shadowy figure that I could barely see through closed lids. I knew I should wake up, but I was curious to see what you would do and I lacked the will to awaken. You touched me. I had been covered, but you removed the cover and I remember thinking "I hope I have a pretty slip on." At first your touch was pleasant, sexual-like, and I felt rather guilty for not letting you know I was really awake. Gradually you began to turn into a sinister figure. You looked into my eyes with a light and said, "That's a lovely blue eye." I barely mumbled, "It's green," feeling that if you didn't know the color of my eyes it meant you didn't know me. I realized with a shock that I didn't know the color of your eyes, either. Brown, I thought, but I wasn't sure. Then you said to me, "What are the things I've told you?" I started to mumble, "Many things." You said, "No, I have told you nothing." I took this to mean that you are absolutely not responsible for anything I might do. These things made you seem sinister to me. You slowly began to change into another man who seemed to be a derelict, and I know I *must* get up. I struggled to awaken myself, and I finally succeeded. I ran to the door and ran out of the room, but there were a lot of people. In a mirror there I saw an utter ruin—I looked 80 years old and terribly ugly and I believe scarred. All the people were old and ugly. It was a village of discarded useless, and helpless people. A feeling of horror overcame me, and, as I stared at that face, I tried to comfort myself that it was only a nightmare and I would soon wake up, and I found it very difficult until I wasn't sure anymore if it was a nightmare or real.

> I finally woke up from the dream so frightened that I wanted to wake my husband, but I decided to try to calm down. I fell asleep again and had a second dream. I dreamed I had stayed up all night writing a paper you asked me to do. I started to bring it into the room you told me to. It was locked. I decided to have some coffee and came back. I did. This time your wife was in the room. She told me who she was. I said I knew. Then she told me she was your daughter's mother as though this made her a figure of great importance and dignity. This made me feel guilty and gave me the feeling that I could not see you anymore. She didn't want me to and in respect to her sacredness as a mother I couldn't.

Had I not become alerted to the beginning transference, which certainly reflected an oedipal problem, I am convinced that my sinister qualities would have become so overwhelming in her unconscious mind that she would have discontinued therapy. As matters stood, we were able to engage in fruitful discussions to a satisfactory interpretation of her dream.

"The task of interpreting a dream" says M. Hollander (1965), "is somewhat like understanding a poem." The therapist sensitizes himself or herself to the *manner* in which the dream is presented and attempts to divine why the patient is bringing up the material at this time. The therapist relates the content to what is known about the patient's past and present interpersonal patterns as well as the character of the immediate relationship with the therapist. The therapist probes into provocative environmental happenings that may have brought out the conflicts symbolized in the dream. He or she searches for dream manifestations of transference and resistance. The therapist avoids employing universal symbolism, focusing rather on allusions and figurative references in the here-and-now, while mindful of the fact that the present rekindles the flames of the past. At the same time the therapist attempts not to overemphasize dreams, for by making too much of them the patient may utilize them to excess, even as vehicles of resistance. The artistry of dream interpretation is selecting out of the tremendous number of variables those that can satisfy the requirements of the immediate therapeutic situation.

42

Identifying Important Trends and Patterns: The Examination of Attitudes toward the Therapist, Including Transference

All people progress from childhood to adult life with attitudes, values, and behavior tendencies that are parcels of past experience. These persist in the form of fixed patterns that repeat themselves compulsively in certain interpersonal situations. Thus, a grown man, intimidated as a child by a punitive father, may respond to all authoritarian men with a cowering, ingratiating set of reactions, as if he virtually still were a little boy awaiting punishment for a misdeed. A grown woman who, as a child, was violently competitive with a younger sister for the attentions of her parents may carry on a campaign for absolute supremacy in important endeavors or situations, as if she repeatedly had to prove that she was "best" and hence worthy of praise and affection. Such patterns, given the proper stimulus, go on repetitively, forming the very fabric of the individual's way of life. They are stoutly defended, irrespective of how irrational they may be or how inherently contradictory they are in operation. The motivants for these drives, and the early experiences that engendered them, seem to exist in the unconscious of every individual. One is aware merely of an impelling urge that forces the adoption, in certain situations, of stereotyped ways of thinking, feeling, and behaving.

Obviously such tendencies, sooner or later, are potentially disruptive to the individual and, when they cannot be controlled, may create difficulties that disorganize adjustment. Normal people are capable of exercising some measure of control by virtue of wanting to avoid the unpleasantness that usually follows unrestrained responses. The defenses employed to curb such impulses may help one to adjust, but in no sense do they minimize the urgency of drives that periodically may express themselves in direct or highly symbolized form.

Fortunately, in addition to immature stereotyped patterns, all persons exhibit

reactions that are reality-determined. These make up many, perhaps most behavioral tendencies.

Thus, the man described above who behaves like a little boy may respond to certain males in an assertive manner once he has assured himself of their good will or has ascertained their incapacity to hurt him. Indeed, with selected men, under special conditions, he may even act the part of authority. Or the woman who competes blindly may be content with a secondary role whenever her security and self-esteem are assured.

Each individual will, therefore, play varying roles with different people, and, contingent on how secure one feels and the measure of one's self-esteem, one will react with either infantile past patterns or more mature patterns.

In Chapter 39 we have considered the examination, through focused interviewing, of the patient's current interpersonal involvements in order to identify disturbing patterns responsible for the emotional disorder. In the present chapter, we shall cover the process of investigating both stereotyped infantile and mature rational responses as they are expressed toward the therapist within the framework of the therapeutic situation.

Before taking up this process, it is necessary to emphasize that in supportive therapy, and in directive forms of reeducative therapy, it is often unwise to delve into the nature of the relationship with the therapist. Such a move tends to challenge the position of the therapist as a benevolent authority and the foundations of faith on which success in treatment may depend. Indeed, the attempt is made to perpetuate in the patient the illusion of the therapist's protective powers, no effort being extended coward examining the irrational sources of the patient's dependency need. The hope is to adjust the individual to less disturbing unconscious impulses, to increase repression of the more destructive ones, to expand existing assets, and to encourage compensations and sublimations so that patient can live as happy a life as is possible with his or her liabilities. Nevertheless should the patient's attitude toward the therapist become disturbing and interfere with the conduct of therapy, they are dealt with as manifestations of resistance to problem-solving and symptom relief.

In some forms of reeducative therapy, however, the more conscious manifestations of stereotyped patterns projected into the therapeutic relationship are explored and discussed in an attempt to modify or to control them. In reconstructive therapy, where an effort is always made to bring infantile patterns and their manifestations to full awareness and to determine their genetic origins, a thorough study of what goes on in the patient's relationship with the therapist is mandatory.

Insight into many of the patient's problems may be gained expediently through exposure of feelings and attitudes toward the therapist. The patient always projects into the relationship strivings that are both reality-determined and conditioned by habitual, unrealistic impulses toward people. The differentiation by the therapist of these two kinds of strivings helps the patient to understand the automatic, compulsive nature of some responses.

There is nothing so dramatic to a patient as to realize that he or she reacts to the therapist, not as a real personage, but as a virtual reincarnation of a parental or sibling figure (transference). The demonstration of how attitudinal and behavioral reactions are rooted in past relationships and how they distort the present reality situation is a living demonstration to the patient of the irrational way that he or she feels and behaves in everyday contacts with people. This realization may start a process of re-evaluation of the self.

One of the important effects of understanding the nature of impulses and attitudes toward the therapist is that it enables the patient to differentiate rational from irrational authority. Expectations of being treated by the therapist in a manner similar to the way that the patient was handled by previous authorities are not fulfilled. Avoiding a punitive, judgmental attitude, the therapist regards the patient's difficulties with sympathy and understanding. Expressions of hostility by the patient are accepted without indignation or retaliation. This allows the patient to display resentment more and more openly. It permits the patient to investigate its source as well as to understand reasons for its present existence.

Although every patient responds to the therapist with some patterns that are unrealistically determined, these may not be openly expressed. Subjected to reality testing, certain impulses are recognized by the patient as irrational. They may be considered threatening to an idealized relationship with the therapist. Accordingly, they are disassociated, suppressed, or repressed. Sometimes they impinge merely on the periphery of awareness, appearing in a symbolized form in dreams and fantasies or revealing themselves in slips of speech and random behavior, such as acting-out. Transference may manifest itself in relationships outside of therapy, the patient discharging toward a mate, relative, friend, or other personal feelings and attitudes that he or she dares not express toward the therapist.

Certain activities on the part of the therapist discourage or encourage the revivification in the therapeutic relationship of archaic patterns. Where the therapist considers that desired goals in therapy can be achieved without the stirring up of excess transference, the therapist may decide to deal with emerging irrational attitudes in as immediate and forthright a manner as possible. Thus, hostility, sexual impulses, and intense dependency are handled by discussion and clarification as soon as they become apparent, an effort being made to keep reality in the fore. The relationship is maintained constantly on a positive level. This is the stance utilized in many, perhaps most, forms of therapy.

Among the techniques utilized to reduce transference are these:

1. Focusing discussions on present relationships and the current life situation

2. Minimizing or avoiding the consideration of the past, including relationships with parents

3. Avoiding dreams, fantasies, and free associations.

4. Avoiding the couch position and employing face-to-face interviewing

5. Spacing interviews no more frequently than once or twice weekly

6. Dealing with any unrealistic attitudes or feelings toward the therapist as soon as

these are perceived

7. Playing a role opposite to that which the patient anticipated on the basis of past relationships with traumatizing authority

8. Exercising activity rather than passivity in the relationship

Through the use of these techniques it may be possible to withhold infantile urges from awareness, or to direct them away from the therapeutic relationship toward outside relationships, or to relegate them to a position where they may be held in check by rational controls.

In spite of these activities and precautions, transference may burst forth in full fury, interfering with the treatment plan. When this happens, it will have to be handled like any other kind of resistance, by such techniques as active interpretation.

Transference, may, however, be encouraged in certain patients whose problems are very deeply repressed and who are constantly being upset by unconscious conflicts. No movement may be possible except through the direct experiencing of their problems in the relationship with the therapist. Among syndromes in which obstinate repression may occur are anxiety reactions, phobic reactions, conversion reactions, dissociative reactions, stress reactions, and certain obsessive-compulsive reactions. Here mobilization of transference as a learning vehicle may be helpful.

Transference may become so intense that the patient will actually live through with the therapist some early developmental blocks and traumatic experiences that produced the original repressions and other mechanisms of defense. The development of exaggerated transference reactions (transference neurosis) enables the patient to reexperience early deprivations and intimidations and to master them in another, more favorable setting with a new, more accepting, more permissive, better disciplined authority.

During classical psychoanalysis the therapeutic situation is deliberately manipulated so as to induce regression. This is considered inevitable and important for the

revivification and working through of the most unconscious conflicts. The patient "will become a child again and be reborn, so to speak. Then he will grow up again, grow up better than he did before, guided by his now more mature intelligence and the warnings and lessons of his unhappy experiences now better understood" (Menninger, KA, 1961).

There is disagreement regarding the necessity for such regression, the neo-Freudians considering the here-and-now problems more important than those of the past, and believing that personality change can be achieved without the patient regressing to the infantile neurosis. Indeed, there are some analysts who, while analyzing positive and negative transference, consider the outbreak of a transference neurosis a sign of bad therapy.

Transference may operate both as stimulant toward and resistance against uncovering the unconscious; it may function, as Waelder (1936) has remarked "as the condition under which it is eminently possible to bring direct influence to bear on the patient." As a means toward understanding the most dynamic drives in the individual, transference has no parallel. The concerted analyses of both positive and negative transference are ways of bringing the patient to an understanding of the self in depth.

> I recall the first patient I had as a "control" when I was in analytic training, who taught me how persistent and irrational a transference reaction could be and how in its proper handling a profound understanding may evolve. The patient was an attractive young lady in her early 20s who had a slight stammer and whose complaint was that she was unable to "fall in love" or even to develop a warm relationship with a man. Yet she had intensely romantic and erotic fantasies about men, which made her actual detached experiences with them so much more disappointing. The technique that I was employing was patterned after the classical model. I judiciously maintained a passive, non-interfering manner under the weekly tutelage of my supervising "control analyst." Several months of free associations rolled by during which I judiciously took notes from behind the couch and waited hopefully for something interesting and dramatic to emerge from the depths of her unconscious. And one day to my consternation it did, with a violence that left me dismayed and somewhat frightened.

> The start of this episode was, to my surprise (since I could see no reason for it), sudden and complete silence on the part of the patient. Whereas she was customarily a spirited and garrulous analysand, a complete change had occurred in her since the session on the day before when she had rambled along enthusiastically, associating vigorously to events in her past. This day she walked into the room, cast a furtive glance at me, and retreated to the couch, where she stared fixedly at the

ceiling with face flushed, fists and jaw clenched. Sensing that something was happening. I waited expectantly in vain for her to reveal her thoughts. After 20 minutes had passed, my curiosity overwhelmed my studied noninterference, and I proceeded to interrogate her. But nothing seemed capable of penetrating her muteness.

Ten minutes prior to the end of the session she precipitously propelled herself from the couch and was about to bolt out of the room. I stopped her before she reached the door, and losing my therapeutic composure, I urgently insisted that she tell me what her reaction was all about. Her response was violent consisting of a torrent of abuse and invective. "You bastard," "You son of a bitch" were among the milder expletives. Shrieks mounted into an accusatory crescendo. "You know, you know what you did!" she repeated with no trace of a stammer.

It required almost a half hour of reassurance to induce her to tell me what had upset her. The pith of her agony, it turned out, was that after she had left my office following the last session, she noticed me dashing across the street against traffic. This was no illusion or hallucination. Opposite my office building there was an optical shop that filled prescriptions for eyeglasses. I had left a prescription there some days previously and, having a few minutes before my next patient arrived, I decided to rush out, get my eyeglasses, and return to my office as expeditiously as I could. I did not notice that my patient was waiting at the corner and that she observed me dodging a few cars in my haste. This, she protested, was exactly what her father would do. He took risky chances to the horror of her mother and the entire family, and he was involved in several serious accidents, finally being killed in a car crash. "You are like him," she remonstrated. "You did it to defy me." My explanation of what prompted my hasty journey fell on deaf ears. I was, she insisted, making up a story to appease her, following the style of her father. It was only after I showed her the receipt of payment for my prescription that she stopped her attack. But for months she was emotionally convinced that I had perpetrated a ruse.

The experience opened up a deep pocket of distrust that she had harbored for men since her childhood. With the help of my supervisor who guided my analytic work, I was finally able to win her trust. This was the start of a new era in her relationships with men. Had I not provided her with a precipitating incident, I am sure that she would perhaps later on have found another reason to justify her transference reaction.

As resistance, transference manifests itself in attempts to gratify childish impulses. Stubbornly refusing to acknowledge their unreality, the patient insists on living them through with the therapist. The analysis of the resistance aspects of the transference is an important aim in all psychotherapies.

Employing positive aspects of the transference relationship to promote supportive

and reeducative measures is common in non-analytic psychotherapy. Positive transference, accordingly, in many forms of therapy is left unanalyzed; it is even encouraged to expedite the therapeutic process. On the other hand, negative transference is always considered an impediment in treatment; it is analyzed and worked through exhaustively as soon as it is perceived.

When one wishes to effect a transference interpretation, rather than dissipating it by some active gesture, one should permit it to build up to a peak without defending oneself. Once the top of the reaction has been reached, one should wait until it has receded somewhat before interpreting it. In the height of emotion the patient will tend to deny the validity of the therapist's remarks or look upon them as evasions of blame. This is in contrast to what is done in classical analysis when interpretations are often made at the peak of the emotion purposefully to foster frustration and in order to put the patient into contact with repudiated parts of the self.

On the other hand, the therapist may seek to prevent the full transference reaction by interpreting it at its start, when it is at the fringe of awareness, from evidences of transference in silences, peculiarities in behavior, dreams, or acting-out. Here the need for stirring up a past emotional reaction in its *full* intensity may either be contraindicated or deemed unnecessary.

The way of making a transference interpretation may be important because the patient needs to be prepared for it. The patient's most natural reaction would be to deny its validity since its roots are unconscious. The therapist first points to the manifestations of the reaction and asks if this may not be more extreme or more unusual than the reality situation demands. Should the patient deny this, the decision may be to wait until the reaction reappears, when again it is brought to the patient's attention. Once the patient acknowledges that perhaps his or her reaction is unusual, the therapist may then suggest its origin in past relationships and perhaps, if there is sufficient evidence, speculate on the person or persons with whom the therapist is being identified. Finally, the therapist should study the patient's response to these interpretations.

The techniques that may be used to accentuate transference are:

1. Employing passivity and anonymity in the relationship.

2. Focusing discussions away from the present life situation.

3. Encouraging consideration of the past, including relationships with parents.

4. Using free association and the couch position. Removing of oneself from the direct gaze of the patient.

5. Concentrating on dreams and fantasies.

6. Increasing the frequency of sessions to 4 or 5 times weekly in order to break down repression.

7. Avoiding answering questions and restricting interpretations.

8. Avoiding dealing with unrealistic attitudes or feelings toward the therapist until these have built up to overwhelming proportions.

9. Acting in a role that coordinates with that assumed by the patient's traumatizing parent.

Patients will respond variably to these techniques, from failure to mobilize transference in certain rigid and detached persons, to explosive reactions that prove traumatic to the individual in borderline conditions. Indeed, in some patients intense transference may promote too great a shattering of repression which, not being reestablished, may eventuate in a psychosis. Syndromes such as borderline conditions, psychotic states, and certain personality disorders, psycho-physiologic reactions, and some obsessive-compulsive reactions do not respond favorably to the deliberate mobilization of transference. Even in cases where it is indicated, the fostering of transference is not to be encouraged by any therapist who has not had extensive analytic training and experience. (See also Chapter 49)

QUESTIONS ABOUT TRANSFERENCE

The following questions are frequently asked about transference to which are given

to accent what has been said above.

1. Aren't transference, relationship, and corrective emotional experience interchangeable terms?

Transference has become a watered-down expression that is sometimes confused with other forms of the patient-therapist relationship. At different times in this relationship the patient will play different roles, depending on the special needs that exist at the time. One of the roles is transference, whose meaning should be restricted to the feelings and reactions that the patient harbors toward significant persons in the past that are now being projected into the present. To a large extent such feelings are repressed and relegated to the oblivion of the unconscious. When they do surface during therapy they give us insight into infantile conflicts. They also tend to distort the immediate reality situation and divert the patient from engaging in goal-directed therapeutic tasks. Because transference can in this way act as a resistance to therapy, an attempt is often made to work it through or resolve it by interpretation whenever traces of archaic stereotyped negative or eroticized reactions manifest themselves. There are circumstances, however, when the allocation and deliberate buildup of transference is encouraged in order to examine its dimensions, origins, and effects, and especially how it engenders the present neurosis or character disturbance.

Analysis of transference is the major task in classical analysis and to elicit transference, techniques are utilized to encourage regression and the acting-out in the therapeutic relationship of repressed feelings and memories. When the buildup becomes so intense that the patient actually confuses the therapist with past important persons, the phenomenon is sometimes termed a *transference neurosis.* In certain patients, like borderline cases, the behavior may be explosive and psychotic-like (transference psychosis). Utilizing the leverage of the therapeutic alliance that has been built up, and appealing to the patient's "reasonable ego," the therapist actively interprets the patient's transferential responses, with the goals of bringing reality into the picture and of inculcating insight.

"Positive transference" is rooted in the patient's ever-present longing for an idealized parental figure who will love, protect, and lead the patient on to happy security and creative self-fulfillment. Positive transference thus is deliberately employed as a catalyzing force to promote supportive and reeducative therapy. It is only when it becomes unreasonable, the patient reaching out for magic in the hope of fulfilling infantile dreams and archaic sexual needs, that the transference must be neutralized by interpretation since its indulgence will interfere with or destroy therapeutic progress.

Positive transference should be distinguished from the working alliance in which the patient cooperatively relates to the therapist with expected trust. Experiencing understanding and empathy, the patient is encouraged to distinguish between punitive and non-punitive authority, and to dissociate the therapist from the judgmental, punitive agencies in his or her past as well as from their precipitates in the superego. It is this unique kind of relationship that facilitates restoration of morale, alleviation of tension, the ability to divulge and face repudiated impulses and hurtful past experiences, tolerance of confrontations, absorption of constructive suggestions, identification with the value system of the therapist, utilization of reinforcements toward more adaptive modes of coping, and acceptance of clarification and interpretations that will lead to better understanding and a working through of one's basic problems. The relationship itself then acts as a "corrective emotional experience."

These varying dimensions of the relationship do not operate exclusive of each other, but may shift from one to the other at different phases of the therapeutic process. It is important for the therapist to recognize what is happening to the relationship to avoid a bad impasse, which, should it happen, will eliminate perhaps the most potent corrective force in treatment.

2. We know that the patient's reactions to the therapist are important. How do you present this to gain the patient's cooperation in reporting his or her feelings about the therapist, which in my experience is too often concealed out of embarrassment, anxiety, and so on?

One can say to the patient: "I am constantly going to look for the manner in which you react to me and how you feel about me. The reason for this is that in these reactions we can learn about how you have reacted to your parents and other people better than in wringing it out of your memories, many of which have been forgotten. So no matter how embarrassing it may seem, or how anxious you get, tell me about your feelings and ideas about me so we can both learn about you."

3. It is paradoxical to me that transference, which is the central issue in psychoanalysis, is not considered to be of importance in many other forms of therapy like behavior modification. How would you account for this?

I believe that this dilemma can be explained. In classical analysis there is a deliberate creation of transference through frequent visits (four to five sessions weekly), studied anonymity, free association, and other devices for the purpose of activating unconscious and repudiated aspects of early experience. The surfacing of this material is often in the form of projection onto the therapist of the incorporated parental introjects. The working through of unresolved past needs and conflicts in the more congenial atmosphere of the therapeutic alliance is for the purpose of resolving unconscious conflict, which is what analysts believe to be the pathogenic core of the neurosis.

In other less intensive forms of therapy no attempt is made to liberate unconscious ideation, the focus of therapy being on the more conscious and here-and-now aspects of experience. Repressive defenses are either unaltered or are approached obliquely, with the consequence that transferential projections do not occur with the intensity that they manifest in classical analysis, where they may take the form of a stormy transference neurosis or frenzied transference psychosis.

This does not mean that transference is absent in symptom-oriented or problem-solving types of therapy like behavior modification. Transference may appear in attenuated forms as in dreams, in restrained acting-out, or in other highly disguised kinds of behavior. Under such circumstances therapy may still not be interfered with and may proceed satisfactorily with achievement of sought-for goals of problem-solving and

symptom alleviation. Sometimes, however, especially where defenses are not too strong, transference may break through in force and act as resistance, under which circumstance its resolution may be required to expedite therapeutic progress.

4. Cannot reconstructions of the past from the history of the patient, dreams, and recollections serve as well as activating the past through transference?

Not at all. Such reconstructions may have some effect, but only an attenuated one compared to the insight gained through living the past through in some dramatic situation in the present such as a transference neurosis.

5. What is the true value of transference in psychotherapy?

Transference reactions enable us to penetrate into the past of the patient and to see how early experiences with important persons, usually parents and siblings, have produced a paradigm around which the individual fashions many present reactions. This knowledge is especially important in patients whose symptoms and behavioral difficulties and problems in their relationships with others are repetitively sustained through the insidious operations of transference. More importantly, the therapist often becomes the target of transference projections and, when this happens, the therapeutic process may get derailed because of resistance to the therapist and to the treatment techniques. Resolution of this resistance (generally through interpretation of what is happening) puts the treatment process back on the rails, so to speak. At the same time, the patient's new insight is an opportunity to appraise one's behavior from a causative perspective, and, if motivated to do so, to correct unrealistic patterns and attitudes so that they are not contaminated by past experiences, traumas, and fantasies. In this way, the therapeutic relationship can act as a corrective emotional experience.

6. Are all positive reactions to the therapist manifestations of neurotic transference?

There are genuine positive feelings in human relationships that do not have to be

considered neurotic or transferential. These must be differentiated from distorted overvaluations and ideas of the therapist's magical powers, undaunted givingness and benevolence that are manifestations of neurotic transference. The former feelings are productive aids in the psychotherapeutic process; the latter are sooner or later destructive to the process.

7. When does transference especially act as resistance?

Transference acts as resistance when the patient tries to live through with the therapist early ungratified needs and impulses at the expense of getting involved with therapeutic work. For example, needs to gratify oedipal wishes through sexualizing the relationship with the therapist (by fantasies, overt behavior during the session, or acting-out away from the treatment) may become an obsession with the patient. Also, needs and impulses, or mere awareness of these, may create anxiety and mobilize resistance to the therapist and to his or her interventions. Another and not uncommon form of transference resistance involves fighting off the influence of the therapist the way the individual fought off an authoritarian and interfering parental figure during the developmental separation-individuation struggle.

8. Can transference occur toward persons other than the analyst?

Of course this can happen, but we must always alert ourselves to the possibility that such a reaction is a displacement from transference on the analyst, which is being repudiated and expressed through a surrogate. Thus, infantile sexual wishes which ordinarily would be projected onto the analyst may be denied and then expressed through the body of another person outside of therapy.

9. Should you try to regard a patient's unusual emotional reactions as manifestations in some way of the transference?

If possible, yes. Often what may be helpful is questioning whether in responding to certain happenings the patient had or now has thoughts, feelings, or fantasies about the

therapist. If the patient denies this, one may casually accept this but should search in the nonverbal behavior, slips of speech, etc., for evidences of transference and confront the patient with such evidences.

10. Can one take transference reactions at their face value?

It is always essential to search for latent content behind manifest behavior.

For example, one of my patients experienced anxiety in one session and hesitatingly revealed a rape dream in which she was the victim and I the rapist. Thoughts of my having sexual designs on her had occupied her for several days. I interpreted her reaction as concealing a desire to be seduced by me. This interpretation started a series of memories related to lascivious fantasies about her father that accompanied her early masturbatory activities. Our focus on her oedipal fears and feelings had a most constructive effect on her relationship with me and resulted in a good deal of progress in her treatment.

11. Are there different kinds of transference interpretations, and if so, which are most effective? Also, is it better to relate transference to the here-and-now or to the past?

Transference traditionally has connoted a concentration on the therapist of the patient's involvements with early objects. Accordingly, the therapist is conceived of as a resource for archaic needs and impulses, as well as a vehicle for defenses against them. This common concept of transference, namely that it acts like a bridge between the past and the present, has been expanded to include reactions related to here-and-now relationships between patients and therapists, as well as between patients and other authority figures. Defenses against such reactions have been also considered aspects of the transferential spectrum. The transference interpretation, while not neglecting exposure of origins in the past, may productively include how the past is influencing present reactions. Some analysts also search for manifestations of the self that are being expressed through transference.

Consequently, when we talk about transference interpretations, we are alluding to a range of activities, such as:

1. relating the patient's reactions to those he or she originally had toward parents or siblings;

2. differentiating the patient's distorted attitudes and feelings toward the therapist from the actual reality of what the analyst is like;

3. pointing out how the manifest behavior toward the therapist shrouds latent intentions;

4. indicating how the patient's feelings and behavior toward the therapist reflect important incidents that have happened in the past; and

5. depicting how drives embodied in character structure operate to create pathology.

Transference interpretations may also embrace displacements from the self onto the therapist.

12. Does interpretation of the transference always lead to insight?

No, the patient may not be ready for or may resist the interpretation. The best results in transference interpretation will be obtained where the patient is immersed in strong emotions and the interpretation links these emotions to the transference situation. Similarly, a current conflict that can be connected with transference may make the impact of the interpretation greater.

13. Some authorities contend that only transference interpretations are important. Do you agree?

There are many analysts who affirm C. Brenner's (1969) contention that "every interpretation must be a transference interpretation if it is to be effective." This implies that true insight can be achieved only through interpretation of the transference. Any analyst who has utilized and witnessed the effectiveness of interpreting the transference

once it has developed to full intensity cannot argue with the sentiment behind these statements, but the implication that other kinds of interpretations are ineffective may certainly be challenged.

When we observe the resistance encountered in analyzing neurotic symptoms and character traits directly, we must credit transference interpretation with making the greatest impact on the patient. But to restrict ourselves to this single activity limits the therapist's flexibility. Indeed, attempting to wedge all events and reactions into a transference formulation may do no more for the patient than to mobilize resistance. Nontransference interpretations can be extremely important in their own right, apart from reinforcing the impact of transference interpretations.

14. How does free association relate to transference?

Free association loosens past memories, which liberate emotions, which in turn tend to activate transference.

15. How truly essential is a transference neurosis for successful analysis?

Most analysts believe it to be indispensable. Some do not. Thus, Gill and Muslin (1976) have pointed to Glover's assertion that "there may be successful analysis … where no transference neurosis develops." Of course we are dealing here with the definition of a "successful analysis." If it means the surfacing and interpretation of the unconscious repressed aspects of childhood, a transference neurosis provides the patient with the best opportunity for the working through of these residues. If it means the achievement of reconstruction of the personality, there is no guarantee that a transference neurosis will accomplish this objective in every case. Nor is there validity in the idea that it is only through a transference neurosis that one can achieve personality reconstruction. Admitting these exceptions, the majority opinion still is heavily on the side of a working through of a transference neurosis as a most helpful vehicle for a successful analysis.

16. Is acting-out always a manifestation of transference?

Where a patient is in therapy, it should be regarded as such unless proven otherwise. But, factually, acting-out can occur exclusive of transference.

17. Why, if transference acts as a resistance to dynamic therapy, do dynamic therapists try deliberately to produce it in their patients?

Transference embodies some of the core infantile conflicts that operate unconsciously to produce neurotic illness. Its elicitation allows the therapist to confront, interpret, and clarify the meaning and purpose of the patient's illness. It may, however, create resistance as it develops; a chief therapeutic task is the resolution of this resistance, the working through of which becomes an important part of the cure. The purposeful encouragement of transference is an aspect of psychoanalytic treatment, particularly in its classical form. In other forms of dynamic therapy no effort is made to mobilize transference, but it still is dealt with by interpretation and clarification where it operates as resistance to therapy.

18. When would you consider it unwise to encourage transference as a therapeutic technique?

Transference should not be encouraged:

1. When the patient already has a problem in reality-testing (as in psychoses, unstable borderline cases, and paranoidal personalities);

2. when there is not enough time to work through transferential dependencies (as in short-term therapy);

3. when the therapeutic alliance has not been firmly established to sustain the rigors of transference;

4. when the defenses of the patient are so fragile that he or she cannot handle anxiety or tolerate frustration (which is inevitable in the transference experience);

5. when the objective in therapy is not deep conflict resolution but, rather, a more harmonious adjustment to the current reality situation.

From a practical standpoint this limits the number of candidates for transference mobilization to a highly selected group. It must be remembered, however, that, as sincere as our attempts may be to limit transference, it may still appear spontaneously, and it will then require careful resolution should it interfere with the therapeutic process.

19. Should positive transference be analyzed?

Positive transference should not be analyzed in short-term therapies, where it is utilized as a catalyzing force. It requires analysis in longer-term therapy where, because of the inherent magical expectations it invokes, the dependency it inspires, and the erotic interest stimulated, it can be a deterrent to progress. Incidentally, when a positive transference is resolved, a hidden negative transference may surface that will, of course, have to be worked through.

20. How soon will transference reactions begin?

They can occur in the first session and even before the first session with fantasies about the therapist and anticipation of what will happen in treatment. Manifestations of transference may be more easily controlled early in therapy than later on when intensity increases. Transference may exhibit itself only in dreams, slips of speech, and nonverbal behavior.

21. There is a form of transference during therapy that we call "falling in love" with one's therapist. Isn't this really a help in treatment?

On the contrary, I would consider it as a resistance. It often comes when the patient is working on especially difficult phases of a problem. This transference is usually not a mere verbalization to appease the therapist, but stems from archaic eroticized needs that have been deeply repressed and have little to do with the real person of the therapist. The patient will urgently and persistently demand gratification, if not in an actual sexual experience, then in intimacies that have symbolic sexual values. The therapist's refusal to abide by the patient's wishes is extremely frustrating to the patient and the patient may

seek external outlets for gratification in the form of acting-out with potentially disturbing and even dangerous consequences. So long as this transference need exists, the patient will resist the real aims of treatment. It is urgent, therefore, to resolve the transference. The best way to do this is to continue refusing to abide by the erotic transference need (gratification of which can be extremely destructive to the patient and the therapist) and to handle it through interpretation both as a form of resistance and as a means of understanding some of the deepest needs, conflicts, and defenses of the patient, certain manifestations of which are reflected in the symptoms for which therapy is now being sought. Interpretation of transference is an art and will call for astuteness and objectivity, as well as awareness and management of the therapist's own countertransference. Analysis of transference provides a way of metamorphosing archaic sexual fantasies and impulses into mature, fulfilling sexuality and constructive sublimations.

22. In dynamic psychotherapy how do you keep a balance of an empathic working relationship and the transferences that you want to come through to give you an idea of the patient's innermost conflicts?

While you are interested in finding out the nature of the patient's infantile conflicts, you try to keep the lid on transference material that will act as too great resistance to you and your techniques. You do not have to use special tricks to bring out these transference manifestations. They will come through, if not in direct behavior toward you then in acting-out away from therapy. You will generally get clues about transference from nonverbal behavior and especially from dreams. If there are evidences of hostility, fear, sexual interest, detachment, or paralyzing dependency, deal with these through open discussion before they germinate into full-blown patterns that may be more difficult to handle.

Even though these manifestations will give you inklings about some of the most urgent conflicts, your first task is to see to it that transference does not interfere with the working relationship, at the same time that you utilize it to give the patient some insight into the origin and nature of some of his or her conflicts. In psychoanalytically oriented

therapy one may want to encourage some transference, but, as I mentioned before, transferences will probably not need encouragement, emerging spontaneously in some form as defenses are challenged. Where controls are rigid, some therapists utilize techniques to encourage transference (more passivity on the part of the therapist, increasing the frequency of sessions, focusing on the past and on early relationships, encouraging dreams, etc.), although too great regression should be avoided. Where one wants to deal with present-day adaptations, transference is discouraged (by its early exposure and interpretation, by decreasing session frequency, by activity in the relationship, and by focusing on real events rather than the past and dreams).

23. How can you tell when a patient is in transference or is going into transference?

Generally, the therapist will be able to discern in the patient a manner that is different from the usual behavior. At the start of therapy the patient is generally highly defended and plays the conventional role of a patient with helping authority. After a while, and particularly where the patient's defenses are challenged, a change in demeanor becomes manifest. The patient may engage in periods of silence, or complain of having nothing in mind or having little to talk about, or cancel or break appointments, or come late, or keep looking at his or her watch if time is passing too slowly, or forget to pay the therapist's bills. On the other hand, the patient may verbally or nonverbally show an extraordinary interest in the therapist's private life, or become competitive with the therapist or with the therapist's other patients, or display dependency on the therapist, hanging onto every word, or openly or covertly make sexual advances toward the therapist. More difficult to detect are acting-out tendencies that the patient conceals from the therapist, in which feelings that are related to the therapist are projected to outside persons or situations. One way the patient has of concealing acting-out is by talking almost exclusively about the past, or speculating on dynamics, or bringing in involved dreams that are extremely difficult to decode.

Often the first intimations of transference are in dreams in which certain behaviors

are exhibited toward symbolized versions of the therapist. The way such intimations are handled will depend upon whether the therapist wants to let transference build up until it reaches a crescendo, as in psychoanalysis, or to dissipate it by exploration and interpretation before it acts as resistance, as in non-analytic treatment.

ILLUSTRATIVE CASES

Example 1

A beginning breakthrough of transference is indicated in the following excerpt.

> *Th.* You know sometimes I get the impression that you act with me as if you are walking on eggs. I wonder if you have any feelings toward me you are not talking about.

> *Pt.* I don't, I don't know. This is one of the disturbing things ... when I'm all tangled up inside and don't know *(weeps)*... I don't want to cry ... I'll wipe my nose ... I don't know why I'm so upset today, really I don't. I felt so much better yesterday.

> *Th.* Perhaps it's because I bring up the subject of your feelings toward me.

> *Pt. (cries)* I feel irritated, just a momentary anger. I haven't been particularly conscious of it. I don't dislike you, just irritated, *(pause)*

> *Th.* Do you want to tell me more about your feelings toward me?

> *Pt.* I don't want to have feelings for you.

> *Th.* You don't want to have feelings for me?

> *Pt.* No. I don't know why.

> *Th.* Perhaps you are afraid of showing emotion?

> *Pt.* I certainly would be afraid of feeling affectionate.

> *Th.* You would?

> *Pt.* I certainly would.

> *Th.* I wonder why?

> *Pt.* I was thinking of it, as a matter of fact, yesterday. I felt...well... if I behaved well ... perhaps you would be good to me ... fatherly like, I mean.

Th. If you behaved affectionately to me you mean?

Pt. Yes, but I'm afraid.

Th. Afraid? Of what?

Pt. That it would not be taken seriously. Would it?

Th. If you felt affectionate toward me, of course I would take your feelings seriously. Perhaps what you're saying is that I might reject you or hurt you in some way?

Pt. What I mean is that I'd be ashamed of my feelings, that this would be a one-sided relationship. I think I feel you'd ridicule me.

Th. Actually, you don't know how I'd act, and yet you behave as if I do ridicule you for your feelings.

Pt. If I had feelings would they be responded to ... would they?

Th. You mean would I reciprocate with the same kind of feeling?

Pt. That's it.

Th. If I did, this would not be a therapeutic situation for you.

Pt. I suppose not.

Th. But if you allowed yourself to talk about your feelings, I might be of considerable help to you in your problem.

Pt. (*giggles*) Now I feel very silly.

Th. Silly?

Pt. I do like you very much.

Th. (*smiling*) Mm hmm.

Pt. And I did feel about you ... that you were able to help me. I did feel you were protective, something like I wanted father to be.

Example 2

The following excerpt is from a session with a patient suffering with a severe anxiety reaction with psycho-physiologic components. During the session the patient brings up a transference reaction that she traces to its source and then recognizes the operation of

similar reactions in her relationships with people.

Th. I notice that you don't want to look at me today.

Pt. I don't want to like you. I'd rather not like you.

Th. I wonder why?

Pt. I feel I'll be hurt. Liking you will expose me to being hurt.

Th. But how *do* you feel about me?

Pt. I don't know. I have conflicting emotions about you. Sometimes I like you too much, and sometimes I get mad at you for no reason. I often can't think of you, even picture you.

Th. Do you feel that you stop yourself in your feelings toward me?

Pt. Yes, I don't want to like you. If I do, I won't be able to stop myself. I'll get hurt. But why do I feel or insist that I'm in love with you.

Th. Are you?

Pt. Yes. And I feel so guilty and upset about it. At night I think of you and get sexual feelings and it frightens me.

Th. Do I remind you of anyone?

Pt. Yes. *{pause}* There are things about you that remind me of my brother. (*laughs*) I realize this is silly.

Th. Mm hmm.

Pt. My brother Harry, the one I had these sex experiences with when I was little. He made me do things I didn't want to. I let him fool with me because he made me feel sorry for him.

Th. Do you have any of the same feelings toward me?

Pt. It's not that I expect that anything will really happen, but I just don't want to have feelings for you. I never liked doctors or dentists, especially dentists. The other day I had to go to a dentist. My mind was filled with crazy thoughts.

Th. Mm hmm.

Pt. These crazy things come into my mind that make no sense. I made this dental appointment, and I thought of the drill going into my tooth. Then I thought of the drill being an egg beater. Later I went to the movies, and in a cartoon I saw eggs. I then realized my attitude toward eggs has always been wrong. As a child my mother scolded me for frying eggs and burning them. Then the day before I went to the dentist, I got nervous. I then pictured eggs being

cooked, and then I had a picture of a raw egg and realized the white of the egg looked like seminal fluid and I got sick. It's like this fluid can kill me. I remember my brother wanted to have sex with me when I was a child. He said he had this fluid in him and it would poison him if he didn't get it out. I let him fool with me. Then he told me about people putting it in their mouth. It disgusted me, made me sick. I have dreams of my mouth being smashed and my teeth falling out. The whole thing seems to be connected with sex.

Th. But what about your feelings for me?

Pt. I know it's the same thing. I'm afraid of you taking advantage of me. If I tell you I like you that means you'll make me do what *you* want.

Th. Just like Harry made you do what he wanted.

Pt. Yes. I didn't want to let him do what he did, but I couldn't stop myself. I hated myself. That's why. I know it now because there is no reason why I should feel you are the same way. That's why I act that way with other people too. It's like what happened not long ago with my art lessons. I went to this art place where I study, and I got very nervous and I had to go home. *(pause)*

Th. Try to connect up what happened.

Pt. It irritates me that I can't paint as well as I should. This woman who runs the art place seems to like me. I don't like that. It's like I'd get too friendly with them. I don't like to have people get too close to me. I think wrong about that. When I was little my sister used to take advantage of me too. But the most of it was my brother. The whole thing is the same as happens with you. It's all so silly and wrong. You aren't my brother and the other people aren't my brother. I never saw the connection until now.

Example 3

A patient on the verge of experimenting with the expression of aggression brings out transference feelings that help her understand some reasons why she repressed aggression.

Pt. I want to talk about my feelings about you.

Th. Mm hmm.

Pt. You sit here, a permissive person who lets me go on. I want to do something now, but I'm afraid you will be disappointed in me if I upset the apple cart, if I explode. I think we are too nice to each other. I'm ready not to be nice. My greatest fear of you is that you are potentially going to be severe with me if I get loose. Also, I fear I will let you down by not performing well, by not being nice. I feel I will gain your disapproval. And yet I see you don't condemn and don't criticize. It is still important to me to gain a nod from you or a smile *(pause)*

Th. It sounds as if you would like to let loose with me, but you are afraid of what my response

would be. *[summarizing and restating]*

Pt. I get so excited by what is happening here. I feel I'm being held back by needing to be nice. I'd like to blast loose sometimes, but I don't dare.

Th. Because you fear my reaction?

Pt. The worst thing would be that you wouldn't like me. You wouldn't speak to me friendly; you wouldn't smile; you'd feel you can't treat me and discharge me from treatment. But I know this isn't so, I know it.

Th. Where do you think these attitudes come from?

Pt. When I was 9 years old, I read a lot about great men in history. I'd quote them and be dramatic. I'd want a sword at my side; I'd dress like an Indian. Mother would scold me. Don't frown, don't talk so much. Sit on your hands, over and over again. I did all kinds of things. I was a naughty child. She told me I'd be hurt. Then at 14 I fell off a horse and broke my back. I had to be in bed. Mother then told me on the day I went riding not to, that I'd get hurt because the ground was frozen. I was a stubborn, self-willed child. Then I went against her will and suffered an accident that changed my life, a fractured back. Her attitude was, "I told you so." I was put in a cast and kept in bed for months.

Th. You were punished, so to speak, by this accident.

Pt. But I gained attention and love from mother for the first time. I felt so good. I'm ashamed to tell you this. Before I healed, I opened the cast and tried to walk to make myself sick again so I could stay in bed longer.

Th. How does that connect up with your impulse to be sick now and stay in bed so much? *[The patient has these tendencies, of which she is ashamed.]*

Pt. Oh … *(pause)*

Th. What do you think?

Pt. Oh, my God, how infantile, how ungrown up. *(pause)* It must be so. I want people to love me and be sorry for me. Oh, my God. How completely childish. It is, *is* that. My mother must have ignored me when I was little, and I wanted so to be loved. *[This sounds like insight.]*

Th. So that it may have been threatening to go back to being self-willed and unloved after you got out of the cast, *[interpretation]*

Pt. It did. My life changed. I became meek and controlled. I couldn't get angry or stubborn afterward.

Th. Perhaps if you go back to being stubborn with *me,* you would be returning to how you were before, that is, active, stubborn but unloved?

Pt. *(excitedly)* And, therefore, losing your love. I need you, but after all you aren't going to reject me.

The pattern is so established now that the threat of the loss of love is too overwhelming with everybody, and I've got to keep myself from acting selfish or angry.

Example 4

A patient with a homosexual problem is brought to an awareness through transference of sexual feelings toward her father that incite anxiety and detachment from men.

Pt. Inwardly I feel like a wreck right now. And yet I just sit here very quietly and calmly as if nothing is wrong.

Th. In other words, you can put on a beautiful front.

Pt. Yeah, I'm doing it right now. You don't know what I look like from the other end. You don't know what I look like. I mean. I wondered what would happen if I came in here and said exactly what I feel. I'm sick of this faking, which I still do in here. But in what respect. I don't know. I'm so scared to tell you a lie; I live in a fear of it. And the other day when you asked me—this is an example of it. You were pointing out an example and asked me. did I see. what was it, "Born Yesterday?" I said, "Yes." But I saw the play, not the movie. Now what the heck difference it makes, I don't know, but it bothered me later. Don't you remember it. But a few sentences later I, I corrected myself and said "I saw the play." because it bothered me. The thought of telling you even that much of a lie is intolerable.

Th. Do you feel you've been lying to me in any other way?

Pt. I haven't lied to you about anything that I know of.

Th. Mm hmm.

Pt. But it's just that I feel I'm still not myself. I want to find somebody to give my whole self to.

Th. Mm hmm.

Pt. That's exactly what I want to do, and still I don't do it. *(pause)*

Th. Still you're holding back.

Pt. But, in what way I don't know.

Th. And you feel somehow that maybe I don't know the real you.

Pt. Yes. Like everything that happened to me all day long. I carry on long discussions with you in buses and trains *(laughs)* and, I say, "I must remember to tell him that tomorrow." And then I never bother to tell any of these things.

Th. Are they any specific kinds of things?

Pt. Yes, now I, I could just pick out one.

Th. Mm hmm.

Pt. Yesterday I went to buy some glasses, dark glasses, with the idea of getting some eccentric looking things—things must be eccentric looking with me.

Th. Mm hmm.

Pt. So I asked the saleslady what she would suggest. So she suggested black. So I said, "That's idiotic, but I'll get black glasses." And they are a bit eccentric looking, but silly, and, I wanted to go and read you something out of a book that I thought about today. But why? Because I wanted you to see those glasses. You see? And I would have gone right through with it, but I doubled back on myself in the train today and said it's silly to do that. And when I put them on on the train, I noticed somebody looking over at me. I'm aware of myself all the time, and of being a fake. I sit down with a book in front of me, one leg over the other. I'm doing it now, and I don't feel this way at all. I don't feel like a blah-blah woman of the world person at all.

Th. What *do* you feel?

Pt. I don't know. I don't know what it is that I feel. All I know is that what I look like— what I believe I look like anyway—I'm not. And I do a billion things during the day which, which are just crazy, which I carry on about.

Th. Do you feel that way right now?

Pt. All the time. And then before I came up here I got weak. By god, I didn't feel I had the strength to walk one block over to the Madison Avenue bus. I took a taxi. Absurd. And then I stopped to have this drink. It's ridiculous.

Th. Maybe you're afraid and tense about coming here.

Pt. No. It, it, it's the idea, it's always been, "If I could only have one person to tell the whole truth to, one person who could see me just nude, period. With nothing on." *(pause)*

Th. Mm hmm. And?

Pt. And that's exactly what I'm not doing. And I try so desperately.

Th. In other words, what you're saying to me is, "Look, I'm putting something over on you. I'm not letting myself be completely exposed to you."

Pt. But why I do it, I don't know, *(pause)* I'm putting up a front with you, or maybe I'm pulling the wool over your eyes, the way I'm pulling the wool over my father's eyes, and my mother's, and over at the school, and with everybody. And I feel maybe you're going to be sucker enough to fall for that.

Th. Perhaps I know you better than you think I know you.

Pt. I have the feeling as though you don't know a darn thing about me.

Th. Mm hmm.

Pt. I mean I've never talked about these things that have meant so much to me, like this morning.

Th. Mm hmm.

Pt. Uh, I go along wearing filthy clothes, underclothes. (*laughs*) I mean what people can't see, I don't care. Nobody sees it, it's so small it couldn't possibly smell, so I don't worry about it. (*laughs*)

Th. Mm hmm.

Pt. And so I didn't bother with it, and I thought about it, "Now here you sit down in the doctor's office, and he sees you look very decent in that. Does he know that you've got filthy underclothes on? There's no button here; there's no button there. Does he know that?"

Th. You feel very guilty about how you are inside, and the kind of person you are. *[interpreting]*

Pt. I want somebody to see it; that's the point of it.

Th. Do you think I'm not observant enough to see it?

Pt. No, but I feel as though I'm putting on an act for you. Oh, I know *(laughs)* it's your business after all, I mean …

Th. Maybe you feel I'm not smart enough to know you, all of you?

Pt. That's not it. I feel that I haven't given you a chance to see everything *(laughs)*

Th. (laughs) I see.

Pt. But I don't know why I'm so upset. It has something to do with you.

Th. What do you feel about me?

Pt. (pause) Number one. *(sigh)* the thing I felt very much about you. I mean, uh, uh, as a person I like you very much.

Th. Mm hmm.

Pt. But I have a tremendous curiosity about you.

Th. Have you?

Pt. Yeah.

Th. For instance?

Pt. Marriage, children, everything about you. I'm interested in knowing.

Th. What about your theories about that? What do you think?

Pt. Well, I, it's always my purpose. I'm concerned with that all the time. When I talk to your secretary, I walk out with a smile and joke about something, and I always think, "Oh, I bet she thinks I'm a really happy little kid running around. I bet she likes me. Or maybe she doesn't like me." Always concerned with what people think.

Th. Mm hmm.

Pt. And, and with you. For instance, there were two men I was putting on the young lady act with, always an act. I dressed up to kill every time I saw them, and all that kind of thing. And then, when I found out they had grown daughters, I felt like a fool. I said, "What are you trying to impress them with? They've got one of their own." And that's why I'm interested in you, too. I, I must impress you still.

Th. Mm hmm.

Pt. I want to know what you think of me. How do I strike you, and how I would strike you if you met me on the street.

Th. Do you have any theories about how I might feel about you?

Pt. Well, the only think you've ever said which stuck in my mind so hard was that you thought it was all right to say what I wanted. But I want to know more. I want to know what strikes you? Every analyst also is, is a casual observer, and I want to know what you think of me.

Th. It's more important for me to get an idea of what *you* think I think of you, than for you to find out what *I* actually think of you at this time. You're not quite sure of what I think of you.

Pt. No, not at all.

Th. You're not sure that I like you?

Pt. Yeah, I believe you like me. I believe you consider me rather intelligent.

Th. Well, how do you know?

Pt. Well, first of all you told my father so.

Th. Mm hmm. Did he tell you that?

Pt. Yeah. I had him repeat it thousands of times *(laughs)* just to make sure. It made me feel like a million dollars that day. In fact, I even celebrated. I went downtown.

Th. Is that so?

Pt. This is absurd, but that's, that's just the way I felt. So concerned over what you must think of me.

Th. Now if I told you I liked you and that sort of thing, it would not help you. In fact, it would prevent you from feeling spontaneously about me. It's important that you become aware of all of the feelings you have, some of which are justified and some of which have nothing to do with reality. We can get important clues about things that are happening to you from your feelings.

Pt. Yes.

Th. It may be a little hard on you if I don't come out and tell you exactly how I feel all the time.

Pt. Mm. Yeah.

Th. If I keep saying, "What do you think I feel about you?" …

Pt. Yeah.

Th. Or, "What are your theories about this or that?" it might be a little hard on you, but in the long run it will be most helpful to you.

Pt. Yes.

Th. But if you resent this kind of role that I'm playing with you, then tell me about it.

Pt. No, it, it's just pleasantly annoying, you know, that's all; it's tantalizing, so to speak. *(pause)* If you asked me to be truthful and tell you what I would most like to do right now, I'd have to say, "I want to sleep with a man, but I want him to have his pants on."

Th. Mm hmm.

Pt. "But no top. Big shoulders. And I would be nude. And I want to inspect his penis, and I want to play with it. And I want him, just, just to sort of annoy me, but I don't want to have to lie back and just take it. I want to be able to just squirm around and let myself go, just be a whole physical thing and no mind at all.

Th. Yes.

Pt. And then I come to think about what would this man have to look like. From his shoulders, right around about here—and that's you. It just came to me. The man is you. I have been thinking these thoughts since I started coming here, sex thoughts.

Th. The man is I?

Pt. Yeah.

Th. Mm hmm.

Pt. I got, I got those feelings of sex now that are driving me crazy. By god, I didn't know I could ever say that.

Th. You couldn't say that to me?

Pt. No, no. Well, but I did. But I thought. "Well, maybe it's not so. Maybe it's just nonsense." But the more I thought about it, the more it was you. I tried to push it out of my mind, but it's true.

Th. Maybe that's why you were upset.

Pt. It's possibly that. But it's a horrible thought that I can think that. I remember seeing daddy without his clothes. His penis seemed enormous. I get a funny feeling. It's repulsive and exciting too. Just like I feel about you. I try not to think about it. *[It is apparent that her feelings toward me are projections of her feelings toward her father.]*

Th. What about your sex feelings about men?

Pt. I just have no feeling about it. Maybe it's safer that way.

Th. Maybe it's safer to feel sexy toward women, because it's not safe to feel sexy with men? [*interpreting her homosexuality*]

Pt. Definitely.

Example 5

The following case illustrates the operation of a transference neurosis in facilitating insight. Sporadic backaches (lumbago) were among the patient's most disturbing symptoms. From time to time backaches became exaggerated during a treatment session. Observing the content of his conversations when this happened, it was determined that backaches developed whenever the patient bragged or boasted about himself, whenever he voiced comments that might be construed as criticisms of me, whenever he expressed demands that I might possible reject, or whenever he mentioned circumstances in which he had behaved in a selfish or intolerant manner. On one occasion, when these facts were brought to his attention, the patient stiffened with severe back pain, which became so intense that he winced. This was coupled with pain in his scrotum and drawing sensations in the perineum. Asked to tell me what was on his mind, he expostulated that he could never express himself frankly with his father. A stern puritanical man, his father had subjected him to severe discipline whenever the patient deviated in the least from the righteous path of moral, unpretentious living. Even childish pranks were forbidden. When

questioned about the form of punishment his father employed, the patient said, "He would beat me across the back with a stick." The area of attack coincided precisely with the zone of his present backaches.

At this point I mentioned that it was rather significant that in talking to me about certain topics, he had symptoms of backache. This sounded as if he were being punished for his thoughts. Seemingly, no impression was made on the patient by the interpretation. However, when he appeared for the next session, he was manifestly disturbed. Hitherto gentle and courteous, he stormed into my office and launched into a verbal attack on me. A fragment of this session follows:

> *Pt.* I haven't wanted to say this, but it's bothered me for some time. Your attitude, I mean. *[The patient is quite anxious as he talks.]*

> *Th.* My attitude?

> *Pt.* You remember when I first came to see you and told you about my flight instruction and taking my instructor's test?

> *Th.* Yes. *[This incident was a minor one that I almost had forgotten.]*

> *Pt.* Well, you acted very flippant and disinterested.

> *Th.* In what way?

> *Pt.* The way you talked and looked.

> *Th.* I wonder. Why didn't you mention this at the time?

> *Pt. (pause)* Well, I thought that I was wrong to boast about it. And I felt you resented my boasting, blowing my horn. I know I feel this, and you'll say it's my imagination, but I feel I'm right that you cut me off from talking. I felt you were contemptuous of me.

> *Th.* If this were true, I certainly wouldn't blame you for feeling the way you do. But searching into myself, and trying to recapitulate what happened, I don't remember wanting to cut you off, or feeling flippant, or deriding you in any way or acting contemptuous toward you. Is it possible that you see in what I did or said, something that wasn't there?

> *Pt. (angrily)* I don't believe you. I think you're saying that to be therapeutic. I feel that.

> *Th.* As if I'm saying this to reassure you?

> *Pt.* Yes, because I feel this is what you did.

Th. Cut you off and acted contemptuous on the basis that you were boasting?

Pt. Yes. It's confusing to me.

Th. Say, how come you bring that up now? This happened 5 months ago.

Pt. Something you said last time I was here made me mad. I don't know what it is now. *[Apparently my pointing out the possibilities of a transference reaction removed his repression and released hostility.]* I still feel you don't want to admit what you did.

Th. Well, I'll try to examine my feelings about you and see if I really did cut you off and deride you. As far as I know right now, this isn't how I felt. As far as I can see right now, I don't feel at all contemptuous toward you.

Pt. It's hard for me to believe that. I mean it's hard to see why you shouldn't be annoyed.

Th. Why should I be annoyed at you?

Pt. Look at the crazy things I did, I told you about. That episode with that woman and everything else that followed.

Th. Maybe you feel I ought to look down on you for what you've done?

At the next session the patient was again accusatory. He said that I acted detached and unfriendly. I did not give him an opportunity to attend my lectures or to socialize with me. He recalled that he had recently met me at a restaurant and that I had nodded but did not offer to share my table with him. Again I assured him that if it were true that I had willfully rejected him, he had a right to be angry. However, the nature of the therapeutic situation was such that any social contact might interfere with an opportunity to work out his problems.

For several sessions we talked back and forth in this manner. I was aware of the fact that the patient was trying to goad me into acting in an angry, recriminatory way, paralleling his father's reactions. Were I to have responded in this way, he probably would have left therapy, convinced that I was an arbitrary, hostile person. Or he would have submitted himself and then developed a dependent, compliant attitude with a continuance of his symptoms. The upshot of our talks was a recognition of his projection into our relationship of attitudes that he had about his father that had conditioned his general feeling toward authority. His ability to challenge my reaction, to vent his hostility, to

understand that his reactions were carryovers of earlier patterns, without encountering counterhostility enabled him successfully to work through his problem in therapy.

Were the patient in formal psychoanalysis, he would have been allowed to experience his feelings intensely without my interpreting and attempting to resolve them as soon as they developed. This would have dredged up from the deepest recesses of his unconscious early memories and feelings, and he would have lived through his infantile neurosis in the transference neurosis. Whether the outcome would have been more successful than that which I had been able to achieve through once-a-week dynamic psychotherapy is a matter of speculation.

43
Exploring Trends and Patterns

Once an important trend or pattern is identified, the therapist should attempt its exploration in as elaborate detail as possible. The relationship of the trend to other aspects of the psychic life, and a study of the conflicts it engenders, may be investigated by focusing the patient's attention on and eliciting detailed associations to every trend manifestation. While doing this, the therapist should attempt to circumscribe the subject coverage so as to prevent rambling. If permitted to bounce along from topic to topic, the patient will pursue a course of least opposition, veering away from pockets of anxiety. This, a manifestation of resistance, is partly without conscious design and must be combatted in the interest of making more rapid progress. A certain amount of rambling is, of course, inevitable, but where it goes too far afield from the subject under inquiry, the patient should be brought back to it.

The immediate preoccupation of the patient may cover such diverse areas as disagreeable symptoms, a general state of unhappiness or boredom, daily happenings and events, obligations, hopes, ambitions, important past incidents, experiences with parents and siblings, current interpersonal relationships, fantasies, dreams, attitudes toward therapy, and feelings about the therapist.

Eventually, these areas may be explored in detail; however, immediately, the learning process will be enhanced where every session is organized around an important theme. Thus, we may, during one session, work on the patient's sexual problems, since these seem all embracing. Or, if the patient is preoccupied with a fear of being exploited or hurt in an interpersonal relationship, this may constitute the area of investigation. Actually, all of the patient's difficulties are interrelated. Consideration of one element will, of necessity, eventually involve others. For instance, in dealing with sexual life our discovery of masochistic impulses will bring out attitudes toward males, females, authority figures, compeers, subordinate persons, parents, and children. Working through

the sexual problem will also involve a resolution of interpersonal distortions. Conversely, if we focus on problems with authority, with subordinates, with parents and other persons, the individual's sexual relationships will inevitably come up for inquiry.

Where a number of trends simultaneously occupy the mind of the patient, a more effective use of the session may often be accomplished by a selection of areas according to the priority rating indicated in Chapter 19. "The Conduct of the Psychotherapeutic Interview."

Generally, however, the matter of selection poses no problems for the therapist because important trends or patterns are usually sufficiently intense to announce themselves in no uncertain terms.

Experience will readily confirm the fact that any pattern under exploration has tendrils that permeate many facets of the patient's personality. Constant exploration eventually brings patients to an awareness of the implications and contradictions of their way of life and to a recognition of how they foster the very difficulties of which they are so intolerant. Insight into the fact that their responses to people are not justified by present-day reality is an important step in the process of getting well. As mechanisms of defense are exposed and resistances are resolved, patients may be increasingly motivated toward experimenting with life on new terms and more and more capable of mastering the anxieties that have conditioned their customary reactions. Life no longer is regarded as a mere arena of past happenings. Situations and relationships are better reevaluated in the light of existing reality.

> To illustrate, we may consider the case of a married woman of 32 years of age, with two children, 4 and 2 years of age. The reasons for her coming to therapy were spells of excessive tension, attacks of anxiety, obsessional fears of her children dying, and periodic bouts of violent scrubbing of her hands, which had become progressively worse during the past 2 years. During the first phase of therapy the patient readily established a working relationship and accepted without too great resistance the structuring of the therapeutic situation.

> A great deal of her concern during the ensuing treatment sessions was with her marriage. From its very onset she had become aware of great boredom in her role as housewife. A successful buyer in a large department store, she had given up her position as soon as she had become pregnant. Whereas previously she had

enjoyed considerable standing as a buyer, she now had very little status as a mother. In addition, her husband's salary did not permit liberties in spending. She was, in fact, forced to conserve in order to budget the family funds. This imposed a great strain on her. Since she had never experienced neurotic symptoms prior to her marriage, she assumed that they were caused by the responsibilities of being a mother, of having no distinction as a wife, and of needing to operate with restricted funds. My comment to these statements was that while hardships undoubtedly had existed, it was likely that she was responding to her situation with certain attitudes and feelings that might bear examination.

Enjoined to observed her reactions to various life happenings, the patient began to make certain connections as illustrated in the following fragment of an interview.

Pt. I had a bad few days last week. Everything got on my nerves. Betty (*the patient's older child*) came down with a bad cold, and I was tied down more than ever. The scrubbing returned, and I was more upset than ever.

Th. I see.

Pt. And on Wednesday I began thinking. (*laughs*) The funniest thing happened. I was working in the kitchen and suddenly I got that awful feeling. It came on me like a squirmy wave. I got scared and tense and the muscles back here *(strokes the muscles in the back of her neck)* got tight and my head filled up as if I had a tight bandage around, and queasy feelings in the pit of my stomach.

Th. Mm hmm.

Pt. And there was something else that happened. I knew something was bothering me and I just didn't know what.

Th. Mm hmm.

Pt. Something bothering me. It's like something I had to do, supposed to do. It was such a frustrating feeling, *(pause)*

Th. A frustrating feeling, as if you just couldn't grasp what was going on?

Pt. Yes, just like that. So out of desperation, I guess, I turned on the radio. The first thing was one of those breakfast Mr. and Mrs. programs. They were bantering back and forth, and I detected a snide attitude toward the woman. This made me boil. And all of a sudden the thing flashed in mind. It came to me that I promised my husband that I'd buy him several pairs of socks a week ago. I've been putting it off, and putting it off, and not thinking of it. When I'd go out, it wouldn't occur to me to get the socks until I'd remember when I got home. *(laughs)*

Th. (smiles) You suspected something was going on inside of you?

Pt. I knew it. As I was listening to the program, it came to me. I suddenly got mad, furious and said, "Darn him, why doesn't he buy socks for himself? Why should I do *his* dirty work?" *(laughs)*

Th. You resented his making this demand on you?

Pt. (laughs) No question about that. My next thought *(laughs)* ... it was, "Damn him, why doesn't he buy socks for *himself.* Why do I have to do *all* the dirty work around here. He wants and expects me to be a slave, just tidy up the place and get nowheres." I thought of him in his nice comfortable office. Then I thought of how wonderful I felt when I was working. At least I felt appreciated and didn't get the constant criticism I get now.

Th. This must re?lly burn you up.

Pt. I suppose marriage is a sacrifice. I do love the children. I don't know what they'd do if I went back to work. But it's the noise, noise, the howling of the kids and the criticism of my husband.

Th. When you were working, you felt you were doing something significant that gave you status.

Pt. You know, doctor, I sometimes feel as if I was absolutely crazy to give up my job. I don't know what I imagined marriage was going to be like.

Th. And it turned out to be something where you have to take care of howling kids and buy socks for your husband.

Pt. You know, as soon as I had these thoughts I got very mad. I screamed out loud, "Why doesn't he buy the socks himself." I had a picture of him *(laughs)* this is silly ... slipping on, *(laughs)* slipping on a banana peel and turning a half somersault in the air, I started laughing. Doctor, do I want him to break his neck? When this all happened I noticed that I felt better. My headache went away and the stiffness in the neck. [*Apparently, realization and acknowledgment of her hostility removed the necessity for its repression and its conversion into symptoms.*]

Th. Now what do you think this was all about? *[testing her insight]*

Pt. I know you have been hinting to me that there must be reasons for the state I'm in. I get very mad at things all the time. Most of the time I'm on fire in here, *(points to stomach)*

Th. But you haven't been too aware of how angry you've been.

Pt. I just began to realize it because after this happened and I still felt mad, I called my husband and asked him to pick the socks he wanted himself. I told him to get them himself. Just like that, I did.

Th. What did he say?

Pt. (laughs) He said O.K.

Th. O.K., nothing more?

Pt. No, he wasn't upset, or mean, or angry.

Th. Did you expect him to be angry?

Pt. Why, of course. You know, doctor, I must be scared to death of my husband to act the way I do.

Th. Maybe you're scared of your own anger too? *[a cautious interpretation]*

Pt. I don't know. I just feel as if this whole thing is mysterious—what happened to me. *[The patient rejects this interpretation temporarily. Later she advances it herself, having accepted its implications.]*

Observation of her responses to varied situations and interpersonal relationships brought the patient to an awareness of attitudes and impulses that mobilized anxiety and generated symptoms. Hostility toward her husband and children had been so repressed that she was only tangentially aware of its manifestations. The recited episode of the radio was an indication that she was attempting to understand and to come to grips with her basic problems. The quarrel between the radio breakfast couple had apparently exposed her own unexpressed feelings about her husband. Further exploration of her resentment at being asked to do a menial chore for her husband, opened up a channel to her feelings about the role she played as a woman, a wife, and a mother.

In later interviews the patient brought up more fantasies, which included the accidental crushing of her husband by a truck while crossing the street, the untimely death of both of her children with a virulent strain of pneumonia, the winning of a radio prize of $50,000 with which she purchased a prosperous business, and, upon the demise of her husband, marriage to a gallant, soft-spoken "sweet" man with qualities antithetical to those of her husband. Hitherto she had paid little attention to her fantasies, their connection with deeper conflictual sources being shadowy to her. But appreciating that there were reasons for her fantasies as well as symptoms, she alerted herself to possible meanings.

Although she had been, to some extent, aware of her unhappiness as a housewife, she was not cognizant of how deeply she resented this role. Exploring her resistances to the awareness of her hostility, however, enabled her to focus on her right to experience and to express spontaneous feelings. As expected, this constituted an assault on her repressions and mobilized guilt and some anxiety. The patient recited incidents when she

was unable to assert herself. However, she also described situations when she was capable of taking a forceful and even aggressive stand. It became apparent that under circumstances when she was in a subordinate position, she became submissive, passive, afraid, and unable to express aggression. Under other conditions, where she was dominant, "in charge of things," and "on top of the heap," she could be expressive and even cruel. As a buyer in a prominent store, she had enjoyed prestige, the respect of her associates, and a considerable amount of power. She had felt free and had been able to stand up for her rights whenever crossed. Indeed, she had gotten the reputation of being a "strong woman." The obvious delight in her voice as she recalled her exploits as a buyer was in contrast to the hopeless, apathetic manner with which she discussed her present life experiences. When this fact was brought out, she agreed that the discrepancy was indicative of what she secretly might be wishing—a return to the security she had had as a buyer.

The patient recalled her feelings of defeat in the past when, as a girl, she was barred from games by the boys in her neighborhood. She had always wanted to be a boy and she deeply resented being "hemmed in" as a girl. Toward a younger brother she evinced great envy, and she recalled with guilt having been envious of his possession of a penis. Shamefully, she admitted that she had anticipated as a child being changed into a boy, and in her dreams as an adult, she sometimes pictured herself as a man. While working as a buyer, she remarked, she donned attire of mannish style, which gave her " a wonderful sense of freedom."

An illustrative dream indicating some of these trends was the following:

> "I see myself on a veranda. Everything seems shoddy and strange. I am in the house with my mother. I see an animal like a rat in the kitchen on a mirror. It is small like an embryo. It makes me sick. Then I see a manly woman with a man on the veranda and am frightfully jealous."

Associations to the dream made it apparent that she conceived of her life with her mother (and perhaps on a transference level her relationship with me) as shoddy and weakening. The rat embryo was a reflection of her debased infantile feminine self. The

manly woman who could appropriate and manage a male was the other aspect of herself that she cherished.

Much of the material during this period of treatment concerned itself with her relationships with her parents and her younger brother. Her mother, she felt, was a cold, rejecting person who gave her little love and acceptance. Her father was a detached, harsh, puritanical individual who spent little time with her and with whom she never developed a feeling of closeness. Her brother remained, until recent years, a source of envy and concern. On the one hand, she felt resentment toward him; on the other hand, she felt strongly attracted to him physically. She never believed that she was respected as a person by any member of her family. For instance, she recalled with bitterness how all efforts to express aggression or to resist the demands of her parents were met with violence. During her entire childhood she was reminded of her stubborn, recalcitrant nature; she was told that she had uncontrollable rages that had to be dealt with severely.

This information was utilized during interviews to facilitate inquiry into the genetic origin of her resentment at being a woman and into the defenses she employed against expressing hostility. To show any hostility when she felt herself to be in a subordinate role threatened her with the same feeling of loss of love and punishment that she had experienced as a child in relation to her parents. To stand up for her rights, and to express aggression, meant that she was "bad," unloved, and unlovable. She equated this with being a woman. On the other hand, when she was in command of a situation, "on top of things," and dominant, she identified herself with males; she felt invulnerable and capable of expressing aggression.

Gradually, the patient could see how she extended these feelings into her environment and how she responded to every aspect of her life situation with attitudes rooted in past misinterpretations. For example, some of her dreams reflected a desire to be married to the husband of her best friend. Her associations revealed great envy of her friend for being wedded to a passive man who allowed himself to be domineered by a woman. In her relationship with me, too, she began to express basic patterns. Encouraged

to verbalize her feelings, she expostulated attitudes of envy and resentment. On one occasion she remarked angrily, "It makes me furious to come here and see you sit comfortably on your behind all day in a nice soft chair, and collect a nice fat fee. I've got to struggle in the kitchen all day and do scut work for nothing. I catch myself thinking, 'Who does he think he is, telling me, what to do?' But I know you don't order me around." Focusing on our relationship, the patient was able to appreciate her competitiveness with me, which was of a quality similar to that which she had sustained with her father and brother.

Her ability to express hostility toward me without encountering retaliatory punishment enabled her to bring up more and more undistorted manifestations of her conflict. Murder wishes toward her husband and children, homosexual impulses, desires to repudiate her femininity and to become masculine, prostitution wishes, compulsions to soil, and many other impulses were verbalized and explored.

ILLUSTRATIVE CASE

The process of exploring a trend may be illustrated by a fragment of a session with a patient suffering from a psychophysiologic bladder disorder, who, coming late for the session, exhibited strong tension and anxiety. The ramifications of a compulsive need to please others are investigated.

> *Th.* You appear to be greatly upset by coming late. I wonder why.
>
> *Pt.* It's that I don't like to come late. I have a feeling you will look down on me and find me out to be an unreliable person. As if you would be displeased with me for not coming on time. *[This suggests a trend related to feelings of being rejected by authority as well as doubts about his capacity to "please."]*
>
> *Th.* What might I do if I were displeased? *[exploring the trend by asking questions]*
>
> *Pt.* You could show your displeasure by acting, say cold, like father did. Even possibly you might not continue treating me. *[introducing one genetic determinant of his reaction and an association of the therapist with his father]*
>
> *Th.* I see. [*I could focus on his relationship with his father at this point, but I decide instead to let him associate at random.]*

Pt. And a feeling of good performance comes into it. I want to be an ideal patient *(laughs)* someone who is on time, someone who cooperates and becomes successfully analyzed. *[This may be another aspect of wanting to be a good boy.]*

Th. In other words, you have to please, *[interpreting]*

Pt. Yeah.

Th. Even if it means getting well to please?

Pt. That would be an interesting motive to get well—to please somebody. But I know what you're saying, that I might do it because I have a need to please everybody, *(pause)*

Th. Everybody?

Pt. Yes. You know, when I first started coming here, I didn't know what I was doing, like needing to please every woman that came along, to do things for *them.*

Th. Do you think you still do that?

Pt. (pause) Why … yes, I find myself doing that automatically, without thinking. It's still a very important thing with me. In that sense I'm getting a satisfaction out of pleasing them. But I find lately that it's more irksome than before. I'm getting a little more selfish than before. I suppose it's good, or isn't it?

Th. You don't sound convinced, *[challenging the patient's conviction that he is doing a good thing]*

Pt. (*laughs*) Well, you know I don't realize I'm doing something to please someone until I begin to think what I did. Then I get mad. *[The thought comes to me that hostility generated by his constant need to please may be responsible for his psychosomatic symptoms.]*

Th. There must be a reason why you need to please others, *[focusing the patient's attention on the purpose of his trend]*

Pt. I don't know why I have to do it.

Th. Well, suppose you start thinking about why anybody should want constantly to please and not to offend, *[more focusing]*

Pt. I can see that I feel I have no worth as a person, except in pleasing people. I mean that's what it seems to resolve itself down to. *[While this is probably correct, the patient is not yet aware of the implications of what he is saying and of the connections of the trend to please with other important aspects of his personality.]*

Th. And if you have no worth as a person unless you please somebody, what do you think happens when you please somebody?

Pt. I achieve, I get some worth.

Th. And if you do please someone, how would you feel about that person after you please?

Pt. Resentment, I suppose.

Th. Well, how *do* you feel, I mean what *has* your experience been?

Pt. I've noticed that often I kick myself afterward, feel I'm a "heeler" and have to toe the mark. Then I start not wanting to see the person. This holds true with my wife too. A wall falls in between the two of us. I just feel nothing toward her for days afterward. *[The patient is aware of his detachment, which, an important part of his character structure, seems to be a defense against further encroachment as well as a manifestation of hostility.]*

Th. Mm hmm.

Pt. It's a very complex problem because, after all, people do like you for your qualities. They can't just like you really for nothing, and they can't like you for being a bastard unless they're sadistic, I mean masochistic, really. If these women, for example, like me the way I am, they must like me because I am the way I am. People have liked me. I would say that with most of the people I come in contact with, I'm fairly well-liked. It must be because of the way I am. *[The patient seems to be defending his character traits.]*

Th. Which is what?

Pt. Which is a pleasant guy.

Th. You mean they like you because you please? That you go out of your way to please?

Pt. I guess so.

Th. You mentioned that if you don't please, then you might be a bastard. People couldn't like a bastard. Does it follow that, if you don't supposedly please people, you have to be a bastard? Or that you just reject, repudiate, and act sadistic toward people if you don't please?

Pt. No, except that that's easier to do than to reach the happy medium. I suppose.

Th. Do you feel that you might have impulses to be a bastard and not to please and just be sadistic toward people? *[exploring possible sadistic traits]*

Pt. I don't consciously, but Jesus, I must be trying to cover up something. I'll show my resentments in disguised ways. I can be very brusque in the office. If people come in to see me when I'm busy, and I don't want to see them, instead of saying—being pleasant about it—sorry, but I'm busy today, come back another time, I convey a feeling to them, I know it, that I don't want to see them. And I wish to hell they'd get out of there. But it's not done in an open way, it's a compromise, I suppose. I can honestly say that consciously I have no destructive feelings at all, to speak of, unless something occurs and my temper might flare up, I used to have ... when I was a kid I threw a hammer at my cousin. But I must have had some display of temper at one time, but it's gone. I actually don't like other people trying to please me. If someone wants to do something for me, a favor of some kind, I don't like it, I don't want them to. Now *why,* I don't know. I never examined why. *[The patient is aware of contradictions in his trends.]*

Th. There must be a reason why you don't want people to do favors for you or to do things for you.

Pt. May be it implies that I, I'm not worthy of being done a favor, and that there are strings attached to favors.

Th. What may happen if you accept a favor from a person?

Pt. I feel that I'm putting them out in some way, and I don't want to put them out. "Why are you doing this for me?" I say.

Th. You distrust their motives?

Pt. Well, I know that I never liked to take anything from my father. He used to be pretty generous in a material way, always used to bring me toys when I was young and presents, usually the best that he could get. Then there was money. From the time I was in high school and college I remember feeling uncomfortable when he gave me the money. So I'm not sure whether it's a feeling that I was unworthy of getting the money. Maybe unconsciously my feelings were so destructive that by taking anything from him I compromised, I don't know.

Th. All right, what might other reasons be for not wanting to accept things from people? For example, have instances occurred where you felt uncomfortable or turned down offers of a person wanting to please you or to do things for you?

Pt. Well, for example, my girl wanted to see me yesterday, and I wanted to see her, but it involved her coming in, making a special trip. And there was a chance that I couldn't see her. I felt that it wasn't fair of me to ask her to come in and she didn't insist on it. I felt under those circumstances it would be unfair and hurtful to her.

Th. That you might hurt her? You didn't want to be hurtful to her. You felt it would be ungracious and aggressive of you?

Pt. It would be an unpleasant experience for her, and she would do all this for me and get nothing out of it. I don't like people to take trouble from me.

Th. Have people taken trouble from you at any time in the past?

Pt. I guess when they took trouble, they let me know that they took trouble, *(pause)*

Th. Who?

Pt. My mother, *(pause)*

Th. What did she do?

Pt. Well, she always would say, for example: "Now be a good boy, oecause you have such a good father. Your father is so good to you, he gets you all these things."

Th. He pleases you; therefore you have to be good to him?

Pt. Yeah.

Th. And under what circumstances would you be angry at father? [*I decide to explore his relationships with his parents to see if the trend we are working on goes back to his childhood.*]

Pt. They'd be damned scarce.

Th. In other words, did she convey to you the idea that because your father did things for you, you'd better not be mad at him? There was no reason why you should be angry at him?

Pt. Well, I don't know if she particularly conveyed to me that there was no reason, but she implied that even if I had a reason, I wasn't justified. He was my father, and he did all these things for me. In fact, she conveyed that *she* did things for me too, and it was trouble for her that she did them for me. She gave the impression that she loved me, but she let me know that she went through a lot of trouble for me. She happens to be a very selfish person, but that was the impression that I had when I was young. So maybe I'm afraid that I don't really want to do anything for anybody, that if they do a favor for me, then I have to do something for them. You have a payment, almost, to make. And paying would be much against what I really feel. And all these years I've been going on pleasing people with, I guess, a very strong resentment against it. But the other extreme of not ever pleasing anybody is just as bad.

Th. Isn't it possible that the problem in your not being able to accept things from people is that there might be strings tied to the acceptance? They'd be pleasing you. but you would also have to please them back. You wouldn't be able to stand up for your rights; you wouldn't be able to fight with them if necessary or feel resentment toward them, if it was justified. It's as if they tried to buy you off and you couldn't maintain your independence. *[This is a tentative interpretation.]*

Pt. If I take a favor, yes. And I don't like to ask people to do anything for me.

Th. Is it also possible then, that your not being able to take things from people means to you the ability to maintain your freedom and to express your feelings of resentment? If that's so, you might also try to keep their resentment at bay by doing things for them. Then they won't be angry at you. Is that possible? *[more interpretation]*

Pt. That's very true. Yeah. Particularly exemplified in these women. I don't like scenes. I don't like resentment shown. I don't like anger shown at me, and if I see them, I see them often so that they won't get nasty and they won't say anything. So it becomes a double-faceted thing, doesn't it. To gain acceptance and also to do away with any resentment or aggressions that they might have. *[The patient shows here a good capacity to make a connection between several important tendencies.]*

Th. What happens when you *are* exposed to aggression or resentment? How do you react then?

Pt. I don't like it at all. It's a feeling that there is no strength inside of me to withstand it. I must be wrong. I guess that's another part of the problem- And, of course, the more significant the people are, the more important it would be to me. I guess with my girl, for example, I don't like it; but I don't get any anxiety feelings. I guess I throw a kind of shield up around myself, separate myself from her when she does get to show resentment. And maybe I feel a little

stronger inside, a little more worthwhile now. I feel that she's wrong in many cases. I never felt really, that *anyone* was wrong, as far as I was concerned. I could always see their side of the picture very clearly. One time, just before I went to California, I'd been working for my uncle. Some people in his business quit and he wanted me to come back, and I didn't want to come back. To me the work had ceased to be important, and we had quite a to-do. He was very angry with me and caused me a lot of anxiety. I wanted to go back, but my girl was on the other side. "Don't do it," she said. "Take your vacation." That sort of thing. But I disliked intensely the fact that he was angry at me. I couldn't feel that he was right. I think that I might feel a different way today in such a situation. I'm sure I wouldn't have the reaction I had then, but the reaction I had then was a very, very anxious one. I couldn't be right; I should go back to work; he's mad at me, my uncle, and that sort of thing.

Concomitant with the exploration of his personality patterns the bladder symptoms improved, and, as his adaptations became more assertive, they eventually disappeared.

44
The Uncovering of Unconscious Material

Where our goal in therapy is purely symptom relief or problem-solving there is no need, as a general rule, to delve into the depths of the unconscious. Treatment planning is focused on biochemical, neurophysiological, conditioning, manifest interpersonal, and social-environmental issues. The use of pharmacological, behavioral, persuasive and other supportive and reeducative interventions usually will suffice to achieve our objectives. It is only where symptoms and behavioral abnormalities are generated by intrapsychic pathology, or where such pathology acts as resistance to our effective employment of symptom-oriented and problem-solving methods that we may have to focus our sights on some areas beyond the zone of awareness. Our hope here is that the mobilization of sufficient insight into unconscious saboteurs will liberate the individual from their obstructive influence.

Illuminating certain aspects of unconscious conflict, however, is an integral part of our therapy where our goal is personality reconstruction. The roots of the disturbance that we seek to eliminate are buried so deeply that the employment of an uncovering process is desirable if not mandatory. This process, oriented around development of insight, is depreciated by many non-analysts who regard it as an unnecessary and even obstructive formality. More rapid and effective relearning can be achieved, they claim, through other cognitive and conditioning procedures. While insight in itself has been grossly exaggerated as a curative force ["as every experienced therapist knows some patients change in therapy without achieving insight and some patients achieve insight without ever changing"(Fierman, 1965)], it is the *sine qua non* to self-understanding. Cognitive restructuring, however, does not follow in the wake of insight; rather it is a consequence of the working through of this knowledge toward an acquisition of new modes of thinking, feeling, and behaving.

The "depth" of exploration of repressed conflictual foci will vary according to the

needs of the patient. It is doubtful that a total divulgence of unconscious material is ever required. Nor is it possible, through the use of any of the techniques known today—focused interviewing, free association, dream and fantasy interpretation, exploration of transference, hypnoanalysis, narcoanalysis, art therapy, play therapy, etc.—to uncover the unconscious completely. There are some repressions that seem to remain insoluble in the face of the most skilled therapeutic handling. Fortunately, however, most people may be helped sufficiently through the gaining of insight into merely some of their unconscious conflicts.

Among repressed and repudiated aspects of psychic activity are fears and fantasies associated with the various bodily functions, particularly eating, excretion, and sexuality. There are hostile and destructive impulses directed toward other persons and toward the self. There are traumatic memories and experiences too painful to be recalled in consciousness. There are incestuous desires and other unresolved sexualized elements. There are impulses toward sadism, masochism, voyeurism, exhibitionism, and repudiated homosexuality. There are such normal strivings as desires for love, companionship, recognition, self-esteem, independence, and creative self-fulfillment, which have developed incompletely or, for anxiety reasons, been abandoned. There are, in addition, rejected neurotic drives for affection, dependence, superiority, dominance, ambition, power and detachment as well as the conflicts that these drives initiate.

Efforts to banish from mind certain painful needs and conflicts may temporarily mask the merciless hold they have on the individual. There may be awareness of some character drives, for example how dependent one is in a relationship. Dependency however, may not be recognized as a key motif in one's life that undermines self-esteem, nurtures helplessness, and kindles hostility and anxiety.

The specific psychic elements that are repressed are a product of the unique experiences of the individual. Any aspect of feeling or thinking or behaving may be subject to repression if it conflicts with social standards, as transmitted to the patient by the parent through disciplines. These injunctions, incorporated into the superego, continue to

exert pressure on the person. In our culture such impulses as sexuality, hostility, and assertiveness are particularly subject to repression. Also commonly repudiated are impulses toward dependency and passivity as well as compulsive drives for power and independence.

In spite of deflection from the mainstream of the individual's thinking, repressed material may gain access to awareness in the form of highly symbolized and distorted derivatives. It is through detection and translation of such derivatives that awareness of the deeper content becomes possible.

THE SYMBOLISM OF THE UNCONSCIOUS

Thus, the patient's dreams, fantasies, free associations, symptoms, and behavioral tendencies may reflect unbelievably primitive or childish symbols. Often, expression is couched in terms of various organ functions. Simple activities, such as sucking, eating, excreting, and sexual functioning, may represent a host of attitudes and strivings. *The form of expression may seem bizarre, senseless, and without rational design.* A need for security and dependency may thus appear as a desire to suck the breast, penis, or nipple. All parts of the body, including the genital organs, may be implemented in this sucking process. Dependency may also be expressed by fantasies of cannibalistic incorporation of a real or nonexistent person. The amalgamation may be achieved by other means, as by entering the body of the person through any of the various orifices, by sexual intercourse, or by changing into a phallus and being sucked up into the vagina and womb. There may be a peculiar extension in which the person on whom the subject wishes to depend is identified with the fecal mass, with resultant overevaluation of excretory products and activities.

Hostile attitudes toward women may be represented by the biting and destroying of a female figure, or of a woman's body contents, breast, or nipple, or of a fantasied penis within her abdomen. This attack may be attempted with the mouth, anus, or penis or with excretory products. Destructive feelings toward males may be symbolized by impulses to castrate, or to devour or incorporate the penis or the body conceived as a penis. Fantasies

of eating or expelling loved or hated persons in the form of feces may occur.

Guilt feelings and fears of retaliation may be symbolized by fantasies of being eaten or castrated by devouring animals, ghouls, monsters, or witches, of being absorbed into a vagina for purposes of destruction, of being attacked by a male sexual organ, a female organ, or an imagined intravaginal penis. There may be fears of being penetrated anally by the penis of a strong man or of being injured and killed by feces. A loss of aggressiveness and intactness may be designated by a fear of castration; this may be accompanied in males by reparative attempts and in females by a denial of the fact that there is no penis or by frenzied attempts to secure one in fantasy from a paternal, fraternal, or maternal person in whose body a penis may be imagined to exist.

Phallic symbolism is extraordinarily common in unconscious ideation. Some persons are more prone than others to use it to express basic needs and attitudes. Sexuality here becomes a magical shortcut to close relationships with people and the nucleus around which the individual's thoughts and symptoms are oriented.

The clinical importance of sexual symbolism lies in its projection and displacement onto seemingly unrelated objects, the complete dynamics of which cannot be understood until the sources in the unconscious are divulged. Possession of an intact male organ is frequently utilized to represent a sense of aggressiveness and power. Strivings for strength, activity, and dominance may thus be symbolized unconsciously by a desire for a penis in a female, who may believe that possession of a penis is a magical solution for all of her problems, including the fear of functioning as a female. Compulsive vomiting may have its origin in need to disgorge a fantasied devoured penis, or it may represent a denial of the desire to incorporate the penis through swallowing. Anorexia nervosa may connote a persistence of the childish fantasy that pregnancy comes about through eating. Phallic overvaluation may also bring about a wish for a larger and more powerful penis in a male. Submission, passivity, and subordination may be signified in a woman by the lack of a penis and in a man by desires for breast, castration, and homosexuality. Where security is sought through dependency and subordination, castration may also be a goal that is

usually countered by a desire for activity and a fear of castration.

Unconscious symbolism is so incompatible with rational thinking that its very existence may be denied, even by professionals who are dealing with some of its manifestations. Rarely do unconscious symbols break through directly, except perhaps in dreams or under the influence of psychotomimetic drugs like LSD. During psychotic breaks also, symbolisms of nuclear conflicts may appear in more or less direct form.

NUCLEAR CONFLICTS

There is imbedded in the psyche of each person products of the inevitable clash of maturing needs and reality restrictions, the mastery of which constitutes one of the primary tasks of psychosocial development. It must be emphasized that these conflicts are universal qualitatively, though quantitatively differing in all persons as a result of constitutional and conditioning variations and the integrity of the existing defenses.

The earliest nuclear conflicts are organized in relationship to the parents. For instance, the infant's association of the presence of mother with satisfaction of his or her needs (hunger, thirst, freedom from discomfort and pain, demand for stimulation) results in her becoming affiliated with gratification of these needs, with pleasure and the relief of tension. At the same time the absence of mother becomes linked to discomfort, distress, and pain. During the last part of the first year the child reacts with what is probably a primordial type of anxiety to separation from the mother, and with rage at her turning away from him or her toward anybody else, child or adult. This blended gratification-deprivation image of mother is probably the precursor of later ambivalencies, powering sibling rivalry and the rivalries during the oedipal period. It also gives rise to motivations to control, appease, and win favors from mother and mother figures, to vanquish, eliminate, or destroy competitors for her interest and attention, and to punish mother and mother figures for actual or fancied deprivations. The mother symbol becomes symbolically linked to later sources of gratification or deprivation. Moreover, if a disruption of homeostatic equilibrium occurs at any time later on in life or if for any reason anxiety erupts with a shattering of the sense of mastery, the primordial anxiety

imprints may be revived, activating separation fears and mother-invoking tendencies along lines pursued by the individual as an infant.

The gratification-deprivation, separation-anxiety constellations, laid down during phases of development early in the period of personality growth will tend to operate outside the zone of conscious awareness. Whenever habitual coping mechanisms fail the individual and anxiety is experienced, the individual may feel the helplessness and manifest the behavior of an infant, and may seek out, against all logic, a mother figure or her symbolic substitute (such as food in compulsive eating activities). It is little wonder that mothers, and their later representatives (protectors, authorities), come to possess symbolic reward (pleasure) values along with symbolic abandonment (pain, anxiety) potentials. This conflict, deeply imbedded in the unconscious, acts as compost for the fertilization of a host of derivative attitudes, impulses, and drives that remain with the individual throughout life. Other conflicts develop in the child's relationships with the world that are superimposed on the conflicts associated with the demand for magic and for the constant presence of the mother figure.

The actual experiences of infants during the first years of life, the degree of need gratifications they achieve, the relative freedom from deprivaton, their learning to tolerate some frustration and to accept temporary separation from their mothers provide them with coping devices to control their nuclear conflicts, which, nonetheless, irrespective of how satisfying and wholesome their upbringing may have been, are still operative (albeit successfully repressed), waiting to break out in later life should the psychological homeostasis collapse.

Nuclear conflicts, to repeat, are inherent in the growing-up process irrespective of the character of the environment. This is not to say that a depriving or destructive environment will not exaggerate the effect of conflict or keep it alive beyond the time when it should have subsided; a wholesome environment will tend to keep in check operations of conflict, helping to resolve it satisfactorily. *Nuclear conflicts are in part ordained by biological elements and in part are aspects of the culture. We should expect their*

appearance in minor or major degree in all persons. Their importance is contained in the fact that they give rise to reaction tendencies that, welded into the personality structure, may later interfere with a proper adaptation. Of clinical consequence, too, is their tendency to stir from dormancy into open expression when anxiety breaks down the ramparts of the existent defensive fortifications.

The exposure of repressed nuclear conflicts *that are creating problems* constitutes a task of dynamically oriented therapy, the object being to determine the distortions they produce in the character structure, their affiliation with current conflicts, and the subversive role they play in symptom formation. It may be possible even in short-term therapy—especially in dreams, transference, acting-out behavior, and certain symptoms —to observe how an important nuclear conflict is continuing to disturb the present adjustment of the patient.

DERIVATIVE CONFLICTS AND THEIR MANAGEMENT

In contrast to nuclear conflicts that are relegated to unconscious oblivion, many derivative conflicts issue from these conflicts and become part of the character structure.[6] A remarkably uniform arrangement of traits occurs in all people, distinguishing features being fashioned by the unique developmental experiences and by the subculture. These traits are not necessarily handicapping except when they become exaggerated and interfere with relationships with people and when they contribute to a defective self-image.

At the core of many problems are *excessive dependency needs* that had not been adequately resolved in childhood. A healthy balance between dependency and independence is essential for emotional well-being. Where it does not exist, problems ensue. Most likely the average person's childhood yearnings for nurture and affection were not optimally met, leaving a residue of unmet needs that tend to express themselves intensely when the pressures of life mount. Or dependency was pathologically encouraged by a mother who utilized the child as a vehicle for her own unfulfilled demands, hampering the child's growth and strivings for independence. *Unresolved dependency is a*

ubiquitous fountainhead of troubles. It stems from what is perhaps the most common conflict burdening human kind—inadequate separation-individuation. And people are apt to blame their troubles on the world: the revolt of youth, governmental corruption, inflation, communism, capitalism, or the atom bomb. Most people, however, somehow muddle through, working out their troubles in one way or another. It is only where separation-individuation is too incomplete and dependency needs too intense that solutions will not be found.

People with powerful dependency needs will often cast about for individuals who demonstrate stronger qualities than they themselves possess. When a swimmer tires, he or she looks about for something or someone on whom to lean or with which to grapple. A dependent person can be likened to a tired swimmer, who wants to find someone or something who can do for one what one feels cannot be done for oneself. What the person generally looks for is a *perfect* parent, an ideal that exists only in a personal fancy. Actually, there are no perfect parental figures who are able or willing to mother or father another adult. So our dependent person is continually being frustrated because his or her hopes and expectations are not met by someone else. A man who weds expecting an all-giving mother figure for a wife is bound to be disappointed. Further, if he does find a person who fits in with his design and who treats him like a helpless individual, he will begin to feel that he is being swallowed up, that he is losing his individuality, that he is trapped. Consequently, he will want to escape from the relationship. Also, as he senses his dependency, he will feel that he is being passive like a child. And this is frightening because he knows that he is not being manly; he may actually have homosexual doubts and fears since masculinity is associated with activity and independence. Women are no less victimized by dependency than are men. And their reactions are quite similar in that they are apt to regard both males and females on whom they get dependent as potential nurturing mother figures.

A second consequence that inevitably accompanies the first is *resentment* (hostility). Resentment invariably fires off because either one must find a perfect parent who will take care of everything or feel trapped when someone does take care of matters thus

prompting feelings of passivity and helplessness. Resentment breeds guilt because people just are not supposed to be hateful. Even guilt does not always keep the hostility hidden. Sometimes when a man has had too much to drink or when he is very frustrated about something, his hate feelings leak or pour out. That in itself can be terribly upsetting because he may fear he is getting out of control; or the mere awareness of his inner angry condition can make him despise himself. *Sadism* and sadistic behavior may be directed at the object of his dependency, who he believes is trapping him or who fails to live up to expectations. It may be drained off on scapegoats: blacks, Chicanos, Jews, communists, capitalists, and so on. Self-hate complicates his existence because it sponsors tension and depression. Hatred directed outward and then turned in results in *masochism,* in the form of major and minor self-punishments. These may range from fouling up a business deal to inability to accept success, to dangerous accident proneness, to physical illness, to foolish, outrageous, or embarrassing behavior.

Dependency and resentment are two sides of the same coin. The picture is not complete, however, without a third consequence, *low independence,* which is an invariable counterpart of high dependence. Low independence is a feeling that one cannot gain, by one's own reason or strength, the desirable prizes of our culture—whether they be love and justice or wine, women, and song. A spin-off of low independence is a *feeling of inferiority,* a lack of proficiency on achieving desirable goals. Part and parcel of inferiority feelings is the uncertainty about being manly and masculine. Self-doubts about one's sexual integrity are torturous; the usual sequel is to try to compensate by being the quintessence of everything powerful: overly aggressive, overly competitive, and overly dominating. Proving himself with women may lead to satyriasis and Don Juanism. Our man may have fantasies and images in his mind of strong men (often symbolized by their possessing large penises) and may be particularly attracted to them because of their strength. But his awareness of how much he thinks about men may cause him to wonder if he is homosexual and to fear the very things that he admires. He may actually on occasion be sexually attracted to idealized male figures, and he may fantasize incorporating their penises into himself. This may produce consternation and guilt feelings.

Interestingly, low independence feelings in women lead to the same self-doubt and compensations as in men. Some women will try to repair the fancied damage to themselves by trying to acquire the characteristics of men (penis envy) through the outer trappings of masculinity (e.g., acting aggressively, swaggering, and wearing male apparel, etc.) that in our culture are symbolically equated with independence. They will compete with and try to vanquish and even figuratively castrate males. In its exaggerated and pathological form, they will act toward other females as if they themselves are males, dominating and homosexually seducing them.

The constant reverberating of these three traits will leave our man feeling spiteful toward himself in the form of a devaluated self-image. He feels he is miserably incompetent, undesirable, and unworthy. Everywhere he sees evidence of his insignificance: he is not tall enough, he has developed a paunch, women do not seem to pay attention to him, his hair is thinning, his job is not outstanding; his car, his house, his wife—nothing is perfect. He may even think his penis is of inadequate proportions. He feels like a damaged person. These feelings torment him, and he vows to prove that he is not as devalued as he feels. He commits himself to the task of being all-powerful, ambitious, perfect so as to repair his devalued self-image. Then he imagines he can surely respect himself. If he can live without a single misstep, all will be well. He tries to boost himself on his own to the point where others will have to approve of him. He may only daydream all this, or he may, if events are fortuitous, accomplish many of his overcompensatory goals.

If he climbs high, he will most likely resent those below who now lean on him and make demands on him. To those who exhibit weakness, he will show his anger. While he may be able to be giving on his own terms, an unexpected appeal from someone else will be regarded as a vulgar imposition. He actually wants for himself someone on whom to lean and be dependent. However, giving in to such a desire speeds up his doubts and makes him feel even worse. He may pursue just the reverse course from his original dependency drive by competing with any strong figure on whom he might want to lean. He shows the pseudo-independence reminiscent of the adolescent who disagrees on

principle with whatever the parents say. And he may compensate for his devalued self-image by exploiting all the cultural symbols of being a worthy person, such as being perfectionistic, compulsively ambitious, and power driven. These compensatory drives may preoccupy him mercilessly, and he may organize his life around them. One failure means more to him than twenty successes, since it is an affirmation of his lowly status.

These difficulties are compounded by the way they interact with our man's sexual needs. When one's dependency needs are being gratified, there is often a pervasive feeling of well-being that floods one's whole body. Upon awakening following surgery, for example, the confident, smiling face of a nurse can suffuse a man with grateful, loving feelings, at least part of which may be sexual. The sexual feeling is not that of adult male to adult female but rather that of a helpless child toward a warm mother. Such a feeling is tantamount to an incestuous surge and may bring with it great conflict and guilt. Should this dependency be the nature of a husband's continuing relationship to his wife, he may be unable to function sexually with her since he is virtually involved in a mother-son relationship. On the other hand, if the nurturing figure is a man, homosexual fears and feelings may arise with equating of the host's penis with a nipple. For women the dependency situation does just the reverse. A nurturing mother figure calls up in her fears and feelings of homosexuality which may or may not be acted out in passive homosexuality with yearnings for the breast. Moreover, low feelings of independence may, as has been indicated, inspire ideas of defective masculinity in males with impulses to identify with muscle men. Fantasies of homosexuality or direct acting-out of homosexual impulses may follow. In women, feelings of defective independence may inspire a rejection of the feminine role and fantasies of possessing a penis, the symbol in our culture of power and independence. Sadism and masochism may also be acted out in sexual activities in both men and women.

The reverberation of all these traits calls for strenuous efforts on the part of our subject. Dependency, activated resentment, together with its components of aggression, guilt, and masochism threw into gear low feelings of independence, which in turn fueled self-devaluation with its many defenses and overcompensations.

Where can a man turn next to gain some sense of composure? He often turns to a fifth characteristic, *detachment*. Detachment is an attempt at escaping from life's messy problems. Our man by now is fed up with the rat race and wants to get out. He says, "No more committees, no more parties, no more responsibilities, no more extras of any kind, no more involvement with people" He wants an island fortress, or at least a castle with a moat around it, and he would pull up the drawbridge and say no to everything and everyone. He is sure that this is the solution; he decides not to become rich and famous.

But it does not work. People need people. Life is not satisfying alone. Our man finds loneliness to be a worse state than what he was enduring before. He realizes that people constitute one of life's richest gratifications. So, he plunges in again. By now his dependency is really driving him. And if he is desperate enough, he may attach himself all over again to a figure who holds out some promise of being the perfect parent. Then the neurotic cycle is on its way again: power, hostility, low feeling of independence, devalued self-esteem, and detachment.

These drives are never entirely quiescent. In the average person outlets are invariably present to keep them going. There is no one whose dependency needs were perfectly met early in life. This hunger lives on, and with this hunger, the mechanism of dependency is continually operative. In our culture, in this generation, the unmet dependency needs set in motion the successive traits just described. As long as outlets of expression are controlled, the individual may manage to keep going, switching from one or the other and turning them off if they threaten to carry one away. To some extent all people are victims of these derivative conflicts—to a minor degree at least.

Dependency inevitably breeds resentment in our culture. If outlets for the resentment are not available and if compensations for a devalued self-image cannot be pursued-in other words, if the individual cannot readily switch from one satisfaction to another—then conflict and stress reach proportions where one feels catastrophically overwhelmed. When tension mounts excessively and there seems to be no way of escape, anxiety strikes with frightening fears of helplessness and dissolution. Operations to

defend against anxiety may then be instituted, but the defense is often ineffective or more burdensome than the condition it was designated to combat.

Sometimes I draw a sketch on a blank paper showing high dependence, low dependence, devalued self-image, resentment-guilt-masochism, and detachment, and repeat the story of their interrelationship. I then ask the patient to figure out and study aspects that apply. If a general description of dynamics is given the patient, along the lines indicated above, a little insight may be inculcated that can serve as a fulcrum for greater self-understanding. The insight may be temporarily reassuring at first; then it seemingly is forgotten with a resurgence of symptoms. A review of what has occurred to stimulate the upset may consolidate the insight and solidify better control. This will have to be done over and over again. An important tool here is self-observation, which the therapist should try to encourage and which will help the working through process, without which insight can have little effect.

> I once treated a patient whom we shall call Roger.[7] At the initial interview a well-groomed gentleman presented himself with an expression of depression and bewilderment. The problem, he said, started while discussing seemingly casual matters with his best friend and partner during a lunch hour. He was overwhelmed with a feeling of panic, with violent heart palpitations and choking sensations, which forced him to excuse himself on the basis of a sudden indisposition. Back at work, he recovered partly, but a sensation of danger enveloped him—a confounding agonizing sensation, the source of which eluded all attempts at understanding. Upon returning home, he poured himself two extra jiggers of whiskey. His fear slowly vanished so that at dinner time he had almost completely recovered his composure. The next morning, however, he approached his work with a sense of foreboding, a feeling that became stronger and stronger as the days and weeks passed.

Roger had obviously experienced an anxiety attack the source of which became somewhat clearer as he continued his story.

> The most upsetting thing to Roger was the discovery that his symptoms became most violent while at work. He found himself constantly obsessed at the office with ways of returning home to his wife. Weekends brought temporary surcease; but even anticipating returning to his desk on Monday was enough to fill him with foreboding. He was unable to avoid coming late mornings, and, more and more often he excused himself from appearing at work on the basis of a current physical illness. Because he realized fully how his work was deteriorating, he was not surprised when his friend took him to task for his deficiency. Forcing himself to go to work became easier after Roger had consumed several drinks, but he found that he required more and more alcohol during the day to subdue his tension. At

night he needed barbituate sedation to insure even minimal sleep.

The surmise that I made at this point was that something in the work situation was triggering off his anxiety. I felt that Roger had attempted to gain surcease from anxiety by implementing mechanisms of control (first-line defenses, see p. 518) such as trying to avoid the stress situations of work and deadening his feelings with alcohol and sedatives. These gestures seemed not too successful since he was obliged to remain in the work situation no matter how much he wanted to avoid it.

> Continuing his story, Roger said that wild, unprovoked feelings of panic were not confined to his work. Even at home, his habitual haven of comfort and safety, he experienced bouts of anxiety, which burst forth at irregular intervals. His sleep, too, was interrupted by nightmarish fears, which forced him to seek refuge in his wife's bed. A pervasive sense of helplessness soon complicated Roger's life. Fear of being alone and fear of the dark developed. Other fears then occurred, such as fear of heights, of open windows, of crowds, and of subways and buses. In the presence of his wife, however, these fears subsided or disappeared. Roger consequently arranged matters so that his wife was available as often as possible. For a while she seemed to relish this new closeness, for she had resented what she had complained about for a long time—his coldness and detachment from her.

What apparently had happened was that not being able to escape from the anxiety-provoking situation at work, and being unable to develop adequate first-line defenses to control or neutralize his anxiety, Roger was retreating to and sought safety in a dependent relationship with his wife (second-line defenses) that paralleled that of a small child with a mother. Various fears of the dark and of being alone were indicative of his childlike helplessness. This kind of adaptation obviously had to fail.

> Not long after this, Roger continued, he developed fantasies of getting into accidents and having his body cut up and mutilated. When Roger confided to his wife that he was greatly upset by these occurring fantasies, she enjoined him to consult a doctor. He rejected this advice, contending that he was merely overworked, and he promised to take a winter vacation, which he was sure would restore his mental calm. Fearful thoughts continued to plague Roger. He became frightened whenever he heard stories of violence, and he avoided reading new accounts of suicides or murders. Soon he was obsessed with thoughts of pointed objects. Knives terrified him so that he insisted that his wife conceal them from him.

The return to a childish dependent position apparently mobilized fears that in too close association with a mother figure he would be subjected to smothering and destruction. Sexual feelings toward his wife were equated with forbidden incestuous

feelings for which the penalty was fierce and bloody. Fantasies of accidents and bloodshed could be reflections of Roger's mutilation fears. The repetition of the oedipal drama thus could follow a shattering of Roger's repressive system. Attempting to reinforce repression by repressive measures (third-level defenses, see [Fig. 37-1](#)), Roger employed phobia formation striving to remove himself from symbols of mutilation such as knives and other cutting instruments.

> When asked if he had other symptoms or fantasies, Roger, in an embarrassed way, confided that in the presence of forceful or strong men, he experienced a peculiar fear, which he tried to conceal. Sometimes he was aware of a desire to throw his arms around men and to kiss them in a filial way. This impulse disturbed Roger greatly, as did fantasies of nude men with huge genital organs. His sexual life continued to deteriorate. While he had never been an ardent lover, he had prided himself on his potency. His sexual powers now seemed to be disappearing; when he approached his wife, he was impotent or had premature ejaculations. This upset Roger and created fears that he never again would function well sexually. To disprove this, he forced himself compulsively to attempt intercourse, only to be rewarded by further failures. Anticipatory anxiety soon made sexual relations a source of pain, and when his wife suggested that they abstain, he agreed, but he was frightened that she would leave him for another man.

The fear Roger manifested of strong males, the desire to act in an affectionate way with them, the terror of homosexual assaults by nude men with huge genital organs were, if we follow our previous line of reasoning, the products of his fear of attack by father figures irate at his appropriation of the maternal object. A disintegration of Roger's sexual life was inevitable because he was relating to his wife not as a husband but as a child. Abandonment of a male role with his wife was, therefore, necessary to avoid anxiety. While serving as a spurious protective device, his sexual inhibition obviously further undermined his self-esteem.

In attempting to make a tentative diagnosis of Roger's condition at this point, I was confronted with the contemporary contradictions that plague our attempts at classification. All emotional difficulties spread themselves over a wide pathological area, involving every aspect of the person's functioning—intellectual, emotional, physical, and behavioral. Based as they are on presenting complaints and symptoms, systems of nosology often lose sight of the fact that the entire human being is embraced in any emotional upheaval. The particular classification into which a patient fits then may

depend merely upon the relative emphasis the diagnostic agent (i.e., the therapist) or the patient puts upon selected symptoms.

This may be illustrated in the case of Roger. His complaints were those of tension, irritability, explosiveness, anxiety, depression, psychosomatic symptoms, phobias, and obsessive thoughts. In addition, he exhibited a character disturbance in such manifestations as excessive submissiveness and dependency. Were Roger chiefly concerned with his physical ailments—his headaches, dyspepsia, listlessness, fatigue, failing health, or impotence— we would be inclined to regard him as a person suffering from physical disorders of psychological origin, that is, a type of somatoform reaction. Should his anxiety attacks have caused him greatest concern and were he to have focused his attention on his anxiety, we might classify him as "anxiety disorder." In the event his depression was of prime interest, a diagnosis of "dysthymia" (psychoneurotic or reactive depression) might be entertained. If emphasis had been put on his obsessive concern with bloody amputations, death, and pointed objects, this might be called "obsessive disorder." His fear of heights, subways, buses, crowds, and of solitude and the dark are those often found in "phobic disorders." Finally, had his submissiveness, passivity, and other character defects been considered his most significant problem, he might be labeled as a "personality disorder." The matter of diagnosis, then, would be essentially a matter of what seemed immediately important. Actually, we might say that Roger suffered from a mixed psychoneurotic disorder with anxiety, depressive, psycho-physiologic, obsessive, phobic, and distorted personality manifestations. This diagnostic potpourri is not surprising when we consider that every individual whose homeostasis has broken down exploits dynamisms characteristics of all levels of defense in addition to displaying manifestations, psychological and physiological, of homeostatic imbalance and adaptational collapse.

> When Roger was asked what he believed had precipitated his anxiety originally, he was unsure, but he hazarded that it might have been related to a change in his position at work. Not long after his tenth wedding anniversary, at age 33, Roger was promoted to senior member of the firm. His elation at this was short-lived as he became conscious of a sudden depressed feeling, which progressively deepened. Inertia, boredom, and withdrawal from his ordinary sources of pleasure followed. Even his work, to which he had felt himself devoted, became a chore.

> Always eager to cooperate, he experienced, during work hours, a vague dread of something about to happen which he could not define. He could not understand why he would react to a promotion that he wanted by getting upset.

Should a therapist not be interested in pursuing the patient's symptoms further to determine their origin in early past experience or in unconscious conflict, in other words, avoiding a dynamic approach, an abbreviated approach aimed at symptom reduction might now be selected without further probing into history.

First, an effort may be made to treat the symptoms through medicaments, like sedatives or tranquilizers for anxiety, and energizers for depression. Roger may be enjoined to slow down in his activities and to detach himself as much as possible. He might be requested to take a vacation, engage in hobbies and recreations in order to divert his mind off his difficulties.

Another way of handling the problem might be to assume the source of the difficulty to be Roger's work situation and to get him to change his job to one that did not impose too great a responsibility on him. He would be encouraged to try to detach himself more from his wife and slowly to begin functioning again on the basis of the customary distances that he once put between himself and others. Active guidance and reassurance may make it possible for Roger to return to his own bedroom and to assume indifference to his wife that might enable him to function without anxiety.

On another level, the therapist might utilize behavior modification methods to desensitize the patient to his anxieties as well as to institute assertive training to promote greater self-sufficiency and independence. Approaches such as these understandably would not correct any basic character problems that lay at the heart of Roger's distress. Yet they might make it possible for him to get along perhaps as well as he had ever done prior to the outbreak of his neurosis.

Since my approach was a dynamic form of short-term therapy aimed at some personality rectification, I proceeded to explore as completely as I could his past life through interviewing and to probe for more unconscious motivational elements through

exploration of dreams and fantasies and through observation of the transference.

> Roger was the younger of two brothers. He was reared by a domineering mother who was resentful of her role as housewife, which had halted a successful career as a fashion designer. Unhappy in her love life with her husband, she transferred her affection to her younger son, ministering to his every whim and smothering him with cloying adulation. Roger's brother, George, bitterly contested this situation, but getting nowhere, he subjected his sibling to cruel reprisal. Roger's father, recoiling from the not too well concealed hostility of his wife, removed himself from the family as much as he could manage and had very little contact with his sons.

The dynamics in Roger's case became apparent during therapy. Basic to his problem was a disturbed relationship with his parents, particularly his mother. The yielding of her unmarried professional status to assume the role of housewife apparently had created in the mother resentment toward her husband and rejection of her children. This inspired a "reaction formation" in the form of overprotection, particularly toward her younger child, Roger. Frustrated and unfulfilled, she used Roger as a target for her own needs and ambitions with the following effects: (1) in Roger, encouragement of overdependence and passivity, strangling of assertiveness and independence, and stimulation of excessive sexual feelings toward the mother, and (2) in George, hostility displayed directly toward Roger as aggression, and (3) in her husband, detachment.

> Overprotected by his maternal parent, neglected by his father, and abused by his brother, Roger took refuge in the relationship offered him by his mother. His dependency on her nurtured submissiveness and passivity, with alternative strivings of rebelliousness and fierce resentment which he repressed because they threatened the security he managed to derive through compliant behavior. Roger both cherished and loathed the crushing attentiveness of his mother. Toward his father and brother he felt a smothering fear, which he masked under a cloak of admiration and compliance.

The withdrawal of his father made it difficult for Roger to achieve the identification with a masculine object necessary for a virile conception of himself. Roger turned to his mother for protection. He revolted, however, against too great dependency on her, fearing that excessive closeness would rob him of assertiveness and that his aroused sexual feelings would bring on him disapproval from his mother as well as punishment from his father and brother. Repudiating competitiveness with the other male members of the family, he attempted to win their approval by a submissive, ingratiating attitude.

> During adolescence Roger emerged as a quiet, detached lad, never permitting himself to be drawn into very intimate relationships. He was an excellent and conscientious student, and he was well-liked for his fairness and amiability. At college he was retiring, but he had a number of friends who sought his companionship because he was so easy to get along with. His romantic attachments were superficial, and the young women he squired to parties admitted that he was attractive but complained that it was difficult to get to know him.

Adopting detachment as a defense against a dependent involvement, and compliance as a means of avoiding physical hurt, Roger evolved a character structure that enabled him to function at home and at school, although at the expense of completely gratifying relationships with people.

> Upon leaving college, he entered a business firm, arrangements for this having been made by his father. He resisted for two years the exhortations of his mother to marry the daughter of one of her best friends; but finally he succumbed, and he seemed satisfied and happy in his choice. The yo ng couple lived in harmony, and he was considered by his group to be an ideal example of an attentive husband and, after his son was born, of a devoted father. His steadfast application to his work soon elevated his position, until he became a junior member of the firm. His best friend and confidant was one of the senior members, toward whom Roger bore the greatest respect and admiration.

His work and marital life, which were more or less arranged for him by his parents, turned out to be successful since he was able to employ in them his compliance and detachment mechanisms. Toward his best friend and other senior firm members, Roger related passively as he had related previously toward his father and brother. Toward his wife he expressed conventional devotion, keeping himself sufficiently distant to avoid the trap of a tempting dependent relationship that would threaten the independent assertive role he was struggling to maintain.

> The only distressing element in Roger's life was his failing health. Constantly fatigued, he evidenced a pallor and listlessness that inspired many solicitous inquiries. Dyspeptic attacks and severe migrainous headaches incapacitated him from time to time. In addition to his physical symptoms was a pervasive tension, which could be relieved only by recreational and social distractions.

Inner conflict between dependency, submissiveness, compliance, detachment, and aggression, however, constantly compromised Roger's adjustment, producing a disruption of homeostasis with tension and psychosomatic symptoms. His failing health, fatigue, pallor, listlessness, dyspeptic attacks, and migrainous headaches were evidences of

adaptive imbalance. What inspired this imbalance was an invasion of his capacity to detach, produced by the demands made on him by his wife and associates. In addition, his submissive and compliant behavior, while protecting him from imagined hurt, engendered in him overpowering hostility, which probably drained itself off through his automatic nervous system producing physical symptoms.

> As might be expected, Roger's affability and needs to please won for him the praise of his superiors at work, and he was advanced and finally offered a senior position.

Had Roger at this point refused to accept senior membership in the firm, he might have escaped the catastrophe that finally struck him. His legitimate desires for advancement, however, enjoined him to accept. His conflict became more and more accentuated until finally he no longer was able to marshal further defenses. Collapse in adaptation with helplessness and expectations of injury announced themselves in an anxiety attack during luncheon with his friend.

As long as he had been able to satisfy to a reasonable degree his needs for security, assertion, satisfaction in work and play, and creative self-fulfillment, Roger was able to make a tolerable adjustment even with his psychosomatic symptoms. The precipitating factor that had brought about the undermining of Roger's capacities for adaptation was his promotion to senior membership in the firm. While Roger had ardently desired this promotion, for reasons of both status and economics, actually being put in a position of parity with his friend violated his defense of passivity, compliance, and subordination and threatened him with the very hurt he had anticipated as a child in relationship to his father and brother. To accept the promotion meant that he would be challenging of and perhaps triumphant over father and brother figures. This touched off fears of injury and destruction at the hands of a powerful and punitive force he could neither control nor vanquish. Yet Roger's desire for advancement, inspired by realistic concerns, made it impossible for him to give up that which he considered his due. Since he was aware neither of how fearfully he regarded authority nor of how he was operating with childish attitudes, he was nonplussed by his reactions.

A dream revealed during one psychotherapy session will illustrate some of our patient's maneuvers that became operative and apparent in therapy (see <u>Fig. 44-1</u>).

Pt. I had a dream last night that upset me. I am in bed with this big woman, big wonderful breasts. She's my wife, but she changes into a negress. She strokes and touches me all over, and I feel completely loved and accepted. I awoke from the dream with a strong homosexual feeling that upset me. [*Here Roger symbolizes in dream structure his dependency impulses, his repulsion against his dependency, his incestuous desire, and the resultant homosexual residue and defense.]*

Th. Yes, what do you make of this?

Pt. I don't know. The woman was comforting and seductive. I always like big-breasted women. Exciting. But my wife isn't as stacked as I'd like her, or as she was in the dream. *(pause)*

Th. How about the negress?

Pt. I never liked the idea of sleeping with a colored woman. Makes me feel creepy. Colored people make me feel creepy. I know I shouldn't feel that way. Last time I was here I noticed you had a tan like you had been in the sun. I said, "Maybe he's got negro blood." I know I shouldn't care if you did or not, but the idea scared me for some reason.

Th. Sounds like the woman in your dream was partly me. *[This interpretation was proffered in the hope of stirring up some tension to facilitate associations.]*

Pt. (pause) The idea scares me. Why should I want you to make love to me? *(pause)* By God. maybe I want you to mother me, be giving, kind.

Th. How *do* you feel about me?

Pt. I want you to be perfect like a God; to be accepting and loving; to be wise and strong. I realize I'm dependent *[motor one],* I resent my need to be dependent on you *[motor two].* When you show any weakness, I am furious. I feel guilty and upset about my feelings. I feel like killing anybody who controls me. I know I must face responsibility, but I feel too weak and unmasculine *[motor three],* I feel like a shit *[motor four]* and hate myself. I am a nothing and I'd like to be a somebody, but I can't.

Th. Apparently it scares you to be a somebody. When you were promoted, you started getting upset.

Pt. Why should 1? I suppose I feel like I'm stepping out of my depth. Like I'm not man enough. The whole thing puzzles and frightens me.

Th. So what do you do?

Pt. I am constantly running away *[motor five],* I get so angry at people. I don't want to see anybody. I'm so upset about myself. I try not to feel. But I can't seem to make it on my own. *[The reinstituting of motor one]*

FORGOTTEN MEMORIES AND EXPERIENCES

In the course of exploring the unconscious, experiences in the past that have been traumatic are apt to be revived by the patient. Forgotten memories may be remembered of which the patient may have been relatively or completely unaware. The importance of this material constantly comes up for appraisal.

There are those who believe that the recall of forgotten traumatic incidents in the developmental history is essential for cure in reconstructive therapy, since repressed memories are fountainheads of conflict. A criterion of cure set by Freud was a removal of the amnesia of the third and fourth years and a recovery of memories during this period that are associated with the patient's neurosis. There are other authorities who tend to disagree with this standard, believing that therapy, focused on immediate interpersonal relationships, can change personality without the need for probing into the past. This, it is avowed, is because the past is always repeating itself in the present and can be better managed when it becomes freshly apparent in contemporary behavior. Actually we are more concerned with a patient's *ideas* about his past rather than what actually happened in the past. The patient's *interpretations* about parental attitudes and behavior can be more important than the actual reality. One may observe this within some families when a parent behaves toward a child in what seems on the surface to be loving and giving, yet the child reacts as if being maltreated and tortured. A prejudiced child advocate might say that the child penetrates the facade of lovingness and recognizes that the parent is merely concealing maliciousness and rejection. But the advocate could be wrong in that it is the child who anticipates and even desires malicious treatment. Parents can communicate destructive designs to their children, wishfully anticipating that their offspring will act out fantasies that they themselves cannot openly express. Children are not entirely helpless pawns, however, and they do act out their own selfish promptings. Do we have to expose all past happenings before a person can get well? It is credibly established clinically that an individual in many ways relives the past in present behaviors, thoughts and feelings, and it is usually through working with present-day distortions that we can rectify the effect of past troubles rather than the other way around.

The mechanism associated with the repression of early experiences is organized around the need to avoid anxiety. In early childhood, inimical happenings are extremely traumatic. One reason for this is that the child feels relatively helpless in a world, the manifestations of which are a constant source of mystery. Relations between cause and effect are indeterminate, and in this world there are many inscrutable menacing events over which the child has no control. One way of coping with childhood anxieties is to project them in the form of phobias. Another way of dealing with anxiety that threatens to overwhelm the immature ego is through processes of repression and dissociation. These phobic and repressive defenses continue to function far beyond the period of childhood, and the ego reacts to the original traumatic events as if it still were too weak and too vulnerable to deal with them. This is possibly the reason why many adults feel that there is something buried deep within themselves so terrifying that they cannot bear to bring it up.

An important question is whether early traumatic experiences are universally damaging. It is difficult to provide a complete answer to this question. All children undergo traumatic experiences of one sort or another during the period of socialization. A cataclysmic happening, however, can bring the effects of minor experiences to a head and can embody the accumulated emotions of all past inimical events.

Traumatic experiences in early childhood thus act upon a sensitized soil at a time when ego resources are relatively limited. Often these experiences, when uncovered, appear so insignificant that one might doubt their potency in evoking such disproportionate emotional responses. Yet, if one considers that the traumatic experience is a condensation of a series of damaging events and that it comes to stand symbolically for all of them, one may appreciate that it can be greatly overvalued.

As a general rule, early traumatic experiences are of two types. In one type the events are so devastating or destructive that no child could be expected to cope with them. This occurs where the child is severely injured physically or witnesses an incident so horrible that the experience takes away security. The other type of traumatic experience

can in no way be considered extraordinary since it is a part of the normal growth process. Growing up involves the capacity to abandon narcissistic and omnipotent strivings, to tolerate frustration, to channelize aggression into socially accepted outlets, to control sexual impulses, and to develop independence and self-assertiveness. In the course of development, the child is subjected to many frustrations that involve abandonment of selfish strivings in favor of those that will bring cooperative relationships with others. Most children are capable of handling such frustrations without too great difficulty. However, an insecure child, and particularly one who has been rejected and denied legitimate demands for love and support, will be so overwhelmed by feelings of helplessness that the child will be unable to tolerate frustration and to withstand traumatic experiences that are a usual component of growing up. Such an individual is likely to react catastrophically to relatively normal hardships such as are imposed on every child. Certain events, like the birth of a sibling, the discovery of the genital difference between the sexes, the witnessing of parental intercourse ("primal scene"), or exposure to any bloodshed and cruelty, may mobilize inordinate anxiety.

The insecure child may feel so threatened by rejection or punishment that the child will find it necessary to repress such impulses as hostility toward parents and siblings, masturbatory desires, sexual curiosities, and strivings for mastery, independence, and self-assertion. The repression of these impulses involves much experiment. The child for a long time defies the parents, even at the risk of incurring retaliatory punishment. Gradually, however, the child may yield to parental discipline. Frequently repression occurs dramatically following a particularly traumatic incident that convinces the child that danger can be real. For instance, an insecure child who retains certain rebellious tendencies may witness the flogging of a dog that has done something to offend its master. The child may be frightened by this brutal treatment and may unconsciously identify with the animal, fearing injury in the same way if he or she persists in defying the parents. The result may be a phobia in regard to dogs, the dynamic purpose of which is to be insulated against fear of aggressive impulses. The event comes to constitute a traumatic experience that may be repressed in an effort to avoid any reminder of pain. The dog phobia will, nevertheless, persist, aiding the repressive process.

During later life, too, even in adulthood, intensely traumatic experiences may shock the organism into a revival of the mechanism of repression. This move is motivated by a need to ward off a threat to the self. There are no better examples of this than those seen in the neuroses of war in which traumatic incidents may be blotted from the mind.

In the course of therapy the recovery of repressed traumatic experiences may ameliorate or dissipate certain symptoms, especially those that serve the function of keeping these memories repressed. Many compulsions, obsessions, and conversion symptoms fall into this category. The most dramatic results occur in simple conditioned fears and in amnesias of recent origin, such as hysterical amnesias, trauma of the skull, and exposure to unbearable stresses like those during disasters and war. Where the personality is relatively intact and the individual has, prior to the traumatic event, functioned satisfactorily in interpersonal relationships, the recall of forgotten events may restore the previous status.

Theoretically, all symptoms have an historical origin. It may be argued that were we capable of probing deeply enough into the past, of penetrating the myriad conditionings, of reviewing every stimulus that ever invaded the senses and every idea that entered the mind, of peering into all influences, pleasurable and inimical that have impinged on patients, we might be able to demonstrate to them how each of their symptoms came into being. This task, however, is impossible, for many vital early experiences that have molded the personality are not accessible to recall, having occurred prior to the phase of mnemonic accessibility, or having been subjected to a practically impenetrable sealing-off process of repression. In spite of a most extensive analysis one is able to recapture only a fragment of the total of life experiences. Even where we have not laid out for ourselves so ambitious a task and are satisfied with reviewing the most important experiences in the patient's development, we find these so numerous as to defy recapitulation.

However, to indulge our imagination, we may conjure up a situation in which we track down the origin of each of the patient's symptoms. Having done this, we should probably find, in most cases, that the symptoms themselves would not vanish. The

expectation that recovery of traumatic experiences will invariably produce an amelioration or cure of the patient's neurosis is founded on a faulty theoretic premise. Even though the individual's character structure is in a large measure developed from the bedrock of past experiences and conditionings, and even though damage of personality has resulted from untoward happenings in early interpersonal relationships, it does not follow that a recall of these experiences will correct the existing condition.

As an analogy, we may consider a focus of infection that operates insidiously over a period of years. The original source of the individual's physical disability is this infective focus, but by the time it is discovered, it has already influenced other bodily structures. It may have produced kidney damage or acted as a stimulus of secondary foci of infection. The removal of the primary focus will leave the body still suffering from the effects of the original infection, and it will be essential to cure these secondary effects before the patient can be pronounced cured. A single catastrophic experience or a series of harmful experiences can likewise act as a focus, engendering in an insecure person the conviction that the world is menacing and that the people in it are not to be trusted. The experience may influence the individual in forming decisive attitudes and reaction patterns. By the time of adulthood, however, the manner of dealing with the conflicts will have been structuralized into behavior so ingrained that the recall of the original trauma will have little effect upon habitual responses. Therapy will involve tedious reeducation and reconditioning long after the recall of the initial traumatic memories.

Often during therapy a patient may recover the memory of a forgotten traumatic happening and through this recall may experience considerable abreaction. The patient may even be liberated from certain associated symptoms. However, the essential difficulty will probably remain. The patient will still be insecure. The circumstances that sensitized the patient to the original traumatic scene will continue to plague him or her in daily interpersonal relationships. The essential task in therapy, therefore, would seem to lie not only in recovery of early traumatic experiences, but also in ascertaining the reasons why the experiences became so catastrophic as to necessitate repression. Ultimately, a remodeling of behavior will be mandatory before we can pronounce our objective as

successful.

It must always be remembered that a neurosis is not a fortuitous happening, dependent exclusively upon early traumatic events. It is rather a form of adaptation to, and defense against, a world that is regarded by the child and later by the adult as potentially hostile and menacing. Current reaction patterns and attitudes, while derived from past experiences, are not an automatic repetition of infantile modes in an adult setting. They are forms of behavior motivated by a desire to escape helplessness, to gratify vital needs, and to allay tension, anxiety, and hostility. The individual reacts to the present with characterologic machinery that is rooted in past experiences; but present-day problems are the immediate results of conflicts deriving from demands, fears, and resentments that arise also from current interpersonal relationships.

Overemphasis on the part played by the past may produce certain unfortunate effects during therapy. The patient may utilize inimical childhood experiences as a justification for neurosis and for resistance to change. Therapy may bog down in a compulsive historical review of the patient's past, a definite cleavage developing to isolate it from the present. Some patients who have familiarized themselves with early theories of psychoanalysis are led to believe that awareness of their past conditionings will magically dissolve their problems and reintegrate them in their dealings with the world. Consequently, the analysis becomes a stereotyped search for an illusory pot of gold at the end of a mnemonic rainbow.

While an exclusive preoccupation with the past imposes definite limitations in therapy, one must not be won over to the fallacious notion that the historical experience can be entirely meaningless. Tendencies in this direction are apparent in certain current insight therapies, and they foster a concentration on relatively recent material. There is in this approach a dichotomization of the personality, as though the individual had two parts —an important present and a past that has little bearing upon prevailing attitudes, values, and goals.

Knowledge of the historical roots of a disorder is in itself not sufficient to produce

cure, but it is of tremendous value in establishing continuity in the individual's life, from infancy to adulthood. It points to weakness and sensitivity of the ego at the time of a particularly traumatic experience. It shows how some repetitive happenings in the present are a reflection of the same problems that existed in childhood. Of particular therapeutic benefit is the ability of the ego to withstand the emotions liberated by the recall of early traumatic incidents. The neurotic individual often has little self-respect because of the constant necessity of yielding to the fear of the past. To be able to master this fear, and to tolerate the anxiety that previously caused the individual to cringe, has an enhancing effect on ego strength.

The relationship with the therapist acts as an important tool in the recall of buried memories. In the transference the patient will be stirred up emotionally and will experience attitudes and impulses that have a potent effect in reviving mnemonic prototypes of what he or she is undergoing in the present. The transference will frequently touch off patterns that cannot be uprooted by any other method.

During therapy, however, some patients may be incapable of remembering any traumatic experiences. This failure need not necessarily block the therapeutic process, and important changes in the dynamic structure of the personality can occur with little recall of the past. Interpretation of the transference and the establishing of an unambivalent relationship with the therapist may enable the individual to function on better terms with himself or herself and with others. It is possible also that the individual may give up infantile defenses without recalling the specific traumatic memories or experiences that inspired them.

On the other hand, analysis of the transference and interpretation of dreams, free associations, and material elicited through interviewing may, in themselves, fail to beget memories. The patient seems to be stymied by a stubborn amnesia relating to vast segments of childhood or later life. The inability to recall vital situations of the past may represent resistance to accepting the implications of certain drives and defenses as they reveal themselves in the relationship with the therapist.

Obdurate resistance to recall frequently constitutes a means of avoiding anxiety of a sort that initially fostered the repression. In some patients it serves to retain the secondary gain inherent in their neurosis. The amnesia affecting recall may be so stubborn that even the most concerted effort will fail to bring the repressed material to the surface. Where, with extensive probing the patient is unable to recover damaging traumatic experiences—although one is reasonably certain that such experiences have occurred—it is probable that the amnesia protects the ego from anxiety that it would be unable to handle if the experiences were recalled. Here the reasonable ego is still too weak to absorb anxiety and to reconsider the experience in a factual light. The ability to recall early traumatic experiences, and to reevaluate them, requires considerable ego strength. In a number of conditions—for example, conversion reactions—sufficient ego intactness exists so as to make possible the handling of fears and conflicts associated with an inimical past. In these ailments the recovery of repressed experiences may suffice to produce a cure of specific symptoms.

In other conditions, however, such as certain personality disorders and psychoses, the ego is so vulnerable and weak that it cannot tolerate either the repressed memories or their implications. Therapy may fail to break down the resistances to recall, or the traumatic experience may be remembered with a peculiar dissociation of its emotional content. The forgotten event may be remembered as a vague experience without emotional implications, what is recalled being enough to satisfy the rational demands of the individual. The damaging emotions and the significance of the experience itself are, however, repressed. The individual reacts to devastating childhood incidents or fantasies in an apathetic manner, as if they were somehow detached. There is no abreactive process. It is almost as though the patient, by recall, seeks to fulfill a dual purpose: first, to retain the good will of the therapist by remembering things and, second, to hold on to his or her resistance by repressing the emotional meaning of the traumatic event.

Failure to uncover buried memories may be due to the fact that therapy has not bolstered the ego to a point where it can absorb the anxiety liberated by the recall of early experiences.

HYPNOTIC RECALL OF FORGOTTEN MEMORIES

In some cases hypnosis may uproot unconscious memories. One may question the efficacy of such a process, for it is axiomatic that a premature confrontation of the ego with unconscious material merely serves to create anxiety and to enhance resistance. Yet hypnosis need not have this effect, providing the recall is adroitly handled. Instead of battering down resistances by forcing memory of things, it is best to give full freedom to recall when the patient feels capable of dealing with such memories. During hypnosis the patient may be told that there are certain experiences and memories that are quite important and that, because of their painful nature, they have been forgotten. Assurance may be given that it is not necessary to remember all details of such memories at once, but that the patient will be able to reveal and to tolerate isolated fragments of these memories and experiences as time goes on. Under the influence of such suggestions the patient will bring out those elements of a forgotten memory or experience that can be tolerated, and as the patient becomes stronger and realizes that he or she is not injured by the recall, more and more material will be available, until finally the fragments can be reconstructed into a consistent whole.

Piecemeal recovery of a forgotten memory or conflict may be furthered by employing such techniques as dream induction, automatic writing, regression and revivification, drawing, and mirror gazing (Wolberg, LR, 1964a). The evidence elicited by all these procedures may make the meaning of the experience increasingly clear to the patient. As a general rule, the implications of the memory will not be accepted until the patient realizes its importance and presents a recapitulation as a product of personal efforts and conviction. Reconstructing the patient's memory in the waking state, from material uncovered during hypnosis, may rob the recall of its therapeutic effect.

One of the best methods of handling material that is recalled in hypnosis is to instruct the patient to forget a revived memory until he or she feels convinced of the truth of the memory and understands it thoroughly. It may be weeks before the patient is capable of bringing up portions of the material spontaneously, with corresponding insight. Even where the patient recalls in the waking state memories recovered in a recent

hypnotic session, the patient will usually be unable to integrate their meaning until the ego has had time to prepare itself. The authenticity of the memory may, of course, be in question since fantasies are common in the process of recall. But fantasies are creative constructs and dealing with them may also have a therapeutic effect. Indeed, sometimes fantasies are more potent sources of conflict than actual past traumatic happening.

THE HANDLING OF UNCONSCIOUS MATERIAL

The actual handling of derivatives of the unconscious depends on the projected goals in treatment. In supportive therapy one may totally disregard unconscious outpourings. In reeducative therapy the most manifest eruptions are selected for exploration. Thus, immediate character distortions and the surface conflicts these initiate may be a chief focus. The less manifest, more repressed aspects of the unconscious are usually deliberately avoided. In reconstructive therapy various strata may be explored, from topical spontaneous unconscious manifestations to those that are so deeply repressed that they require mobilization through the dissolution of repressive barriers.

Among the techniques in reconstructive therapy exploited to stir up unconscious activity and to remove repression are employing a passive role in the therapeutic relationship; focusing on dreams, fantasies, past experiences, and early relationships with parents; increasing the frequency of sessions; and using the couch position and free association. These activities may lead to a transference neurosis. Sometimes narcoanalysis, hypnoanalysis, art analysis, and play analysis are utilized as adjuncts for the probing of unconscious material. Of all measures, the provocation of a transference neurosis is perhaps most effective.

Unless the therapist is trained to do reconstructive psychotherapy, it is unwise and even dangerous to stir up unconscious material. Explosive forces may be liberated by a lifting of repressions with which the untrained therapist may be incapable of coping. Where, in the course of supportive or reeducative therapy, disturbing unconscious material spontaneously appears, the therapist may strive to help repression by avoiding discussion of the material, by dealing with it reassuringly, by focusing the interview on

reality matters, and by the use of greater activity in the relationship.

There are a number of ways in which unconscious feelings and attitudes can be expediently brought to the patient's attention. Some activities employed during interviewing are restating, reflecting, and interpreting whenever the therapist recognizes an unconscious trend in the patient's verbalizations, dreams, fantasies, slips of speech, free associations, or transference reactions. These activities at first register themselves only minimally on the patient's mind since acknowledgment of unconscious trends is laden with much anxiety. Incredulity or polite acceptance without conviction may mark the first reactions of the patient to the disclosures.

As has been indicated, a patient may be helped to accept repudiated aspects of the psyche by the recollection of early traumatic experiences and memories. The realization that traumatic memories were being repressed, and the understanding of their symbolic significance may provide the patient with a wedge with which he or she can penetrate into unconscious conflicts and gain insight into their significance.

When interpretations are presented to the patient, it may be important to recast the wording of early memories or experiences in the very terms utilized by the patient, even though these parallel the expressions used as a child.

ILLUSTRATIVE CASES

Example 1

The following excerpt illustrates the verbalization in transference of unconscious sexual impulses on the part of a male patient toward his father. The material was expressed explosively with great anxiety, following a prolonged period of silence. This is from a session in which free association was employed.

> *Pt.* My God. I feel I'm in love with you. I can't break away from you, but I want to come. I want to come here every day.
>
> *Th.* Every day?

Pt. I'm afraid of you. You are so high and I am so low. I'm afraid of my feelings for you. Oh, God, as I talk I think of your penis. It's in my mouth. Oh, oh …it makes me afraid. It makes me so afraid … oh, oh. *[The patient seems to be in a transference upheaval.]*

Th. Why?

Pt. You're so big and I'm so little. I'm down on the floor. Oh God, I'm frightened … oh, oh. I'm afraid you'll stick it up. This is awful. Please don't. I have to do what you want me to do. I want you to put me down on the floor. I want you to be powerful like my father. I want you to tell me what to do. I want to love you, and I want you to love me. I don't want you to hurt me or kill me.

Th. You feel I may hurt you?

Pt. I know this isn't real, but I have a feeling you are my father. I want to reach out and grab my father. He is sitting there, gentle and strong. I want to scream and cry. I want you to come to me. Father, come to me! Please come to me! I want you to kiss me and hold me close. Everything is whirling around. I can't stand it. I see myself nude. You are standing over me. Oh, God, please give it to me.

Th. What is it that you want?

Pt. Don't get near. Oh God, don't kill me. I'll do anything you say. I feel so little when I talk. I'm afraid to be big. I can't be the same as you. I don't want to, I don't want to. *(cries)* I don't want to … no, no, no. *(cries)*

Th. Why don't you want to?

Pt. I don't want to grow up. I can't fight like the other boys. I never could. I love you. I want to wear your suit, but I can't wear it. I can't touch it, anything you wear, *(continues crying and then begins to act more cheerful)*

Th. Well, how do you feel now?

Pt. God, that was a horrible experience. It was like I was a little boy again. I can't understand why I said the things I said. I remember father. He never let me do anything. I always thought I hated him and was afraid to do anything, not even shovel the snow. He acted like he always had to be the boss. Kind of hard on me, I can see it now. I always felt that I never wanted to grow up; I wanted to be a little boy. Maybe I wanted to be punished because I felt guilty about not liking my father. Even now, when I am near him. I am afraid he will hit me. He goes into such a rage. I wonder what would happen if I hit him back. I felt the same way about you, but I never realized these sexual feelings. It scares me to think about that, *(pause)*

Th. It scares you?

Pt. It's funny I never wanted you to touch me. It scares me. It scared me suddenly to realize I want you to treat me like a woman. On the other hand, I want you to touch me. I was afraid for father to touch me. Maybe I felt the same way toward him as toward you. This whole thing must be some way connected with my fear of homosexuality.

Th. And with fantasies about your father.

Pt. I just remembered a dream I had last night. I'm at home, the house we had when I was little. There is a bed against the wall. Father is there in the room. He is undressing. I wonder if he is approaching me. I'm in bed. There is a funny excitement, repulsion, and fear. His body is big. It has a nauseating smell. His penis is enormous, enormous, big and red, fearful. I feel repelled by his body. I know he wants to stick his penis up my rectum. This I realize will kill me. I grab a gun and shoot at him, but it doesn't go off. I keep firing, but the bullets shoot out a couple of inches and fall on the floor. Father comes closer. I want to scream and can't. I then woke up screaming and found I had an ejaculation.

Th. What do you think this means?

Pt. It must be connected with what we've been talking about—my fear of women, my fear that they'll reject me. I must be scared of being rejected or even killed for my interest.

Example 2

The following interview illustrates the use of hypnosis in recovering the memory of a traumatic incident, in the form of a "primal scene," which engendered an hysterical conversion symptom.

The patient, a woman of 28, came to therapy because of anxiety that was so severe that it absorbed all of her attention and energy. It had its inception in a particularly violent quarrel with her boyfriend, with whom she had expressed growing dissatisfaction. The imminence of a rupture in her relationship with her friend caused the patient to respond with panic, since she was devoted to the man and marriage had been contemplated in the near future. She was aware of the fact that she was repeating a pattern, because all of her relationships with men had terminated in the same kind of violent disagreement. During one interview, while working on her sexual attitudes, the patient complained of a blurring of vision. She confided that this symptom had appeared on certain occasions when she looked into a mirror. She then searched the room intently with her eyes, and asked if a mirror were present.

The following is an excerpt of the recorded interview, during which the meaning of her eye symptom becomes apparent. The patient is in a waking state at the start of the session.

Pt. (panic in voice) I have that funny feeling again about a mirror—looking at it, *(pause)* and everything is blurred.

Th. You act somewhat upset by this.

Pt. Everything is upside down.

Th. Upside down?

Pt. Not really, but it seems like it. *(pause)* Do you have a mirror here? I don't see one, but it feels like it.

Th. What does it feel like?

Pt. I … don't … know … An upside down feeling … I'm doing something with a mirror reflection … a reflection.

Th. Tell me about it.

Pt. It's like last night. The same thing happened. I was at a friend's house, thinking of coming here. There was a mirror table in front of the sofa, when I was sitting there … I looked in the mirror, and everything I saw in the mirror began to look more real than the women in the room. And I thought, that's strange, and it looked like I could walk right into the room … the mirror room.

Th. Almost as if it were a different world?

Pt. Well … well, it didn't seem to be upsetting anyhow, *(pause)* It looked very inviting.

Th. You were not afraid to walk into that mirror room?

Pt. Now, it looks very frightening, but I have been dreaming about a mirror, *(pause)*

Th. Tell me more.

Pt. Upside down, backward, and all the letters and all … *(pause)* everything you say— everything has to be read backward. I used to do mirror writing when I was little.

Th. What about your writing; you say it was mirror writing?

Pt. Oh! I wrote quite a lot.

Th. What did you write?

Pt. Oh, just the way I felt and whatever I did when I was a child. I sometimes would doodle something about a mirror. A mirror of some kind seemed to be on my mind.

Th. You did write about a mirror?

Pt. Well, sometimes.

Th. Do you remember seeing anything unusual in a mirror?

Pt. I can't think ... I can't remember.

Th. Maybe I will put a pen in your hand, and we'll see. Let your hand just do what it wants. [*I try to induce automatic writing in the waking state, which may be possible in patients suffering from hysterical reactions. This may reveal repressed material.]*

Pt. I use the typewriter.

Th. You can write freehand pretty well, can't you?

Pt. I guess so.

Th. Just let your hand move along as it wishes. Just let it do as it wishes, and pay no attention to what it writes. Just put the pen right down, and don't look at it as you talk to me; just let your hand travel along as it wishes. You will notice that it will be almost as if an outside force pushes your hand along without paying any attention to what your hand writes. Just talk to me. You acted a little bit nervous when you walked in here today.

Pt. Yes.

Th. Are you any less panicky than you were?

Pt. Well ... it isn't panic exactly.

Th. What is it then?

Pt. I don't know.

Th. Like something deep down underneath that bothers you?

Pt. Uh huh.

Th. Are you now aware of what that something is?

Pt. Oh! It's disgusting—something I saw, I guess.

Th. Something you saw?

Pt. Uh huh.

Th. What?

Pt. I don't know.

Th. There was something you saw?

Pt. Uh huh.

Th. Put your pen down, and maybe your hand will tell us more about what you saw— what it actually was that you saw. *(The patient's hand scribbles a few words.)* Can I see that? I mean the sheet you wrote on. Your hand seemed to scribble something while we talked. Now let's see what your hand wrote. *[The patient responded to the suggestion to write automatically.]*

Pt. It says, "You used to have a mirror to write in when you were a girl."

Th. You used to write in a mirror?

Pt. Yes, it was a mirror with a barricade in front of it, and when you put the paper down, you couldn't see what you were writing, but you had to look in the mirror and then you could see. That was the mirror writing.

Th. I see. How old were you then?

Pt. I guess around 8, 7 or 8.

Th. Around 7 or 8?

Pt. Uh huh.

Th. It would seem that perhaps around that period of your life something quite significant happened to you.

Pt. Yes, I guess so.

Th. Do you know what that was?

Pt. (pause) I can't remember.

Th. Now I would like to have you sit just exactly as you are. *[Hypnosis is induced at this point.]* And I want you today to bring your hands up, this way—clasp them together closely. I want you to watch them—watch your hands. I am going to count from one to five. You are going to notice when I count from one to five that your hands will become pressed together, the muscles will stiffen, you hands will get tighter, tighter, and tighter, so that at the count of five it will be difficult or impossible for you to open them. Keep gazing at them. One. tight; two, tight, tight; three, tighter and tighter; four, as tight as a vise; five, so tight now that when you try to separate them, you cannot. *(pause)*

You notice now that your eyelids will get very heavy, that they close, they shut, they feel as if little steel bands are pulling them together. Your breathing gets deep and automatic, and you go into a deep, deep sleep. You are very, very drowsy; you are very tired—very, very sleepy; you are going to get drowsier, drowsier, and drowsier. You are going to fall asleep now, and you will stay asleep until I give you the command to awaken. You'll stay asleep until I give you the command to awaken. You feel very relaxed. Let your breathing become regular and deep. You feel more comfortable and relaxed. You are very, very sleepy. I am going to unclasp your hands now—just like this. I am going to bring them right down to your sides.

I am going to take this arm and stretch it out in front of you now, and as I do this, the arm is going to get very stiff and rigid. The arm will get stiff and heavy and rigid, heavy and stiff like a board. I am going to count from one to five. At the count of five, the arm will have got so firm, stiff and heavy and rigid, that it will be difficult or impossible to bend it. One, firm; two, heavy; three, firmer and firmer; four, just as firm and stiff and rigid as a board; five, just as firm and stiff and rigid as a board. Notice how stiff it is. The harder you try to bend it, the heavier and stiffer it becomes, until I push it back the other way, and then it loosens up. Bring it down, bring your head down this way. Relax yourself and go to sleep. Go to sleep, deeply asleep, very deeply asleep. Just relax all over, *(pause)*

Now I am going to give you a suggestion that you begin to enter into a deep sleep, so deep that you don't keep anything back from me. I am going to help you to a point where you will be able to see what it is that is behind the mirror. *(pause)* I want you to start getting very, very little. I want you to start feeling very, very little.

Your head is getting smaller; your arms and legs are getting smaller. You are going back, back, back to the time when you had that mirror. You are going right back to the time of the mirror. Your feet are getting tiny, you are shrinking, you are getting little, you are getting very small, you are shrinking, you are getting very, very small, you are getting very tiny. You are very, very small and tiny as if you are little again, just the way you were then. You are little, you are tiny. How old are you? How old are you? [This is a technique aimed at regression and revivification.]

Pt. Eight.

Th. You are 8 years old. (*Patient appears to be trembling with fear.)* Are you afraid? You look afraid. Tell me what you are afraid of. What are you afraid of? Tell me.

Pt. (panicky) Of myself.

Th. Anything else?

Pt. I don't know. It's a secret.

Th. You are afraid of yourself, afraid of yourself. Now listen carefully to me. I am going to ask you now to make your mind a blank; I am going to ask you now to make your mind a mirror. You are a little girl, and you are looking in a mirror. In your mind you will see a letter that will appear in the mirror. Every time when I clap my hands together, you will see a letter. It will appear in the mirror. The letters all put together, in whatever order they may come, will spell a word. That word holds the secret of what frightens you. One, two, three, four, five—watch the mirror, *(clap)* [This is a technique of circumventing repression.]

Pt. K.

Th. K—one, two, three, four, five—watch the mirror, *(clap)*

Pt. F.

Th. F—one, two, three, four, five—watch the mirror, *(clap)*

Pt. U.

Th. Now, when I clap my hands together, see the entire word.

Pt. F-U-C-K.

Th. F-U-C-K. Now watch that mirror again—watch that mirror, and when I clap my hands together, you will see that secret, you will see that secret. Don't be afraid now … One. two. three, four, five, *(clap) (pause)* Tell me about it.

Pt. Woman up on top of a man. *(Patient is panicky as she talks.)*

Th. Who? *(Patient moans in a distressed manner.)* You see a woman on top of a man. All right now, watch that mirror. Watch that mirror.

I am going to clap my hands together, and then, all of a sudden, the face of the woman in the mirror becomes clear. As soon as I clap my hands together, it will be as if you see the face, you see the features. Watch carefully, *(clap)*

Pt. Mother.

Th. Your mother! Now watch carefully. I am going to clap my hands together. The minute I do, you will be drawn right into the mirror, and the man's face will become clear.

Pt. (with fright) My father.

Th. Your father. Are you afraid? What do you think is happening?

Pt. I am afraid.

Th. Now listen carefully. If this is an actual scene—an actual memory—you finally will be able to understand it. Your fear is getting less now; you are beginning to get less and less fearful. Don't be afraid; don't be afraid. Good I want you to sit here for a while, then I'm going to help you start growing up to your present adult age. If you like, you can remember what you saw, remember everything that happened, when you awaken. After that you can talk to me; we can talk this thing out. You would like to be well, completely well and unafraid, wouldn't you?

Pt. Uh huh. (The patient is breathing heavily, sweating, and is obviously shaken.)

Th. Good. In a moment I am going to wake you up. *(pause)* Now listen carefully to me. When you awaken, I want you to begin talking. Try not to be afraid even if you remember an actual memory. If you remember all the details, I want you to remember also the reasons you became afraid and had to forget them. I want you, if you can, to remember your fears, whatever they were. When you talk to me, the thing may come back as it happened, just exactly as it happened with all details. If you remember, tell me exactly how it happened. You have spent your life running away—hiding. You may not want to hide now. I am going to count from one to five, and on the count of five open your eyes suddenly and talk to me rapidly. One, two, three, four, five, *(patient awakens)* How do you feel?

Pt. (mumbles)

Th. I can't hear you.

Pt. Very funny.

Th. Tell me all about it.

Pt. I don't know. What shall I do now?

Th. Do you remember what happened here?

Pt. Yes.

Th. What happened?

Pt. (somewhat fearful) The mirror writing happened … and then mother and father vanished.

Th. Did you ever see your mother and father together—intimately?

Pt. I know I did. It's all been in the mirror writing.

Th. Do you recall the incident when you saw your mother and father together?

Pt. Yes.

Th. Are you afraid now?

Pt. My father's dresser with the mirror was next to the door, and that was reflected then. I was outside and I saw it all. [*It would seem that the image inspired such anxiety in the patient that she attempted to repress it. Yet the mirror image also caused great excitement. The consequence of this conflict was mirror writing and blurring of* vision.]

Th. I see. So you stood outside there, and you saw the mirror reflection?

Pt. I saw mother on top of father.

Th. So you saw your mother on top of your father?

Pt. I think so.

Th. A child, when she perceives these things, thinks of them in different terms than an adult. What might you have thought as a child, what could have been going through your mind? What do you think was happening? You must have thought something, *(pause)*

Pt. They keep turning around.

Th. Do you see the two of them now?

Pt. Yes, when I close my eyes.

Th. Do they keep turning around:

Pt. Yes.

Th. Describe to me what they do.

Pt. First father is on top, and then mother is on top now. First mother is on top, and then father is on top. *(There is fear and excitement in the patient's voice.)*

Th. Now what's happening?

Pt. Upside down.

Th. Do you remember the first few weeks when you came to see me? You were so upset, you said everything was upside down.

Pt. Uh huh … upside down.

Th. Perhaps you were excited by what you saw?

Pt. Yes, yes.

Th. Do you have any thoughts of upside down?

Pt. I don't like it upside down, *(pause)*

Th. Why?

Pt. I feel as if it's been killing me.

Th. You feel what?

Pt. As if it's been killing me.

Th. What's been killing you?

Pt. It isn't real, like in the mirror.

Th. Now keep your eyes closed, and when I count from one to five, you will be asleep. *[Hypnosis is reintroduced here.]* One, go to sleep; two, sleepier and sleepier; three, go to sleep, deeply; four, deeply asleep; five, deeply asleep. *(pause)* How did you feel about your mother when you saw that thing? What did you think about your father when you saw a thing like that?

Pt. I don't know. [*It is possible that the patient has repressed some of her feelings in relation to this memory.]*

Th. Now listen carefully. I want you to sit there. I am going to count from one to five, and then clap

my hands together. When I do, you are going to have the same emotion that you had when you looked into that mirror, if you actually did look into that mirror. You won't be able to keep it back. Just let it come out spontaneously. As soon as I clap my hands together, tell me the emotions that you feel. One, two, three, four, five, as soon as I clap my hands together, tell me the emotion, *(clap)*

Pt. Anger. (Patient speaks in a drawl with her fists clenched.)

Th. You feel anger? Listen to me now. When I count from one to five and clap my hands together, you will see who it is that you are angry at. One, two, three, four, five, *(clap)*

Pt. (pause) Mother.

Th. Mother. You were angry at mother; at what you saw?

Pt. Yes, but I always try to see backward.

Th. Why?

Pt. I was angry at father, too. She didn't really want him.

Th. She didn't want him?

Pt. No.

Th. Why?

Pt. Mother didn't seem to want to bother with him, I guess.

Th. Did you love your father?

Pt. Yes.

Th. You did love him?

Pt. Uh huh, very much, but I stopped loving him.

Th. What made you stop loving him? How old were you when you stopped loving him?

Pt. I don't know. Maybe I didn't love father because of mother.

Th. Did you feel that you would eventually like to find a man like your father?

Pt. Oh, I did in my teen age, yes. Father is quick—he used to be very clever and funny. Once he got angry with mother, and he didn't speak to her for a long time. He was very jealous. He was very cross with me.

Th. He was very cross with you?

Pt. Yes, father was when I started going out with boys.

Th. He did not like to have you go out with boys?

Pt. He was always … *(pause)* jealous.

Th. He was jealous.

Pt. Yes, he was.

Th. What was his name?

Pt. Lewis *(laughs)*

Th. Why did you laugh when you said Lewis?

Pt. 'Cause your name is Lewis.

Th. 'Cause my name is Lewis?

Pt. Uh huh.

Th. Do I in some way resemble your father?

Pt. Not very much. I got awfully upset when I saw that mirror thing.

Th. What sort of person was your father?

Pt. He was very determined.

Th. Determined?

Pt. Uh huh. Maybe I liked him too much.

Th. Most little girls love their father. Little girls often get infuriated with their mother for having father, but they finally decide that they will find a man of their own, that they don't have to have father.

Pt. Mother was always like that, telling me that too.

Th. Did she want you to go out with men?

Pt. Yes, she did *(pause),* oh, yes; but I think she turned me against them.

Th. What did she do to turn you against them?

Pt. Oh, always blazed at me; she's always blazed at me. I think she really hated men.

Th. She really hated men?

Pt. Uh huh.

Th. How did you learn that?

Pt. I ... I ...I just felt it.

Th. Now I am going to wake you up. When you feel you understand the meaning of what we have been discussing, you will remember what is necessary. I will count from one to five. At the count of five, open your eyes and wake up. One, two, three, start waking up, four, five.

This excerpt has illustrated the use of hypnosis for the recovering of a traumatic memory or fantasy by hypnoanalytic techniques of regression and revivification, along with a counting procedure. These adjuncts are of aid in circumventing repression. Because repression is sponsored by anxiety that the patient is yet unable to control in the waking state, she is given a suggestion at the end of the session to remember the incident only when she has worked through its implications. In this particular case she was able to understand in a short while the significance of her mirror fixation and eye symptom and she was then able to integrate her reaction to the traumatic scene of childhood. She was also able with further therapy, to resolve her difficulty in her relationships with men.

In Chapter 19, "The Conduct of the Psychotherapeutic Interview," a number of techniques have been described by means of which insight may be propagated. Among these are (1) *accenting* certain verbalizations, (2) *summarizing* what the patient has said in order to coordinate and emphasize specific aspects, (3) *restating* the remarks of the patient to elucidate on situations that the patient has overlooked, (4) *reflecting* back to the patient the emotional forces behind his or her utterances, (5) *establishing connections* between symptoms, feelings, and inner conflicts, (6) *maintaining tension* in the interview to stimulate a thinking through of a problem, (7) *extending measured support* when tension threatens to shatter the cognitive functions, and (8) *making interpretations* by which the more unconscious elements of the psyche are brought to the patient's awareness.

Interpretation as a vehicle for insight is particularly valuable in reconstructive psychotherapy since there is, in this form of treatment, an emphasis on unconscious aspects of mental activity. In the present chapter we shall deal with the dynamics and methods of interpretation.

VARIETIES OF INTERPRETATION

Interpretation consists of seeing beyond the facade of manifest thinking, feeling, and behavior into less obvious meanings and motivations. Involved in interpretative activities are different degrees of directiveness. The lowest degree consists of waiting for the patient to interpret things, giving as few cues as possible. Next, the patient is enjoined to attempt the interpretation of representative experiences. Of greater degree is a piecing together of items of information, and of seemingly unrelated bits, so that certain conclusions become apparent to the patient. Leading questions are asked to guide the patient to meaningful answers. More directive is the making of interpretations in a

tentative way so that the patient feels privileged to accept or reject them as he or she chooses. Finally, the therapist may deliver very strong authoritative interpretations, couched in challenging, positive terms.

Helping the Patient to Make Interpretations

The insights that patients achieve through their own reasoning powers have certain advantages over those that are defined by the therapist. Accordingly, wherever possible, the therapist works toward stimulating the thinking through of problems by restating the material that a patient has verbalized, by summarizing, by emphasizing important connections, by focusing on pertinent data, by asking specific questions, and by arranging cues in such a way that inferences will be more easily forthcoming from the patient. Understandably, patients, bewildered by their neurosis, will want the therapist to provide answers to their questions. They resent the responsibilities that the therapist imposes on them. Particularly, they are dismayed at the therapist's refusal to make absolute pronouncements. They may, therefore, require a reason why the therapist does not act as a detective who uncovers dramatic facts, but rather assumes the role of an objective helper who merely aids the patient to arrive at his or her own discoveries. As a general rule, self-interpretations are possible only where the patient has become sophisticated in the understanding of dynamics and where significant material is not too deeply repressed. Interpretations, when they are presented by the therapist, are made to dispel resistances to self-understanding and to remove blocks to learning rather than to apprise the patient of the content of the repressed. However, once the patient has made what seems to be a valid interpretation, the therapist may elaborate on this.

In the following excerpt, a patient is helped to an awareness of the projection into his present relationships with women of attitudes that he had toward his mother.

> *Pt.* In the presence of women I find myself wanting to please them. I don't know why that is. It doesn't occur with all women. Where a woman has no physical attraction to me, it makes no difference; but even there, I try to please them to some extent. Physically attractive women I must please. Then I pick up weaknesses in them and then feel contemptuous of them. I look for perfectionism in women. But then I try to please them. I realize that there is something funny about trying to please someone you also have contempt for, but I want them to think

I'm a certain kind of person.

Th. A certain *kind* of person?

Pt. Yes, I want them to think of me as attractive. Maybe that's why I have to please them.

Th. How do you feel when women make all the effort in wooing and pleasing you?

Pt. Wonderful, I like that. I get very happy and relaxed.

Th. But when they aren't forward?

Pt. I've got to make the passes.

Th. To get from them something?

Pt. Yes, to get praise and love from them.

Th. But when you have to make the effort to get that, you start finding fault with them. I wonder why?

Pt. I want it to be spontaneous. My mother used to do things for me until my younger brother was born. Then I felt out of things. But I remember the tantrums I had. When I raised hell, I got attention. *[He seems to be aware of the fact that his tantrums were attention getting devices.]*

Th. You had to make an effort there to get praise and love from her. *[emphasizing the association]*

Pt. Yes, yes, yes, just like the feelings I get now when I have to force myself on someone to get praise from them. *[The patient makes a connection with the present.]*

Th. How did you feel when you did this with your mother?

Pt. Angry, disgusted, bitter toward her.

Th. And with these women you try to please? *[presenting cues to the patient so he can come to certain conclusions]*

Pt. Exactly the same.

Th. So the conclusion is what?

Pt. That I'm treating other women as if they are my mother or I want them to be my mother. But that's nuts. But it must be so that I act that way. *[This seems to be an important insight.]*

Making Tentative Interpretations

The presentation to the patient of the therapist's observations, hunches, and

conclusions, prefaced by such phrases as "Perhaps," "It may be," "Possibly," and "Do you think it's possible," is an excellent way of making interpretations. This allows the therapist to confront the patient with facts in a non-authoritarian manner, permitting the patient freedom to accept or to reject the interpretation on the basis of personal judgment and without the feeling of having offended or contradicted the therapist. This makes for a relationship of cooperation, in which the patient feels that he or she is an active participant and that his or her voice carries at least as much weight as that of the therapist.

A patient comes in to a session with a headache. Through tentative interpretations, she arrives at its source and dynamics.

> *Pt.* I really feel I'm an ungrateful person. In many ways people have done things for me, and I do little in return. At the office, for instance, my boss told me I could have an extra week off for vacation this year, with pay. It made me feel good, but I was left dissatisfied and I've had this headache since. *[The patient recognizes the irrationality of her having responded with a headache to a thoughtful gesture by her employer.]*

> *Th.* What about your feelings about your boss?

> *Pt.* He's a wonderful man, energetic, and he knows what he wants. He's really gotten places.

> *Th.* Mm hmm. How do you get along with him?

> *Pt.* Oh, fine. We get along well. Of course he irritates me sometimes. He acts as if he knows everything. But he's an all right guy.

> *Th.* But it's funny you had this headache after the boss gave you an extra week off. *[exploring the situation that led to her feeling of dissatisfaction]*

> *Pt.* Yes, I did.

> *Th.* Do you have any idea why?

> *Pt.* No.

> *Th.* What does his giving you a week off mean to you?

> *Pt.* Well, I appreciate it, but I shouldn't be like that. I always was independent and liked to be on my own. My father wanted me to go into medicine, but when he died, all those plans went out of the window. But I've tried to be on my own. *[This sounds as if the patient interprets her boss's gesture as threatening her independence. If she takes something from him, she may put herself in his power.]*

Th. Is it possible that you resented your boss's gesture because it put you more under his power, and threatened your independence? *[tentatively interpreting this hunch]*

Pt. (laughs) It's more than possible. I don't like to have people do things for me. It makes me feel helpless. I don't want to owe anybody anything. *[She responds favorably to the interpretation.]*

Th. So that you might possibly feel that this gesture by your boss took away from you an important thing—your independence, *[a further tentative interpretation]*

Pt. Well it does, doesn't it? *[This indicates that my hunch was correct, since she seems to equate the two.]*

Th. You think it does.

Pt. Don't you?

Th. There may be other ways of looking at this thing. Because you may need to maintain a sense of independence for special reasons, any relationship or situation that does anything for you may destroy this security mechanism and arouse resentment.

Pt. But isn't it silly for me to feel that, because I know Mr. Meyers *(her boss)* doesn't want to take me over. [*She recognizes the irrationality of her feelings.]*

Th. Is it possible that *you* might be afraid that you, deep down, want him to take you over, to become dependent on him? *[tentative interpretation of her resistance to possible dependence on anyone on the basis of a deep desire to be dependent]*

Pt. No, I don't. I mean I don't really want to be dependent, *(pauses and laughs)* or maybe I do. (*laughs*) You know my headache is lifting now and is practically gone. *[We seem to have hit an important conflict.]*

Th. Do you see the connection between your impulse toward independence, your possible striving for dependence, your reaction to your boss, and your headache?

Pt. Yes, I believe I do. *[The patient continues to explore the interrelationship.]*

Making Authoritative Interpretations

Sometimes the repressions of the patient are so intense that they impair the capacity for critical thinking. Here the patient may be unable to make connections or to arrive at insights through his or her own efforts, no matter how adroitly the clues are presented. Even tentative interpretations may have little impact on the patient. During reconstructive therapy, especially, it is sometimes desirable to employ a bold and even confrontational authoritative approach in offering interpretations. This is a deliberate step, calculated to

upset the balance between the repressed and the repressing forces. The released tensions and anxieties mobilize defensive reactions that can then be observed and explored. One of the defensive devices is a denial of the validity of the interpretation. Eventually, however, the patient may work through resistances to its acceptance. Acceptance of an interpretation does not always mean that it is valid. It may be that the patient is so intent on pleasing the therapist or fearful of contradicting the therapist that he or she will incorporate a false explanation. If the patient is suggestible, he or she will grapple also onto a spurious commentary with the eagerness of a religious convert.

Because of the anxiety that is apt to be stimulated, authoritative interpretations should be made only where there is sufficient frequency of visits to handle any disturbed reactions that may occur. As a rule, interpretations of this type are made only when there is some preconscious awareness of a pattern. The stronger the ego of the patient and the better the working relationship between patient and therapist, the more unconscious may the material be with which one deals.

A patient remarked during a session that a peculiar uneasiness came over her recently while in the presence of her husband. This feeling had started 2 weeks previously and had become increasingly intense since then. Through an authoritative interpretation she was helped to realize that the basis for her reaction was transference toward the therapist, which she had repressed.

> *Pt.* I have this dead feeling toward Tom. *(her husband)* I have a feeling he will hurt me and beat me. I remember his slapping me when he was drunk a time ago. I was badly frightened but furious. I feel I'm wasting my life with him. The whole relationship sounds impossible.
>
> *Th.* Do you have any positive feelings about Tom?
>
> *Pt.* Yes, I'm terribly attracted to him sexually. This type of man is charming but kicks your teeth in.
>
> *Th.* Under what conditions does he do this?
>
> *Pt.* Whenever I am in any way critical of him. I feel like half a person. I'm afraid to say anything critical. *[She will feel critical toward her husband and expect counterhostility.]*
>
> *Th.* Does this fear of being critical relate to other people? *[exploring for a neurotic pattern]*

Pt. Not everybody.

Th. How about me? *[This is a confrontational attempt to see if her critical feeling applies to me.]*

Pt. (*pause, patient's eyes tear*) This is silly. I'm afraid you'll think me silly, *(cries) [The fact that this emotional reaction is evoked shows that transference may be operating.]*

Th. You are afraid to be critical of me. *[authoritative interpretation of her reaction to the expression of criticism toward me]*

Pt. (*continues crying*) There have been several things you said that hurt my feelings, *(cries)*

Th. Like what?

Pt. A long time ago, *(cries)* when I first came here, I told you I felt I hadn't grown up. You said I'd have to grow up to be well. You said it as if you were blaming me. I can't help it if I'm this way. I wouldn't be here if I was well. *[The patient has taken something I said out of context, distorted it, and is using it to justify her feeling toward me.]*

Th. Did I give you the impression I was critical of you?

Pt. You sounded like you were. You gave yourself away. I've been afraid to say everything that came to my mind since then. Afraid to stir up your anger, *(cries) [This is good evidence that transference is operating.*]

Th. Perhaps I gave you that impression, but I'm not aware of wanting to criticize you in any way.

Pt. But you did.

Th. You *felt* I did.

Pt. Yes, and this is how everybody has been with me. *[Fear of criticism seems to be a basic pattern.]*

Th. All your life?

Pt. Yes, as far back as I can remember. I was never allowed to tell my parents what I felt, my disappointments. They hushed me up when I cried for anything. It happened with my teachers, and it happened with my husband. It's still going on.

Th. And it happened with me.

Pt. (*smiles*) I'm being awful, I know, feeling like this. I know you don't intend to be like that, but I can't get confidence to be myself. And if I can't, I'll never get well.

Th. It is important for you to be yourself and tell me everything you think. Actually, I don't feel critical toward you, but I may give you that impression. As a matter of fact, you are injecting feelings in your relations with me that are the same as those you had toward your parents. Suppose you think about that. [*authoritative interpretation*]

Pt. (smiles) I feel better talking about it. I expected you to reprimand me. I remember when I was 8 and played hooky with a girl. *[The patient goes on to relate an incident for which she was criticized.]*

CONTENT OF INTERPRETATIONS

Interpretation choices are usually in the following order:

1. Resistances of any nature, particularly to a working relationship with the therapist, to insight, and to the translation of insight into action

2. Defense mechanisms of various types—their nature, purpose, manifestations, and origin

3. Indications of transference, especially those aspects that serve as resistance

4. Personality traits and patterns—their form, expression, purpose, genetic origin, and contradictions

5. Conflicts, impulses, feelings, attitudes, and other repressed aspects of the psyche of which the patient is at least partially aware

6. Current sources of stress and their interaction with personality needs and defenses

7. Early experiences as revealed by the patient in relation to conflicts, defense mechanisms, transference, and personality patterns

INTERPRETIVE ACTIVITIES

The manner of presentation of interpretations is as important as the content. The following points may prove helpful:

1. The language in which interpretation is couched should be as simple as possible, employing terms familiar to the patient.

2. Most patients integrate short, pointed interpretations rather than an elaborate exegesis. Certain patients, however, seem to require long, intellectual explanations. Sometimes the use of metaphors, analogies, and illustrations from the problems of other people are helpful. Interpretations should, if possible, be related to a basic theme.

3. Too many interpretations or scattered interpretations should be avoided, for the patient can learn only a little at a time.

4. Tentative and even authoritative interpretations should be tactfully presented in such a way that the patient has a right to reject or accept them without feeling that the therapist is being offended. Under no circumstances should the therapist argue with the patient or act chagrined if the interpretations are not accepted.

5. Before making an interpretation, the therapist must be reasonably convinced of the verity of the assumptions. To advance an opinion in a hit or miss manner, hoping that it will touch something off in the patient, is worse than useless.

6. The timing of interpretation is important. The patient must be prepared sufficiently for an interpretation so that it does not take him or her too much by surprise. One index of preparation is preconscious awareness of a trend or pattern. The dynamics of the patient's problem may soon become known to the therapist. It may require an enormous amount of restraint to withhold interpretations until the patient displays a modicum of awareness thus indicating a degree of ego strength favorable to understanding. Interpretations prematurely presented to the patient will create resistance since they act as a warning to the ego that its defenses have been penetrated and that a further attack is impending. A barrier of resistance may unnecessarily be created.

7. Attitudes and beliefs of the patient should never be ridiculed, nor should interpretations be made in such a manner that the patient assumes them to be accusations. Where attitudes and patterns are to be undermined because they wield a pernicious influence on the patient, the patient may be shown that he or she has been forced to employ these devices as defenses. For instance, a woman complains that she is never able to keep the interest of men because she is much too eager to make an impression on them. She relates an incident in which she forcefully attempts to establish a relationship with a new male acquaintance. An incorrect interpretation would be, "See what you are doing; you are throwing yourself at the man." This interpretation involves an accusation and a moral judgment. A better interpretation would be, "Perhaps you are acting too anxious here about setting up a relationship." This poses a problem that the patient must ponder.

8. Interpretation is most effective where there is good rapport between patient and therapist. Where a patient feels negatively toward the therapist, the patient will usually be unable to accept interpretations.

9. Some therapists believe that a "terminal interpretation" is useful at the end of each session, summarizing the important material of the session. Other therapists find no need to employ this procedure.

In reconstructive therapy, where interpretation of very deep unconscious needs and defenses is deemed necessary, special handling will be required. Neurotic defenses are elaborated in early life by a weak ego threatened with overwhelming anxiety. The mature accretions that later invest the ego may not destroy the core of helplessness laid down in childhood. The patient, afraid of being overwhelmed by feelings of catastrophic helplessness that once threatened to destroy, will, when an anxiety experience is imminent, attempt to overcome the threat by employing the same original protective defenses. Logic plays no part in this process.

The rational approach in dealing with an ego that has swathed itself in impenetrable defenses is through an analysis of resistance. Interpretation of the resistance accomplishes the purpose of confronting the patient with what is being defended against. This leads to an uncovering of unconscious impulses, fears, and conflicts, and it opens the way of access to deeper and deeper material. The dangerous nature of the material again stimulates anxiety and mobilizes further resistances, usually of an unconscious nature. It is essential to demonstrate to the individual the manifold disguises that resistances may assume, for unconscious resistances can crumble only when their conscious derivatives are repeatedly presented to the patient. The interpretation of layers of resistance progressively exposes the deepest drives and impulses and ultimately leads to the original nucleus. Only through such work is the patient able to appreciate the purpose of resistance, its historical origin, his or her active participation in maintaining it, and, finally, the unconscious impulses the resistance is opposing. This permits the patient to tolerate more and more undisguised derivatives of impulses and eventuates in a gradual recovery of repressed elements of the self.

How aggressive the attack on the resistances should be depends upon the quantity of anxiety that is present and upon the ability of the ego to withstand the attack. Interpretation of resistances will often produce tension, anxiety, and hostility. If the patient is already suffering from as much anxiety as can be handled, the additional emotional burden may be too difficult to bear, and the patient may react with an increase of resistance. In such cases it is essential to proceed more cautiously. On the other hand, if the patient manages to repress anxiety through the operation of continuing avoidance, a more aggressive attack on the resistance will be necessary. This may be undertaken as early as possible in order to mobilize anxiety for the purpose of increasing self-observation.

The technique by which interpretations are presented is also of vital importance in determining the acceptance of components that the ego is warding off. The patient may present evidences of hostility, erotic strivings, castration fears, and penis envy. To interpret these as such to the patient may accomplish little or nothing. As a general rule an interpretation is futile if the patient does not have an idea of what is going on. Interpretation will produce no real change until the unconscious is represented by preconscious material familiar to the patient. Consequently, when an unconscious derivative makes its appearance in the field of awareness, the patient's attention may be directed to considering what may be behind the derivative. For instance, one patient, while discussing his relationship to me in glowing terms, became aware, through my calling his attention to it, of the clenching of his fists and the tension of his muscles. At first he denied these facts, but as I repeatedly called his attention to his mannerisms and as I presented him with the possibility that there might be a reason why he became tense and clenched his fists, he thereupon became aware of hostile feelings.

It is essential to demonstrate the connection between symptoms, feelings, and attitudes in order to show patients how a purposeful trend runs through their lives. In this way they may learn that their behavior is not a series of random events, but that it has continuity and meaning. They also must realize that their symptoms are not fortuitous, that they themselves are bringing about what they believe they are experiencing

passively. They must become aware of the purpose of evasions, of how they fallaciously draw the past into the present, of what compromises they make with life, and of the consequences of these compromises on their functioning. It is also often essential to trace symptoms back to their historical origins. Here the manner in which interpretations are made is also of the greatest importance. It matters little how accurate interpretations may be if patients are unable to understand their meaning, and it is important to integrate the meaning within themselves in the form of insight.

In tracing genetic origins of drives, defenses, and conflicts there is often a tendency to interpret present behavior as if it were a mere stereotyped repetition of earlier patterns in the relationship with the parents. As a practical matter, this type of explanation usually has little effect on the patient. It is true that everyone carries over in one's character structure attitudes and patterns molded out of specific conditionings in early interpersonal relationships. It is true also that one reacts to people as if they were virtually reincarnations of one's parents, with attitudes, fears, and demands such as are expressed in early relationships. Such a repetitive process, however, does not occur automatically. It is dynamically motivated by needs in the individual that are so intense that no amount of logic can swerve one from one's purpose. To say to patients that they have hostilities or erotic wishes directed toward the therapist because the latter is a symbol of their mothers toward whom they once had an erotic urge that was repressed is not really a helpful interpretation. What is essential is that the patient understands what motivations underlie the present emergence of hostile or erotic feelings toward the therapist. Ultimately, of course, we are concerned with why and under what circumstances the patient developed certain attitudes toward parents that have functioned as nuclei of later interpersonal strivings. Explaining to the patient that unresolved strivings in relation to parents must be present, because the therapist is a parental surrogate toward whom there are irrational feelings, arouses merely an intellectual acknowledgment without any deeper understanding.

Once we concede that all behavior serves a dynamic purpose, we must attempt to define the purpose behind the patient's present behavior. For instance, we must discern

the reasons why the patient feels erotic in the therapeutic situation. In analyzing the motives behind the erotism, we may find that the patient is becoming more and more anxious about the therapist and that the erotic feelings constitute a wish to absorb the latter within oneself in order to gain exclusive love and support. Or the patient may have become more and more fearful of the therapist and may wish to disarm the therapist by expressing extreme devotion and sexual love.

If patients act in a hostile manner toward the therapist, it is rot sufficient to show them that they are using the therapist as a father substitute, creating a new childhood situation in the present. It would be more meaningful to discover the immediate circumstances associated with the hostility. Thus, a patient may feel frustrated by the therapist, for no apparent reason. Upon investigation the therapist may discover that the reason behind the frustrated feeling is a secret desire to engage in an extramarital affair, along with a fear that the therapist will frown on such a venture.

To interpret the patient's strivings as related to something that is happening in the present helps to provide the patient a picture of interpersonal attitudes in operation. It permits the patient to see how drives relate to feelings that actually have no source in present-day reality. The patient comes to realize that feelings do not arise out of nowhere and that one is not working with intangibles. Eventually, the patient may be able to appreciate how similar impulses operated also in relationships with important persons in the past and that there, too, they served a vital purpose, of a sort similar to the purpose they serve now. Considerable activity on the part of the therapist may be necessary since the patient usually has a tremendous amount of resistance to divulging the motives behind feelings. The patient's drives, neurotic as they are, constitute a way of life that is not easily relinquished.

One of the tasks of reconstructive psychotherapy can be the recovery of important unconscious memories and experiences (see Chapter 44). The mere revival of forgotten traumatic events will not in itself correct the damage that has been done to the ego. While it is true that the ego has been rendered weak by inimical childhood happenings, other

defensive attitudes have also been elaborated on the basis of experiences relating to persons and circumstances in the patient's later life. Interpersonal reactions are composed of a chain of patterns that show a continuity, each link predisposing the individual to later reactions. If the patient is to understand how early inimical experiences relate themselves to present behavior, it is necessary to analyze and to interpret the intermediate links. This does not mean a discarding of important deep material that is brought up during therapy. It means that the patient must be given the task of working back from immediate character patterns and interpersonal attitudes to disclose the connection with the deeper experiences and impulses.

The proper interpretation of the transference makes it possible to establish the connections with these deeper impulses. It must be emphasized again that in interpreting the transference, it is not enough to tell the patient that he or she is acting out an irrational striving that has its origin in what happened in early relationships with the father, mother, or siblings. Such an explanation is interesting and possibly true, but, practically judged, it is without therapeutic value. What is important is to demonstrate to the patient the reason why such infantile reactions persist and what purpose they serve in the present.

In a certain number of patients the therapist will be overwhelmed with unconscious material while no effort is made by the patient to relate this material to the present malfunctioning. In such persons there is probably a dissociation of the past from the present. There may be a minimization of current feelings in the desire to conserve the secondary gain derived from the neurosis. The outpouring of unconscious material here is somewhat in the nature of a confessional. The patient may seek to relieve the sense of guilt and to avoid responsibility for the symptoms through the absolution obtained in divulging the past. It is always essential to get the patient to realize that current problems cannot be solved merely by revealing unconscious material. The material must be related to what is happening in the present. Hidden wishes, conflicts, fears, and early traumatic experiences certainly condition habitual behavior patterns, but it is essential to work out with the patient an understanding of how they manifest themselves in every act and thought in daily life.

The exploratory process is likely to bring out an enormous amount of sexual material, and one may get the impression that the only existing difficulties are of a sexual nature. The therapist will certainly be led into a blind alley if unconscious symbolisms are taken at their face value. Presentation of raw oral, anal, and phallic material may be very confusing to the patient, not only because of a need to repress the implications of this material, but also because the language of the unconscious is inscrutable to the conscious mind. Emerging from unconscious strata, it is like foreign speech. The material is, possibly valid, but it must always be translated into constructions that are meaningful to the patient in terms of one's relationship to others.

It is not enough to demonstrate to a female patient beyond any vestige of doubt that unconsciously she desires to possess a penis. It is essential to correlate this wish with her envy of men and with her rivalry and destructiveness in relation to them. It is particularly important to understand what the desire for a penis signifies in terms of the current needs of the patient. It may, for example, be a means of refuting a fantasy of being irreparably injured, or it may constitute a striving for superiority that is rooted in a sense of helplessness.

Desire for, or fear of, castration must also be explored from the standpoint of what purpose these strivings serve in the psychic economy. It is not sufficient to assume that preoccupation with castration is the mere continuance of an infantile fear or wish that has never been completely resolved. The persistence of such an impulse indicates that it serves some purpose in the present. For example, a castration fear may originate in a current feeling of loss of self, a solution for which is sought in strivings for passivity and dependency, which are equated with femininity and castration. Again it must be emphasized that all conscious and unconscious behavior is dynamically motivated and has a definite meaning and function.

RESPONSES TO INTERPRETATION

Inexperienced therapists, impressed by readings in dynamic psychology, often operate under the illusion that they need merely to bring the patient to an awareness of

the problems for these to come to some kind of dramatic halt. In practice this does not happen. Indeed, the effect may be, not an amelioration of distress, but its exaggeration.

The individual's reaction patterns have already been set up in an almost reflex way. Many values accrue to a habitual manner of life, no matter how disturbed this may be. Knowing that the individual reacts with certain patterns and appreciating why they exist does not eliminate the need for such patterns. A confronting of the patient with interpretations may do nothing more than to create a sense of hopelessness because the patient feels powerless to inhibit customary responses.

The patient's reactions to interpretations will depend on a number of factors, including intelligence and the capacity to understand the interpretive meanings. They are conditioned by how basic the patient's neurotic patterns are to security and self-esteem. The manner in which interpretations are presented and the quality of the existing relationship with the therapist are other important items. Any interpretation may seriously unbalance the equilibrium between the patient's defenses and the repressed conflicts. The responses to interpretation may, therefore, reflect an upset in homeostasis and contain customary defensive efforts to restore homeostasis as well as experimentation with new and better defensive devices.

Acceptance of Interpretations

Possible signs of acceptance of an interpretation are expressions of surprise, enthusiasm, relief, excitement, increased flow of associations, and confirmation of the validity of the interpretation. The accuracy of an interpretation is often registered by acknowledgment that it "rings a bell" or "clicks." An immediate acceptance does not necessarily mean that the patient will continue to subscribe to the accuracy of the interpretation or to put it into operation. Indeed, untoward later responses may be the consequence of interpretation due to resistances that are set into motion by the challenging of primary and secondary neurotic gains and the mobilization of anxiety. This is why such phenomena as apathy, depression, or defiance may follow a successful session during which the patient accepts and responds well to interpretations. On the other hand,

the acceptance of interpretations may sponsor a start toward working through of the particular pattern under exploration, in the course of which new trends are uncovered, requiring further interpretation and working through.

The ability of a patient to accept an unpalatable interpretation will be proportionate to positive response to the therapist. If the patient trusts the latter, or is convinced of the therapist's good will, or realizes that one has the right to reject the interpretive offerings, the patient usually will be able to tolerate the interpretation more readily and without undue transference reactions. Resistance to interpretation is most common in the absence of a good working relationship. It is often caused by a fear of succumbing to the therapist, of being overwhelmed and dominated, and of losing one's independence.

Stimulation of Tension and Anxiety

Since interpretation upsets the balance between the repressed and the repressing forces, it is bound to mobilize anxiety that may express itself in nascent form or may release depression, hostility, aggression, or psychosomatic symptoms. This effect may be desirable where there is little activity in the therapeutic process. Here, interpretation may provoke anxiety, which, in turn, will stimulate movement. The arousal of anxiety, however, may not be intended, or, if calculated, the quantity of anxiety may be so great that it threatens the working relationship. Here, the therapist will have to stop the investigative process temporarily and attempt to stabilize the patient, perhaps using supportive measures if the integrative capacities of the patient show signs of shattering. Such undue anxiety may be the product of the improper timing of interpretations, of the inaccuracy of the interpretive effort, or of the presentation of the interpretation in an accusatory, belittling, or derisive manner.

Rejection of the Validity of the Interpretation

The immediate rejection of an interpretation may mean that the patient's capacities for insight are not yet sufficiently developed, that resistance is being mobilized to protect the status quo, or that the interpretation is incorrect. Forms of rejection are many, such as

outright denial, shifts in the content of verbalizations, inability to think, evasions, anger, or detachment. More deceptive is a surface intellectual acknowledgement of the possible accuracy of the interpretation with no real emotional conviction. The rejection of an interpretation does not preclude its therapeutic effect. There may be an uncalculated absorption of the interpretation and an activation of conflicts with a marshalling of defensive forces. A delayed reaction occurs here, the working-through process operating on an unconscious level, resistance being resolved slowly with an eventual restructuring of patterns.

Handling Untoward Effects of Interpretation

If the patient responds to interpretation with anxiety, rage, or other disturbing reactions, the therapist may have to reassure the patient to offset a deterioration of the working relationship. The following excerpts from treatment sessions are suggestive of how this may be done.

Interpretation to a patient of a pattern of destructive aggression toward persons with whom the patient became friendly brought this response and reply:

> *Pt.* I feel ashamed and hopeless when I realize what I've been doing to people. I can hardly face myself, but I can't stop myself. *(cries) [The patient may be utilizing a masochistic defense here to support survival of his pattern.]*
>
> *Th.* The fact that you see the problem doesn't make you bad or any worse than you were before. But in seeing your problem more clearly, your guilt is being aroused and you may want to torment yourself. Actually you *can* do something about your problem if you do have a desire to get well. But it will take a little time, and you must try not to be impatient.

This reassurance brought out more constructive responses from the patient and helped the working-through process of his aggressive pattern.

Another patient presented the following dream:

> My wife left me, I cried uncontrollably, and my mother came in to console me and pet me. I wanted consolation and somebody's sympathy. Then my mother's face changed to that of my wife, but her face had a Roman nose. She wanted sex. She wanted to go down on me. I said no, but she insisted and I succumbed. The room was filled with people, and as I looked at her she seemed taller. She said, "Don't forget to get in touch with me. My name is Janet

James, and I am at the Edison Hotel." Then I overheard a conversation about my wife, Flossie. I heard she was pregnant. I was astonished. I felt it was impossible unless she was unfaithful.

In his associations the patient interpreted the dream as a need for a mother figure in his wife. He expressed disappointment with the mothering his wife had given him. When asked to associate to "Janet James," he remarked that James was the name of a boyhood friend with whom there had been mutual masturbation. This friend, who had a Roman nose, had written to the patient last week saying that he planned to visit New York in the fall and requested that the patient make arrangements to meet him. At this point I made a tentative interpretation that disappointment with his wife might cause the patient to think about the sexual earlier childhood relationship with a boy friend. In response to this interpretation the patient blanched and complained of panicky feelings. An excerpt of the interview follows:

> *Pt.* Does this mean I want to be homosexual? My God, if that's true! (*Patient is obviously upset.*)

> *Th.* Of course not. You know the mind thinks in symbols. When a person is disappointed in his wife, the mind may say, "Oh, the hell with women; maybe a man would be better." (*I laugh, and the patient rapidly overcomes his panic and laughs with me.) [Months later the patient began working on his homosexual impulses.]*

ILLUSTRATIVE CASES

Example 1

The following session illustrates the technique of helping a patient make her own interpretations. The patient, a young newspaper woman concerned with a sexual problem, with symptoms of frigidity and vaginospasm whenever she attempted sexual relations with men, translates the meaning of her symptoms from her dream symbols.

> *Pt.* I had a complicated dream last week. The first part concerned a ship in drydock. It was surrounded on either side by land but was pointed toward the sea. it was being repaired to go out to sea.

> *Th.* Mm hmm.

> *Pt.* And the rear end of the ship was like one of the landing ships that were used for tanks or something like that. It had sort of a drawbridge drawn down to the drydock.

Th. Mm hmm.

Pt. And it opened from the bottom of the ship, not from the deck. It opened actually into a dry river bed. it had a lot of pebbles and stones, and there's no vegetation around any place. *(pause)*

Th. Rather stark and drab.

Pt. Yeah, and the problem was to get this ship repaired before this enemy army arrived and …

Th. There was a war going on?

Pt. There was a war of some kind going on. And, they were approaching from the other side of the river. When it became apparent that we wouldn't have time to finish getting the ship ready to go to sea, we decided something had better be done for defense against the enemy. *(pause)*

Th. Mm hmm.

Pt. And I was more or less in charge of the project and decided that the thing to do was to build up the hill on the other side of the dry river.

Th. As a defense?

Pt. As a defense and disguise so that the enemy might be confused. And I was in the process of doing it when a man came along, an unidentified person, and said, "Well, I think I can do a better job. I have some bulldozers that can build the thing up." So I said, "Fine," and I didn't actually see the bulldozers in operation, but the hill began to build up. and it had a, a series of sort of turrets on it, made out of earth, probably phallic symbols.

Th. Phallic symbols?

Pt. Yeah.

Th. Why do you say that?

Pt. Well, because of the way they just sort of rose out of the ground.

Th. I see. You mean their shape?

Pt. Yeah. And when he got that built up, I saw it was a magnificent job. And then I realized that there was danger of a flood and asked him what should be done in those circumstances about the ship. And he said, "Well, we could close all the doors and windows on the ship and tie it down to the drydock and just let the water flow over it."

Th. You mean a flood was about to happen?

Pt. It was about to happen.

Th. In addition to the invasion.

Pt. Yeah, and I asked him about water on the deck, and he said, "Well, that happens all the time, and there wouldn't be any damage there. So we'd be quite secure staying on the inside of the ship." The character of the flood was sort of a flash flood that would be over in a very short time. We knew that the waters were backed up.

Th. Mm hmm.

Pt. And we didn't know whether, whether the flood would hit, but we had to be prepared in case it did. Then we went back to the ship, and I couldn't get the door at the rear end to work properly. It wasn't opened quite far enough. Either someone had, had knocked a lever and it had closed a little bit, or a spring had slipped. But it wasn't wide opened, and there were several levers, and I was confused as to which one to use. I asked the man which one to use, and he told me, and I tried it, and the door began to close more, and I said, "Here, I want it opened." And he said that you have to push another lever as well.

Th. Mm hmm.

Pt. So I did and the door came on opened. And in that circumstance I felt a little helpless, as if I didn't quite know what it was that I needed to do.

Th. And this man came along to help you. *[The thought occurs to me that the man may represent the therapist.*]

Pt. Yeah. And it was the same one who helped build the hill.

Th. Oh, yes.

Pt. Then the next dream had to do with a big courtyard, cobblestone courtyard with stone buildings around it. European style, completely deserted. And, again, an army was going to make an invasion. And this dream also was very stark. It was like a drawing rather than like an actual scene. And a woman came into the courtyard, and she was sort of an animated cartoon and not a real person. And it could be seen that she'd been drawn with charcoal, actually. She came into the courtyard, obviously fleeing the armies. I knew that she was hunting a place to hide, and I knew that there was no place really to hide. Well, she went into the ladies room. The door for it was on a flat stone wall and shaped like a Gothic window with the point at the top, very narrow, so narrow that you had to turn sideways to get into it. And I knew that she was going to be found anyhow and that when she was found, that all kinds of horrible things would happen. Because it was the Communist army that was coming in, and she was known as a very active anti-Communist.

Th. Mm hmm.

Pt. And it was more as if I were watching a movie that was going on. *(pause)*

Th. Mm hmm. Any other elements to the dreams?

Pt. I think that's all.

Th. Well, now, what associations do you have to those dreams?

Pt. Well, the first one in the ship, my parents are at sea on a, on a ship now. i don't know whether it has anything to do with them or not. But certainly the ship lying in a drydock, again it's sort of like a vaginal canal, *(pause)* And it needed repair and wasn't ready to go to sea. perhaps going to sea, is sallying forth in a, a sexual light.

Th. Mm hmm.

Pt. And, who the enemy was I don't know. But it was very stark and very cold and, no vegetation of any kind, no real warmth.

Th. It sounds very bleak.

Pt. And, the bleak feelings, I think, are the same bleak feelings that I have about my sexual life.

Th. Uh, huh.

Pt. And about relationships with men. *(pause)*

Th. All right, now, what about the bleak feelings that you have about your sexual life and relationships with men? And what is there that may have inspired the bleak feelings? Do you have any idea?

Pt. It might have been our discussion the other day about Howard. *[Howard is a married man with whom the patient started having a sexual affair.]*

Th. Mm hmm.

Pt. I have feelings of not quite knowing where I stand in the relationship.

Th. Not knowing where you stand in the relationship with him.

Pt. No.

Th. How could that have stirred up the feeling that you were about to be attacked?

Pt. Gee, I don't know.

Th. What else did we talk about the other day?

Pt. We talked about the, the seduction scene in the "Ways of Love,' which I feel is, is a matter of an attack. In fact, it probably means that to me very much. I know whenever a pass is made at me, I feel as if it's, it's kind of an assault.

Th. Mm hmm.

Pt. And, less a compliment than the reverse. And I feel that there's an aggression against me rather than, than for me.

Th. Mm hmm.

Pt. And that it's something I have to fight.

Th. You're conscious of a feeling of danger when anybody makes a pass at you?

Pt. Yeah, very much.

Th. Well, now specifically in terms of what we have been talking about in the past couple of weeks, what danger might there be related to facing something you perhaps want to face?

Pt. Yeah. (*laughs*) The going out and making an acquaintance with a man that would come to a satisfactory relationship. *[There was evidence that the patient conceived of a relationship with a married man as safe. Unmarried men frightened her since she feared being trapped by them in marriage.]*

Th. Do you think that that could have stirred up the dream?

Pt. I think it very probably could. I know it could.

Th. So that in the face of our talking about the necessity of not marking time with a safe situation, Howard, and experimenting with unmarried men, there may have been anxiety.

Pt. Yeah.

Th. Now, what could those anxieties be in terms of the dream?

Pt. Well, I felt that the ship which is, I think, obviously *me* had to be repaired.

Th. The ship had to be repaired. It wasn't yet completely repaired

Pt. Yeah.

Th. And?

Pt. And the door at the rear end of the, of the ship, I think is certainly a symbol of the genital area.

Th. Mm hmm.

Pt. And that was where the entrance and exit from the ship were made. It's obvious that it's in a sexual sense the repairs have to be made and a feeling that the enemy is going to arrive before the repairs are made.

Th. Mm hmm.

Pt. Before the ship is really secure, and ready to sail, on the sea itself.

Th. The enemy being symbolized by the war?

Pt. Yeah.

Th. And the actual invading enemy was what?

Pt. The flood.

Th. The flood, and in previous dreams water had meant what?

Pt. It's a sexual symbol.

Th. The flood is a sexual symbol. Now here you were then in charge of yourself and your own sexual functions, and the feeling was that repairs had not been completely made and, as such, you would be vulnerable to attack?

Pt. Yeah.

Th. Or to drowning. And you go off on to the shore and procure the help of a man. Now what does that bring to your mind?

Pt. Well, he came up to me and volunteered to help. And my feeling about it was one of, uh, I was very happy that he had because I felt that I needed help. I welcomed it. And then when he built up the defenses against the flood and against the enemy, I felt that he'd done a very adequate job.

Th. Mm hmm.

Pt. And it had given me time, and it had helped to know what to do. You see, the flood came along, but still I felt secure.

Th. But what kind of defenses were they that he had built up?

Pt. The phallic.

Th. Phallic? Now what would that mean in terms of you • own defenses?

Pt. Homosexuality.

Th. Homosexuality and also masculinity? *[The patient had assumed masculine attitudes, dress, and mannerisms.]*

Pt. Yeah.

Th. So that in the masculine facade that you might have displayed, there was a defensive attitude, wasn't there?

Pt. Yes.

Th. Which might explain perhaps the wearing of the masculine-cut clothes, the assumption of a kind of masculine role in life.

Pt. Yeah.

Th. As a defense against what?

Pt. Against a pass. (*laughter*)

Th. Against a sexual approach by men, against war, against invasion. It seems that your mind conceived of masculinity as something behind which you could hide.

Pt. Yeah.

Th. All right. Now in the dream the man assures you that you could seal up.

Pt. Mm hmm

Th. What does that remind you of?

Pt. Mm, of the conversion hysteria, the tightening of the vaginal canal, the spasm, and pain.

Th. The lightening of the vaginal canal. The vaginal spasm. The sealing up, and also other elements of detachment from men.

Pt. Yeah, keeping a distance from men.

Th. That is, keeping a distance, keeping a cloak around yourself, making yourself invincible, a fortified city that no man can approach. Not making dates with men, keeping away from men, all that as a defense against invasion. All right, now let us examine the next part of the dream, that is, the second dream. This involves also a war, and you're in an open court and there are many buildings around. There is this woman who's playing some kind of a role; she's drawn into this thing.

Pt. Mm hmm.

Th. What is going to happen to her?

Pt. She's about to be captured.

Th. Captured, and what are the horrible things that might happen to her if she is captured?

Pt. Probably death.

Th. Death?

Pt. But torture before.

Th. Torture and death. Now, in terms of the previous dream, what is the torture and death equated with?

Pt. With sex.

Th. With sex.

Pt. Yeah.

Th. If there is an emotional attitude toward sexuality that equates it with torture and death, understandably it would have very little pleasure value for you.

Pt. Yeah, that's right, and that's how it's been.

Th. And if your feeling toward sex was that emotionally it was like torture and death, well, nobody could blame you for wanting to run away from it. All right, now, what did this woman in the dream do to escape?

Pt. She went into the ladies room.

Th. The ladies room. She goes into the ladies room thinking this would be her sanctuary?

Pt. That maybe it would be, but knowing that she probably would be caught anyway.

Th. That was escape into femininity? It was like a church, a Gothic structure?

Pt. The door was, but yet I think the door was nearer a phallic symbol than a church.

Th. Like a phallic symbol?

Pt. Yeah, uh huh. it was, it was narrow, she had to go into it sideways, and it was twice as high as she was tall.

Th. I see. What type of symbol would that be?

Pt. I think a male phallic symbol.

Th. Male phallic symbol? So that no matter what escape she tried, the outcome was inevitable, wasn't it?

Pt. Yes. Well, in this dream, I was. I was sort of a spectator and didn't really take part in it. I just watched these things going on. I'd had some fear for my own safety. But I seemed to be separated from the dream. I wasn't really taking part in it. *[Detachment is one of the patient's characterologic defenses.]*

Th. Yes.

Pt. And my concern was for this woman who had really stood up and asserted the things she believed in.

Th. Mm hmm.

Pt. And I felt that she was unjustly going to be caught and tortured.

Th. Yes. Well, now in terms of your own feelings, how did you feel in the dream? Was there anxiety?

Pt. Um, not so much anxiety as a sort of detached feeling, a feeling that the whole thing was going on sort of coldly and relentlessly.

Th. And you had no way of controlling it?

Pt. In the, in the first dream I felt that there were some means of control, and in the second one I really didn't have anything to do with the dream, with what went on in it.

Th. Do you think I'm pushing you too hard in therapy? [*I ask this question to see if the patient feels threatened by what is happening in treatment and to probe for transference.*]

Pt. Uh, I don't feel I'm being pushed too hard.

Th. Because in the dream the inevitability that you feel about what is going to happen and the fact that you're helpless in the situation would seem to indicate that maybe if you did get yourself involved with an unmarried man, it would be to please me. That old pattern of compliance?

Pt. Mm hmm.

Th. The old pattern of not being able to resist. I'm just throwing this out to you because it may complicate your feelings for me if you feel yourself pushed into a relationship without your wanting it.

Pt. No, I don't feel pushed. I think I see the inevitability of it from my own standpoint.

Th. How?

Pt. Well, it comes down to a choice between I guess the boat being overcome by the flood and closing itself off and going forth and maybe facing it. A choice between having no relationship with a man and having one.

Th. Mm hmm.

Pt. Dissociating myself from what's going on or getting into the swing of it.

Th. In other words, either detaching yourself the way you have previously or facing the dangers you've invested in sex.

Pt. Yeah.

Th. And in running away from men you would be letting all your sexual emotions drain off in a relationship with a woman.

Pt. Yeah.

Th. Well, how do you feel about that? I mean, which of these choices do you feel you want?

Pt. Well, I want to make the heterosexual choice.

Th. You do?

Pt. Yeah.

Th. But it may be awfully hard, *[anticipating resistance]*

Pt. Yeah, and I, I, I feel that it will be. I feel that I'm going into, I think like that second dream, that I'm going into a world that I don't really have any feelings in.

Th. Mm hmm.

Pt. Um, except maybe feelings of torture and fear of death. Um. *(pause)* I feel reluctant to do it. *[The patient has good insight into her resistance.]*

Th. Mm hmm.

Pt. But I feel that, that it has to be done.

Th. Why do you feel it has to be done? [In treatment of patients with a homosexual life style any desired change should always be the complete choice of the patient.]

Pt. Well, I don't think I can mature as a person unless I do it.

Th. Yes. And you really feel that you want to make a try at it?

Pt. Yeah.

Th. It may be hard. You may feel as if you're being invaded and may want to run away. The emotions certainly are powerful, as the dreams would seem to indicate. They might impel you to just break off the relationship, break off therapy, return to the old status quo of homosexuality, and all that sort of thing. *[Mention of possible setbacks helps forestall disappointment if setbacks occur.]*

Pt. No, I don't think so. *(laughs)*

Th. Well, what do you think?

Pt. I don't know. I know that I'll, I'll resist making the relationships.

Th. Mm hmm.

Pt. And I anticipate going through anxiety states.

Th. Mm hmm.

Pt. As I try to make the relationships.

Th. Mm hmm.

Pt. I think that I've got enough of a one track mind that I'll stick to it, *(laughs)* until I get it done, by golly. And, I, I feel like I've started something, and I feel the need to finish it.

Th. Wanting to get it done is nine-tenths of the battle. The fears and the panicky feelings which are so vivid inside, and which you've undoubtedly experienced or have prevented yourself from experiencing by detaching yourself, the hysterical defenses of spasm and frigidity, and all that sort of thing, you feel you can begin to handle?

Pt. Yeah.

Th. Now, the intensity of your feeling will probably still be there. You can anticipate that you're going to get scared because, after all, this is an emotional thing. You may not even know where the feelings come from. All you'll feel is a vague kind of panicky feeling or a cold feeling that there's nothing in sexuality. Or another feeling may be that in some inscrutable way you may be damaged or hurt in a sexual role.

Pt. Yeah.

Th. This isn't absolutely definite. You may now have the strength and the motivation to experiment with men and see just what actually does happen, always anticipating the old defenses, which are what? What are your old defenses against heterosexuality?

Pt. Well, homosexuality mainly.

Th. Homosexuality. That's one defense, certainly, because it keeps your sexual energies drained off and it keeps you in a dependent relationship, as we've seen.

Pt. Yes, and the other defenses are there too, the sealing off, vaginal spasm, the running away, and acting masculine.

Th. And the whole assumption of a masculine role. Now all these things you may find operating insidiously as you begin to function in a heterosexual role.

Pt. Mm hmm.

Th. And it may be awfully hard. The temptation to go back to homosexuality may be terribly great because the starker the fields on this side, the more green the fields seem across the river.

Pt. (laughs) Well, I've had sort of flash backs insofar as dreams are concerned, and once in a while in terms of conscious feelings, toward homosexuality. I've always known that, that it was in relationship with Howard, if I felt helpless, or felt that I was being aggressed against, then immediately the homosexual thing would happen. It would just sort of be like pushing a button, *(laughs)* Not only that, but almost as if, whenever there was any kind of heterosexual involvement of any kind, that it was just like pushing a little button and a picture would come on the screen.

Th. And the fields may possibly begin to grow and get greener and even abundant with vegetation, as experimentation proceeds. With Howard, which was really a break in this homosexual pattern, you experienced, at first, pain, and then no pain, but no feeling.

Pt. With Howard I was able to make that break because I felt safe in that relationship. I felt very safe in it.

Th. In what way?

Pt. Well, a lot because of his attitude. I didn't feel that he was overly aggressive. I didn't feel that he was possessive.

Th. Mm hmm.

Pt. And I didn't feel that he'd force himself on me when I didn't want him to.

Th. Mm hmm.

Pt. And often when he would come to see me, he would ask me, "Are you busy?" or "Do you expect someone else?" or "Is there something else that you had planned that I'd be interfering with?" And I always knew that if I said, "Yes, I am busy," or "Yes, I am expecting someone," he'd go away.

Th. I see. So he was not a formidable enemy.

Pt. No. (*laughs*) I felt that he was rather cooperative.

Th. Mm hmm. And that gave you an opportunity to begin to handle some of your anxieties about men. But you may have doubts about other men. You have doubts that they can be as gentle, or could be handled as easily, or that you'd have as many escape routes as with Howard.

Pt. Yeah, well, the escape routes were always there with Howard, and I was always conscious that they were there.

Th. Mm hmm.

Pt. In fact I pretty well had to be conscious that they were there in order to be able to make a relationship with him.

Th. Yes, after all, he was tied down to a wife, if you ever wanted an escape route.

Pt. (*laughs*) Yes, that was true.

Th. Envisaging a relationship with another person, however, who was not tied down, and who would not perhaps be as diffident, and, as he fell in love with you, would be more insistent about seeing you when *he* wanted to see you, this might produce a little more anxiety, mightn't it? [preparing her for an eventuality]

Pt. I imagine it would.

Th. Yes. On the other hand, a relationship need not be entirely made up of anxiety. There may be some positive values there for you as you begin to work this thing out.

Pt. I find that in my general relationships with, with men that their personalities come through. Which didn't happen at all before. Before it was sort of like dealing with someone in an animated cartoon. It was a person without personality or life.

Th. Almost as in the last dream, this woman sort of going through motions like an animated cartoon.

Pt. Yeah.

Th. Going through a sexual attack perhaps. It'll be very interesting, when you get a man who's worthwhile, to begin experimenting to see just whether the feelings still duplicate the feelings in the dream. It will be rather interesting to see that.

Pt. Well, I felt in the dream that this woman was an admirable person because she had stood up for her rights.

Th. Mm hmm.

Pt. And my sympathies were with her.

Th. Yes.

Pt. She was very aggressed against and helpless in the situation. And the things she really stood for were going to be killed, which I think is myself in a heterosexual relationship.

Th. And the things she stood for that were likely to be killed in a heterosexual relationship were what?

Pt. Yeah, my own aggressiveness, my own creativeness, and my own plans toward my personal life.

Th. Your creativeness, your aggressiveness, your plans, which are symbolized by what?

Pt. By masculinity.

Th. By masculinity. And in a feminine role your masculinity is likely to be taken from you?

Pt. Yeah.

Th. And that which you have cherished so ardently may possibly just be smashed to smithereens if you get into a female role. Now that's a rather dismal concept.

Pt. I should say it is.

Th. That creativeness, aggressiveness, productivity, being worthwhile are so equated with masculinity is interesting. It is something we may have to work out very, very carefully, in order to permit you to go on. Because, if it is really true that your creativeness and aggressiveness and productivity will be crushed in a female role, there is no reason why you should want a female role. But this is a misconception and a challenge. Why there has been this equation, what the meaning of it is are interesting things we may begin to explore.

Example 2

A man, with a reputable position in the community, allowed himself to be picked up by a prostitute. Falling in love violently with this woman, the man abandoned his wife and his three children and, to the horror of his friends, took up residence with the prostitute. Of all persons, only his minister was able to make enough of an impression on the patient to get him to seek psychotherapy. After 3 months of treatment the patient, realizing how destructive his behavior was to himself and his family, left the prostitute and returned home. This was accomplished without pressure from me. I had the feeling, however, that the patient felt resentful that therapy had deprived him of a source of intense sexual excitement. This anger was not openly expressed, but I intuitively sensed it. In the following fragment of a session, the patient presents enough material for me to make both tentative and authoritative interpretations of his resentment.

> *Pt.* I know I shouldn't want Marie (*the prostitute*) as bad as she is. The whole thing is silly, the kind of person she is, I mean.

> *Th.* But you do seem to want her in spite of her faults, *[reflecting underlying attitudes]*

> *Pt.* I know she is bad for me, Rita (*his wife*) is so much more of a real person. But I can't get Marie off my mind. I don't want to go back to her though because that same mess will happen all over again. I would like to be able to think about Rita all the time, to be thrilled by her. But I can work better now and would like to help Rita get the art training she wants. (*long pause*)

> *Th.* I see. *(pause)* What are you thinking about?

> *Pt.* A flash came to me, a fantasy of my standing on the subway platform. A person in front of me. As the subway approaches, I imagined myself pushing this man off.

> *Th.* What kind of a person is this?

> *Pt.* Unidentified. I couldn't identify the man. I seem to see him with a blue suit. He seems sinister for some reason. Sometimes when I stand on the platform of a subway, I have a fear I may jump off or that someone may push me off.

> *Th.* But in your fantasy you push this man off. You're angry with him?

> *Pt.* Oh, no, I don't feel ... I didn't feel anything. Just like pushing him off. *(yawns)* I'm kind of tired today. I had a hard day at the office, all kinds of pressures. I thought of canceling my appointment today because my secretary had forgotten to mark it and I forgot it, and I was supposed to talk to one of the out-of-town advertising people. *[This sounds like resistance.]*

Th. How do you feel about coming here? Do you feel it's an inconvenience to you? *[handling his mention of wanting to cancel his appointment]*

Pt. (*laughs*) It is. I come because I think it's necessary, not because I want it. There isn't anything enjoyable in it.

Th. So maybe you resent coming here, [*a tentative interpretation*]

Pt. No, I don't think I resent it because I know I *should* come. *[He rejects the interpretation.]*

Th. Mm hmm.

Pt. But it is a lot of work to get here; it does take time. It isn't anything I would do for fun. And then I feel that I have the responsibility to my family to get this thing straightened out.

Th. But how do you feel about doing it for yourself?

Pt. Frankly, I'm doing it for my family. Indirectly, I suppose, I benefit from it.

Th. You know, I get the feeling that you really resent coming here, *[an authoritative interpretation]* Let's take that fantasy. Here in fantasy you do an aggressive thing to someone in a blue suit.

Pt. Yes.

Th. What kind of suit do I have on?

Pt. (startled) Why *your* suit is blue! *[The patient seems astonished.]*

Th. Maybe I'm the man in the fantasy and you want to get *me* out of the way. If so, you do seem to resent me. *[tentative interpretation]*

Pt. Oh. I almost forgot. *[He reaches in his pocket and pulls out a check.]* I've been carrying this around for 2 weeks and always forget to give it to you when I'm here.

Th. There must be a reason for that.

Pt. (blushes) You mean I might not have wanted to pay you?

Th. That's possible, *(pause)*

Pt. But I did have the intention to pay you. I just forgot.

Th. People forget for definite reasons very often. Could you possibly not have given me the check because you felt critical of me? *[a tentative interpretation]* If that's the case, then your giving me the check now is making up with me for being critical.

Pt. (laughs) Well, I'll tell you, I have been annoyed having to come here. I've even resented your good intentions. Not that you've ever told me to stay away from Marie, but I've been ashamed to go on the way I did. I've even wanted you to tell me Rita was better than Marie

for me. But, damn it, the pull is there, the excitement. I can't go back, but I can't seem to push myself forward either.

Th. You see, there is a contradiction in some of your strivings. Your present stalemate is a result of being wedged in between your desire for Marie and your guilt and sense of responsibility to the family. You want me to make the choice for you and you are angry if I don't. *[authoritative interpretations]*

Pt. Yes, I can see that, and I know that attractive as Marie is, life with her would be poison for me. I don't need you to build up Rita because she's a person with quality.

Th. Now, were I to make the choice for you, you'd have trouble. For instance, if I told you to give up Marie, I'd become the repressing authority you've been fighting all your life. As a matter of fact, you may find Marie attractive and want to kick over the traces to defy this authority and to do as you please. Then our relationship would get bad because you'd probably want to defy me. On the other hand, if I encouraged you to give up Rita and to yield to your desires, you would be contemptuous of me. And if you went back to Marie, you'd blame me for exposing you to something from which you got pleasure, but which was very destructive to you. *[more interpretations]*

An accident-prone patient with an obsessive-compulsive personality sought therapy for anxiety and depression. From early childhood on he had been fearful of harboring a dreadful disease, the present form of which is cancer. At the fifth session when it became apparent that reassurance had failed to allay his fear of succumbing to a cancerous process of the brain akin to that of a colleague in his profession, the therapist confronts him with his masochistic need through authoritative confrontation.

Th. I realize that, as you have told me, doctors make mistakes. But I get the impression that in your case, with so many medical and neurological checks, there is little chance that you have cancer of the brain. More important than this is why you have to torture yourself with this idea or with other fears. Like all the other cancers you thought you would develop in the past and didn't.

Pt. Doctor, I tell you, I get so upset. I can't eat or rest. I get up in the middle of the night with a cold sweat.

Th. {firmly}) Now listen to me. You are giving yourself a hard time. Now why in the devil do you *have* to wear a hair shirt all the time. One torturous idea after another. You've always had it. I really feel you've always had it. I really feel you've got a stake in punishing yourself. All the guilt feelings you have about your parents. You must feel that you are a terrible person for feeling the way you do. *[authoritative interpretation]*

Pt. I can't get the thoughts out of my mind about what will happen to me when they die.

Th. Like what?

Pt. {pause) I don't know. I'm afraid I can't get along without them. And yet I have these awful thoughts that something terrible will happen to them. *[Obviously the patient is caught in a conflict of dependently needing his parents, feeling trapped, resenting his helpless dependency, fearing that his anger will somehow bring about their death and turning this resentment back on himself. His guilt feeling enjoins him to punish and torture himself. This will probably prevent him from benefitting from therapy. To try to take away his masochistic need for self-punishment without dealing with the basis for his guilt would prove either futile or would only be temporarily successful.]*

Th. Now look. You have this need to punish yourself and all the torture you're putting yourself through, and all your symptoms and the messes you get into, accidents and all, are, I feel, directly related to this need for self-punishment. The reason I bring this up is that as long as you have this need, you will block yourself from getting well in our treatment. What we are going to do is plan how you can break this vicious cycle.

A treatment plan then was evolved to help him break his dependency ties by getting him to take vacations away from home and then to find an apartment for himself away from his family. Having been enjoined to vent his anger, the patient became increasingly able to tolerate his hostility and to accept his parents for what they were. With support he was able to resist their insinuations that he was a disloyal son for leaving them and for living his own life. A dramatic change occurred in his symptoms, and a 2-year follow-up showed continued improvement and maturation.

46
The Handling of Resistances to Cure

Despite our best intentions and the most heroic efforts, even where patients express hope and determination to conquer their problems, they may sometimes be unwilling to relinquish them. Personality change is painful as progress takes hold. Anachronistic patterns regressively pull the individual back to the dreams and demands of the past. Temporary secondary gains and the desire to avoid anxiety at all costs hold patients in a grip from which they may be unable to release themselves.

Interpretations of these defensive operations help patients gradually to an understanding of their unhealthy patterns and to a discovery of what, if any, vicarious satisfactions they gain from them. In this way the patients learn to master some of the anxiety that made the defenses necessary. However, because certain drives serve a protective function and yield intense gratifications, the individual is apt to fight treatment desperately. Under these circumstances, therapy is interpreted as an assault on secret wishes and expectations.

FORMS OF RESISTANCE

In his book, *Inhibitions, Symptoms and Anxiety,* Freud (1966) emphasizes five types of resistance: (1) "repression resistance," which is motivated to protect the ego from anxiety; (2) "transference resistance," inspired by a refusal to give up hopes for regressive gratifications from the analyst, along with a desire to frustrate him or her; (3) "episonic gain resistance," which follows upon a need to indulge secondary gains and the advantages of symptoms; (4) "repetition compulsion resistance," motivated by a drive to repeat neurotic impulses under the lash of a self-destructive principle; and (5) the need for punishment to appease guilt. Psychoanalysis is a "never ending duel between the analyst and the patient's resistance" (Menninger, KA, 1961).

Resistance operates not only in psychoanalysis but in all forms of psychotherapy. This is not remarkable because therapy threatens to upset the delicate balance between various elements of the personality. To give up defenses, however, maladaptive as they may be, expose patients to dangers or deprivations that they consider more upsetting than the inconveniences already suffered as a result of the symptoms.

Resistance may take myriad forms, limited only by the repertory of the individual's defenses. Patients may spend time on evasive and aggressive tactics: fighting the therapist; or proving the therapist is wrong; or winning the therapist over with gestures of helplessness, praise, or devotion; or seeking vicarious means of escaping; or evading treatment. Fatigue, listlessness, inhibitions in thinking, lapses in memory, prolonged silences, intensification of complaints, pervasive self-devaluation, resentment, suspiciousness, aggression, forced flight into health, spurious insight, indulgence in superficial talk, engagement in irrational acts and behavior (acting-out), and expressed contempt for normality may occupy patients to the detriment of their progress.

Resistances may consume the total energy of the patient, leaving little zeal for positive therapeutic work. Sometimes a skilled therapist may bypass resistance by prodding reality into the face of the patient. Sometimes it may be handled by interpretations. Often it operates in spite of attempts to dissipate it, bringing the best efforts of the therapist to a halt. Because resistance is so often concealed and rationalized, it may be difficult to expose. Even an experienced therapist may be deceived by its subtleties.

In supportive therapy resistance may be manifested in a refusal to acknowledge environmental disturbance or in a defensiveness about one's life situation. There may be a greater desire to cope with present known vexations than to chance unknown and perhaps grievous perils. There may be a reluctance to yield inimical conditions that gratify needs for self-punishment and justify one's recriminations against the world. In reeducative therapy, resistance to the changing of modes of relating to people cannot be avoided. New interpersonal relations are, in the mind of patients, fraught with danger.

They can be approached only tentatively and with great hesitation. The patients may accordingly remain oblivious to their interpersonal distortions, no matter how frequently they are brought to their attention and how thoroughly they are interpreted. They will repeat the same patterns, with continuous bouts of suffering, and seemingly little insight into what is going on. In cognitive therapy, attempts to alter values or modify belief systems are often met with a confounding reluctance to yield anachronistic and debilitating self-statements. In reconstructive therapy impediments are even more manifest. A most complex array of resistances may materialize. This is especially the case where a weak ego creates an inability to face and to master anxiety related to unconscious conflicts.

Suppression and Repression

Any material that is emotionally disturbing will be suppressed or repressed by the patient until enough strength is gained to handle the anxieties evoked by its verbalization. This material may seem, and actually may be, insignificant or innocuous. It is essential to remember, however, that it is not so much the events or ideas that are disturbing, but rather the meanings given to them and the feelings they inspire.

> Thus, a female patient suffering from feelings of hopelessness and depression, relieved through excessive alcoholic indulgence, could talk freely about her bouts of antisocial behavior that bordered on the criminal, with little disturbance; yet she required one year of therapy before she could relate an experience of removing the clothing of her younger brother and observing and handling his penis. The excitement of this experience and the guilt engendered by it were so intense that she had isolated the memory in her mind.

Only when I had proved myself to be a non-condemning person, who would not punish or reject her for the desires that produced this incident, was she able to bring it up and to reevaluate it in the light of her present-day understanding.

Intensification of Symptoms

One of the earliest symptoms of resistance to cure is a reinforcement of those neurotic devices that had previously kept the individual free from anxiety. Something to anticipate, consequently, during therapy is an acute exacerbation of neurotic symptoms.

An explanation that the patient may possibly get worse before getting better is often a safeguard against interruption of therapy.

Self-devaluation

An insidious type of resistance is that of self-devaluation. Here patients refuse to concede that there is anything about them of an estimable nature or that they have any chance whatsoever of achieving worthwhile status. To every interpretation, they respond with the allegation that they are lost, that there is no need for them to continue, that they are hopeless, that it is too late in life to expect a change for the better. The inner image of themselves is often that of a hideous, contemptible person, and any attempt to explain to them that this is a distorted picture usually falls on deaf ears; their self-contempt is used as a bulwark to progress in therapy. There may be, in addition, a deep wish to be cared for like a child by rendering themselves helpless (parental invocation). The desire to depreciate themselves may be in the nature of escaping criticism by anticipatory self-punishment. A masochistic indulgence is also a cover for a fear that if one acknowledges oneself to be an able person, active and independent efforts will be expected of one. Patients with this misconception will hang on to their self-contempt with a determination that is astonishing, and only painstaking analysis of this resistance can lead them out of their morass. Sometimes self-devaluation is masked by surface narcissism and grandiosity.

Forced Flight into Health

Another form of resistance is "forced flight into health." Here individuals try to convince themselves and the therapist that they are well and that they no longer need treatment. Any implication that they are not making a good adjustment is resisted with vigor. Actually, patients may conduct their affairs with a semblance of normality in that they appear to be confident, self-reliant, and normally assertive. Yet the trained observer may detect a false note and often can perceive the tremendous effort that is needed to maintain the illusion of health. This form of resistance is usually associated with the need to maintain a rigid watch over everything one says for fear one will lose control. From a

pragmatic point of view, it makes little difference if a patient flies, swims, walks, or crawls to health, as long as one gets there. However, assumed health, fashioned by resistance, is generally short-lived.

Intellectual Inhibitions

The urge to ward off the therapist may result in a reluctance to think, to talk, or to feel. The patient, yielding to this urge, will insist that there is nothing pressing to talk about. Thus a singular sterility in the associations develops with an inability to think constructively about pressing problems.

The patient may break appointments, come late, forget to mention significant aspects of the day, block off memory of the dreams and fantasies, manifest inattention, show an inability to concentrate or to remember what has gone on before, relapse into silence during the interview, or display a mental fogging that persists both inside and outside of therapy.

The following excerpt from a session illustrates this phenomenon.

The patient, a divorcee of 32 years of age, with an hysterical, infantile personality, involved sexually with 2 men who were supporting her, came to therapy after making a suicidal attempt. After one year of treatment, her recognition of her dependency caused her to decide to get rid of her lovers and to get a productive job. The patient came a half hour late for the session that follows:

> *Pt.* (*apologetically*) I've been forgetting things lately. Absent-mindedness for about 6 months. Last week I forgot to go to an important meeting. I will make appointments and completely forget them. I forget things to do.

> *Th.* Let's explore that and see if we can learn something about it.

> *Pt.* I keep forgetting names and telephone numbers. I don't know why. Maybe I'm so preoccupied with what's to become of me.

> *Th.* Are you preoccupied?

> *Pt.* I am. I can't remember anything.

Th. What *is* on your mind?

Pt. I have the constant worry that I better hurry and do what I have to do. I am concerned with dying. I keep thinking I may not be here long. I noticed yesterday that my shoes on the floor were empty. I then said, "What will people do with my shoes when I die? I wonder who'll go over my papers."

Th. What's this all about? Do you feel the life you are now living is not worth living?

Pt. I feel threatened by giving up these people who are supporting me. I wonder if I can live and get along. What will become of me?

Th. Maybe you resent giving up these dependent patterns?

Pt. I must resent it; yet even though I do, I can't tolerate them any longer. I've gotten to the point where I can be casual with my supporters and tell them exactly what I feel. I told Max that I can't go to bed with him; he's too old for me. This is terribly threatening for me because the instant I do that my income is cut off.

Th. Mm hmm.

Pt. And Max told me he would give me money without strings tied to it.

Th. This must be a great temptation.

Pt. It is, and I see myself not wanting to give it up. I've accepted it in my mind to try it out.

Th. You may be in a great conflict between being dependent and being active and independent.

Pt. Yes, I don't know which to do.

Th. That's something that you yourself will have to work through.

Pt. I suppose my mind is in a fog because I don't know what to do, but somehow I feel I'm getting stronger. *[The mental fog and her coming late for the session are apparently signs of resistance.]*

Very frequently, negativistic resistant states develop several weeks or several months after the patient appears to have entered into the spirit of treatment, spontaneously analyzing difficulties and making what appears to be good progress. Suddenly, without warning, a blocked, inhibited pattern develops.

Acting-out

Along with unwillingness to verbalize ideas and impulses, the patient may indulge in

irrational acts and behavior in everyday life. This "acting out" appears to be a way of supporting the inability to talk during treatment. The acts serve to drain off anxiety and leave little energy available for work during the treatment hour.

Superficial Talk

Another form of resistance is a veering around one's problems in superficial talk. Here verbal comments are used as a defense to ward off basic issues. The patient may spend the entire time of treatment in talk that embraces topics of the day, current events, or past experiences portraying personal tragedy and martyrdom. There is little of deep significance in the conversation, and, if allowed to do, the patient may continue for years to discuss material that is interesting enough but that actually has little to do with significant problems. Often the patient will want to monopolize the interview and will resent the therapist getting a comment or an interpretation in edgewise. Rarely will the patient talk about attitudes toward the therapist, who may begin to feel merely like a sounding board for the patient's boasts and diatribes. It is almost as if in superfluous conversation the patient defies the world to make him or her talk about innermost problems. Associated with this, there may be an attempt to intellectualize, to figure out convoluted connections, and to present a rigid and logical system of what must have happened to one.

Insight as Resistance

A device that is apt to be confusing to the therapist is the use of insight as a form of resistance. Here patients routinely will go through a detailed accounting of how well they understand themselves, using the best accepted terminology, presenting the dynamics and mechanisms of their disorders in approved textbook style. To all appearances they have gained complete insight into the origin of their problems, into their compulsive trends and distorted relationships, and into the consequences and destructive influences of their neuroses. Yet in their daily experiences they go right on with their usual neurotic modes of adjustment, manifesting the same symptoms that originally brought them to treatment. It is probable in such cases that the patient's insight is a highly intellectualized

affair that is employed to confuse himself or herself and the therapist.

There are many reasons why a person utilizes insight as a smoke screen behind which to indulge customary neurotic trends. One of the most common reasons is the desire to escape criticism and detection. Here, a dissociation exists between how the patient thinks and feels. It is often easy for the therapist to minimize the seriousness of the patient's disorder when confronted during treatment with a beautiful recitation of psychopathology. Behind the camouflage of insight it is apparent that the patient uses knowledge of mechanisms as an instrument to allay guilt and to forestall criticism in regard to daily actions.

This mechanism is often found in extremely dependent patients who have magical expectations of what therapy will do for them. The chief motivation for entering treatment is the feeling that the therapist will bring about those neurotic objectives that they, themselves, have failed to obtain through their own efforts. Compliance here is the keynote, and the patients, by reciting their spurious insights, will feel that the therapist must reward their aptitudes in learning with anticipated bounties. The facade is at least partially unconscious, and the patients may really believe that they understand themselves thoroughly. The clue to what is going on is usually furnished by the outbursts of hostility and criticism that eventually are pointed toward the therapist when, after months of precise and punctilious performance, the patients do not magically get from therapy what they originally set out to achieve.

Dissociating the Treatment Hour from Life

Sometimes resistance takes the form of the patient's utilizing the treatment hour as a special event dissociated from life. Regarding it as such, the patient will go into the mechanisms of interpersonal relationships with complete freedom, displaying insight that seems to end after he or she exits from the therapist's office. It is obvious that with the therapist, the patient is operating under a set of standards entirely different from those used with other people in general. There seems to be something recondite about the treatment hour, for it is set apart from all other experiences. The special resistance here is

that of not seeing how the material that is uncovered in the treatment hour relates to everyday situations. This isolation of treatment from life is often rationalized by the patient on the basis that the therapist is a scientist, who does not condemn one for acts for which one would be punished by others. In this way the patient will lead a dual existence and seemingly be unable to fill the chasm between what happens in treatment and experiences outside of treatment.

Contempt for Normality

An insidious kind of resistance expresses itself in a fear of, or a contempt for, normality. Associated is a refusal to assume responsibility or to make an effort on one's own. By substituting new patterns for old, patients believe that they are yielding up something valuable, something they may never be able to replace, that they will become a prosaic bore, or that they may be exposing themselves to dangers with which they will be unable to cope. This type of resistance appears most intensely in reconstructive therapy after the patients have gained insight and are ready to execute it into action.

A patient with a phobic reaction extended to subway travel made a trip to my office by subway for the first time since treatment had started. She entered the room sullenly and remarked fretfully that she was furious with me. Her anger had started when she discovered that she had no great anxiety riding on the train. A fragment of the session follows:

> *Pt.* I am so angry and resentful toward you. *(pause)*
>
> *Th.* I wonder why.
>
> *Pt.* I feel you are gloating over my taking a subway. I feel mother is gloating too. *[Originally accompanied to my office by her mother with whom she had been living since her divorce, the patient with therapy gradually overcame her agoraphobia except for riding on the subway.*] I resent her too. I felt she was pushing me, trying to force me to break away from her. She gloats if I do something that makes me independent. I feel that when I go ahead you gloat too. *[The patient had become so pathologically dependent on her mother that she was scarcely able to let mother out of her sight. Mastering some dependency and walking alone was achieved previously in therapy, although the patient was very reluctant to give up this aspect of her dependent relationship.]*

Th. It sounds as if you are angry about being able to travel on the subway.

Pt. Mother seems to be anxious to give up her responsibility for me. I resent that. But I also don't like the idea of my being so close to mother too.

Th. I see, as if you want to continue being dependent and yet resenting it.

Pt. When I get sick at night, I ask her to make me some tea; and then I resent her patrician attitude when she does this.

Th. But what about your feeling about me?

Pt. It's like giving in to you. But yesterday I felt liberated by the idea that I'm in the middle of a conflict and that coming here offers me hope. I realize that my neurosis is threatened by my getting well. (*laughs*)

Th. What part of your neurosis do you want to hold onto?

Pt. (laughs) None. But I have a feeling that I don't want to be normal, that in giving in to you I'll be like anybody else. Also that you'll expect more things of me. And (*laughs*) that if I get too well you'll kick me out. *[Here the patient verbalizes a variety of resistances: namely, a desire for uniqueness, a contempt for normality, a fear she will be expected to face more anxiety-provoking situations, a reluctance to give up her dependence on me, a punishing of her mother and of me by refusing to acknowledge improvement, and an unwillingness to yield her masochism and the various secondary gain elements accruing to her neurosis.]*

Occasionally a psychosomatic complaint may be a manifestation of resistance, as illustrated in the following fragment from a session with a male patient:

Pt. Everything was going well until this morning when I got stomach cramps. They have been with me all day.

Th. Mm hmm.

Pt. I find it hard to concentrate because my stomach bothers me so much. Mondays I always have a hard time for some reason. It's happened the last few Mondays.

Th. Seems like an unlucky day for you. *(pause)*

Pt. I was thinking about how long it takes to get well, and I was wondering if others did any better than I do. Of course, things are a lot better now, and I was thinking of taking a course in journalism up at the New School. The only thing is that it comes on Mondays, and that's hard. I … uh … uh … *(Patient brings hand to his abdomen.)* I had something I wanted to say … but I can't think of anything but these cramps. *(He takes a cigarette from a pack, reaches into his pocket for matches but cannot find them.)* Do you have a match?

Th. I believe so. Here's one. *(pause)*

Pt. Well … *(coughs)*

Th. You were saying that Mondays are pretty tough on you? Perhaps something happens to you on Mondays that upsets you.

Pt. I … I … I don't know.

Th. You do come *here* on Mondays.

Pt. Why … yes … yes … I mean I do.

Th. Maybe something is upsetting you in coming here?

Pt. I don't know what it might be. *(pause)* Maybe I'm upset that you feel I'm not doing well. *[We discuss his feelings that he is not living up to expectations. This is what has been giving him anxiety. His cramps are manifestations of internalized resentment and act in the service of resistance. [The symptoms soon vanished completely when he could see their connection with his faulty assumptions.]*

Reluctance to Yield the Pleasure Values of the Treatment Hour

A form of resistance that is frequently overlooked is one that involves reluctance to yield the positive pleasures that the patient gets out of the treatment itself. The patient may derive such comfort from the therapeutic hour that other gratifications seem dubious, and may refuse to give up the neurosis because of a desire to continue therapy indefinitely. This is frequently the case in a very dependent patient, who looks forward to the hour to get a "fix," who perhaps pays lip homage to all the dynamic principles uncovered during treatment, but whose chief motive for therapy is to get suggestions and courage to carry on with daily routines. Unless one watches oneself carefully, the therapist will fall into a trap laid out by the patient and may, by the patient's helplessness and apparent inability to do things voluntarily, feel forced to feed the patient with doses of advice and admonishments, which the patient absorbs as if these were pronouncements from the Deity.

Transference Resistances

Perhaps the most common and disturbing of resistances are those that are produced in response to the relationship with the therapist or that take the form of transference.

Contact with the therapist is understandably disturbing when it mobilizes attitudes, impulses, and feelings that threaten the repressive forces. Patients will, in the attempt to escape from the associated anxiety, exhibit their usual characterologic defenses to detach themselves, make themselves helpless, control and overwhelm the therapist, or render themselves invincible by pseudo-aggressiveness. In supportive and some types of reeducative psychotherapy the patients will manage to restore their equilibrium through the medium of such defenses, and they will, more or less successfully, repress disturbing irrational, unconscious drives. In reconstructive therapy, on the other hand, the therapist constantly interprets the nature and purpose of the various defenses as they arise. This constitutes an assault on the integrity of the repressive system and will precipitate much tension. Eventually the patient cannot help coming to grips with the emotions and drives that hitherto have been successfully avoided. The patient will then mobilize further protective devices to reinforce the crumbling repressions.

One of the earliest manifestations of this struggle is an intensification of symptoms, which seems to serve the desperate function of restoring psychic equilibrium. Soon the struggle becomes more personalized as the patient realizes that relationship with the therapist is the womb of the distress. Resistance once exerted against awareness of the original unconscious material is now shown toward projected and animated representations in the transference.

The patient may exhibit a disarming dependent attitude toward the therapist, who is regarded as the embodiment of all that is good and strong and noble in the universe. This kind of resistance is often found in individuals who are characterologically submissive, subordinate, and ingratiating and who strive to adjust to life by clinging parasitically to a more powerful person. It is as if the individual had an amputated self that could be restored only by symbiosis with a stronger individual. There is even an associated tendency to overvalue the characteristics and qualities of the therapist. This type of relationship is extremely shaky because the patient regards therapy as a magical means to security and power. Consequently, the therapist must always live up to inordinate expectations that are sheerly in the realm of fantasy, beyond possibility of fulfillment. The

patient will make unreasonable demands on the therapist, and, failing to get what he or she secretly wants, be filled with outrage.

Another form of relationship resistance is based on an intense fear of the therapist as one who is potentially capable of injuring or enslaving the patient. This attitude stems from a hostile image of the parent that usually is applied to selected authoritative individuals. Treatment in such cases proceeds only when the patient realizes that the therapist does not desire to punish or condemn for the impulses or fantasies, but instead is benevolently neutral toward them. Little progress is possible until the patient accepts the therapist as a friend, not foe.

Sometimes patients display a disturbing need to be victimized and unfairly treated. They will maneuver themselves into a situation with the therapist in which they feel they are being taken advantage of. They may even exhibit various symptoms that they attribute to the harmful effects of therapy. In order to reinforce their waning repressive system, they thus seek to transform the therapist into a stem authority who commands and punishes them. Where this happens, they will experience severe anxiety if the therapist is tolerant and condones their inner impulses.

When resistance is displayed in the form of hostility, the resulting reaction patterns will depend on the extent to which the patients are able to express aggression. Where the character structure makes it mandatory to inhibit rage, the patients may respond with depression and discouragement. They may then want to terminate therapy on the grounds that they have no chance of getting well. They may mask their aggression with slavish conformity and perhaps evince an interest in the therapist's personal life, assuming an attitude of camaraderie and good fellowship. There is in such efforts a desire to ally themselves with the enemy in order to lessen the danger to themselves.

On the other hand, where the patients are able to express hostility, they may exhibit it in many ways especially where the transference becomes intense. They may become critical, then defiant, challenging the therapist to make them well. Irritability is often transmuted into contempt, and the patients may accuse the therapist of having

exploitative or evil designs on them. Feeling misunderstood and humiliated, they will manufacture, out of insignificant happenings in their contact with the therapist, sufficient grounds to justify their notion of being mistreated. They will become suspicious about the therapist's training, experience, political convictions, and social and marital adjustment. They may enter actively into competition with the therapist by reading books on psychoanalysis to enable them to point out the therapist's shortcomings. They may become uncooperative and negativistic.

Sometimes hostility is handled by attempts at detachment. The need to keep the therapist from getting too close may burn up a great deal of the patients' energy. They may refuse to listen to what the therapist says. They may ridicule in their minds proffered interpretations. They may forget their appointments or seek to discontinue therapy, inventing many rationalizations for this. They may strive to ward the therapist off by discussing irrelevant subjects or by presenting a detailed inventory of their symptoms. In their effort to keep aloof they may attempt to take over therapy, interpreting in advance their unconscious conflicts, the existence of which they suspect or fabricate. An insidious type of defense is a preoccupation with childhood experiences. Here the patients will overwhelm the therapist with the most minute details of what must have happened to them during childhood, presenting a fairly consistent and logical survey of how previous inimical experiences must have produced all of their present difficulties.

Occasionally the impulse toward detachment is bolstered by contempt for the therapist's values; the patients will feel that their own standards are what really count. Because of this they will be convinced that the therapist cannot like them and will "let them down." They will rationalize these feelings and say to themselves that the therapist is no good, or incompetent, or of no importance, or that psychotherapy is nothing but nonsense.

The desire to control the situation may reflect itself in many ways. Some patients may seek to shower the therapist with gifts and favors, or they may develop a sentimental attachment that assumes a sexual form. Therapy may be regarded as a seduction, the

patient experiencing in it intense erotic feelings. One of the motives involved in falling in love with the therapist is to put the latter in a position where there will not be too close probing into the patient's deepest secrets. The incentive may be to devalue, test, influence, get the whip hand, or fuse with the therapist; in this way taking a shortcut to cure.

Many patients come to treatment not because they desire to function more adequately in their interpersonal relationships, but rather because they seek to obtain from treatment the fulfillment of neurotic demands that they have been unable to gratify through their own efforts. In such cases resentment and resistance develop when the patient does not receive from the therapist the specific type of help that was expected.

Upon analyzing what the patient wants from the therapist, it turns out that what is sought is not a cure for the neurosis, but an infallible method of making it work. Many patients desire to achieve neurotic expectations without having to pay the penalty of suffering. The individual with a power drive may thus insist on a formula whereby one can function invincibly in all activities. The perfectionist will want to find a way to do things flawlessly, with as little effort as possible. The dependent individual will expect to amalgamate with the therapist and to have all whims gratified without reciprocating. The detached soul will seek the fruits of social intercourse, while maintaining distance from people. When these drives are not gratified in therapy, when patients sense that these are instead being challenged, they will become tremendously resistive.

In sicker patients, resistance is sometimes exerted against accepting the idea that it is possible to function adequately without repairing a fantasied injury to the genital organs. In the female this may be expressed in the expressed refusal of continuing life without the possibility of ever procuring for herself a penis, which she regards as the bridge to activity and self-fulfillment. In males, the assumption of a passive role is often interpreted as equivalent to being castrated, and resistance may be directed against assuming any role that does not involve aggressive "masculine" fighting or "machoism." Even accepting help from the therapist may symbolize passivity.

Psychotherapy may produce other unfavorable resistance reactions in patients with immature ego structures. The transference can become so dramatic and disturbing to these patients that they respond to it in an essentially psychotic manner. They will accuse the therapist of being hostile, destructive, and rejecting, and they will refuse to acknowledge that their attitudes may be the product of their own feelings. The reasonable ego here is very diminutive and cannot tolerate the implications of some surfacing of unconscious drives and conflicts. The patient acts out inner problems and constantly avoids subjecting them to reason. The acting-out tendency permits the neurosis to remain intact. Where the therapist is seen as a cruel or lecherous or destructive being who threatens the patient with injury or abandonment, any action or interpretation is twisted in the light of this delusional system. Fear and anxiety issuing from the patient's irrational strivings lie like boulders in the path, barring the way to a more congenial therapeutic relationship. In such cases therapy will be prolonged, and the relationship must be worked on actively so as to constitute for the patient a gratifying rather than threatening human experience. (See also Chapter 42)

METHODS OF HANDLING RESISTANCE

Little has been written on how definitely to solve the paradox of the patients who seek help yet resist any external control or guidance toward change. What would seem to be indicated is a participant model for therapy in which the patients take responsibility in treatment, monitoring their own behavior and determining the nature of their interactions, environment, and their future plans.

In psychoanalysis, early in treatment the patients gather from the passivity of the analyst that they have to make their own decisions and work through their blocks toward utilizing insight in the direction of change. Interpretation of resistances is the prime modality used and the analyst hopes that the patients will in the resolution of these obstructions generalize their learnings in therapy toward making new constructive adaptations.

In psychoanalytically oriented therapy, the therapist is more active and employs

techniques in addition to interpretation to help the patients effectuate change. These techniques often draw from many schools and are more or less eclectic in nature.

In behavior therapy, the therapist is highly active, utilizing when necessary a rich assortment of devises, including systematic desensitization, operant conditioning, modeling of preferred behaviors, role playing, work assignments, and cognitive therapy. These treatments are sometimes blended with counseling.

At the outset it often becomes apparent that what some patients want from therapy is to overcome suffering without giving up attitudes and behaviors that are responsible for their suffering. What is required before any progress can be made is to work toward motivating the patient to change and to formulate worthwhile objectives in treatment. In behavior therapy these are delineated and persistently pursued.

In his chapter on self-management methods, Kanfer (1980) describes a behavioral model drawn from Skinnerian methods and research findings in social and cognitive psychology as well as current clinical practices. Through various techniques, the patient acquires skills for use in problem-solving. The patient is also trained in altering noxious elements of the environment. Development of constructive repertoires is conducted through negotiations with the patient. Past experiences are reviewed only to provide information during behavioral analysis on the circumstances surrounding the original conditions when the maladaptive behavior was developed, and to point out the present inappropriateness of this behavior.

In controlled environments like a hospital or in military organizations, reinforcement contingencies may be relatively easily applied. But in one's ordinary living environment these are not so readily arranged, and it is for this reason that manipulation of cognitive variables through cognitive behavior therapy can be valuable in order to help evolve constructive self-reinforcing attitudes. A good deal of support will be required from the therapist at the start of treatment, but this will diminish as the patient becomes more skilled in self-management. A contract is usually negotiated, details of which spell out the required behavior, the time goal, the reinforcements for fulfillment of obligations, some

aversive consequences of nonfulfillment of the contract, and the way reviews and evaluations will be conducted. Where required behaviors occur outside the range of observation of the therapist, self-monitoring is mandatory and here the patient will benefit from keeping a careful record of his or her behaviors. Assignment of tasks expedites self-observation and hastens the development of new behavioral repertoires. Techniques are employed to set up environmental conditions unfavorable to the undesired behavior, and to establish contingencies for self-reinforcement. Discussions cover the patient's experiences in self-management with the object of helping to transfer learnings and skills to situations that may develop in the future. There are other models one may follow if one is pursuing a behavioral program, but the one I have outlined seems to cover the essential points.

As soon as the therapist realizes that resistance is interfering with therapy, it is necessary to concentrate on the resistance to the exclusion of all other tasks. This may be done in a number of ways. In supportive and reeducative approaches, this is done by reassurance, persuasion, and various manipulative and strategic maneuvers. In reconstructive approaches a cognitive attach or the resistance itself is instituted.

Identifying the Resistance and Exploring Its Manifestations

Calling the patient's attention to the resistance itself and exploring its manifestations are essential procedures.

For example, a patient has for the past few sessions arrived 5 to 10 minutes late. The sessions are spent in a discursive account of family events, including the impending marriage of his son, the forthcoming graduation of his daughter, and the attacks of "gall-bladder trouble" suffered by his wife for which she may need an operation. The responsibilities imposed on him by his business and social position also occupy his attention. He mentions having suggested a 2-week vacation in Florida, but his wife promptly vetoed the idea. He pauses in his conversation and then remarks that there is nothing on his mind.

Sensing resistance, I direct the interview along the following lines:

Th. I wonder if there is something on your mind that bothers you that you are not talking about.

Pt. Why, no, not that I'm aware of.

Th. The reason I bring this up is that you have been coming late to your sessions, and during your sessions you have kind of rambled along, not talking about things that bothered you too much. At least I have that impression. *[pointing out possible resistances]*

Pt. Why no, I mean you want me to talk about anything on my mind. I'm supposed to do that, am I not?

Th. Yes.

Pt. Well, I haven't had anything else bothering me.

Th. Perhaps not, but have you had any symptoms that upset you?

Pt. No. I've noticed though that my jaws tighten up sometimes. And my wife tells me I'm grinding my teeth in my sleep.

Th. Mm hmm. That sounds like tension of some kind.

Pt. I know I feel a little tense.

Th. A little tense?

Pt. I've been upset that I have to do, do, do for other people, give, give, give, and get little in return.

Th. As if people expect things from you and do not want to give anything?

Pt. Yes, I'm getting fed up with my life, the way it's been going.

Th. I see. This could be upsetting.

Pt. I suppose you'd say I feel frustrated.

Th. Well, what do *you* say?

Pt. (laughs) It's hard to admit it, but I am. Sometimes I'd like to chuck up the whole thing, and be single again, without responsibilities, to do what I want to do.

Th. I should think you would feel frustrated that you can't. If this is what you really feel this is what you want.

Pt. Lately I've been getting this way. *[The patient discusses his secret ambition of wanting to be a writer and admits that he was embarrassed to talk about this. He also was, he remarks, afraid*

to admit that he resents being tied down to a routine family life and has fantasized divorce. His resistance to talk about these things along with his internalized rage at his life situation seem responsible for his muscular symptoms.]

Pointing Out Possible Reasons for the Resistance

Where patients are cognizant of their resistance but do not recognize its purpose, the therapist should point out various possibilities for the resistance. The defensive object of the resistance may be interpreted along with the facades; the patients may be shown that their resistance protects them against the threat of change. Thus, a patient hesitates repeatedly during a session; the periods of silence are not broken by the usual interview techniques.

> *Th.* I wonder what the long silences mean.
>
> *Pt.* Nothing comes to my mind, that's all. I kind of wish the time was up.
>
> *Th.* Perhaps you are afraid to bring up certain things today. [*suggesting that her silence is a resistance to prevent her from bringing up painful material.*
>
> *Pt.* Like what?
>
> *Th.* Well, is there any event that happened since I saw you that you have not mentioned to me?
>
> *Pt.* (*silence*) Yes. there was. I met a man last Wednesday who sent me. I made a big play for him and am going to see him Sunday. *[The patient's infidelity to her husband is one of her symptoms, of which she is ashamed.]*
>
> *Th.* I see.
>
> *Pt.* I have wondered why I did this. I realized you wouldn't tell me not to, but I feel guilty about it.
>
> *Th.* Was that the reason why you were silent?
>
> *Pt.* (*laughing*) Honestly, I thought there wasn't much to talk about. I minimized the importance of this thing. But I realize now that I didn't want to tell you about it.
>
> *Th.* What did you think my reaction would be?
>
> *Pt.* (*laughs*) I guess I thought you'd think I was hopeless or that you'd scold me.

Reassuring Tactics

Reassuring the patient in a tangential way about that which is being resisted necessitates an understanding by the therapist of the warded-off aspects.

For instance, a woman with an obsessional neurosis comes into a session with symptoms of exacerbated anxiety. She has no desire to talk about anything but her suffering. This seems to me a sign of resistance. When I inquired about dreams that she may have had, the patient reveals one that, in a disguised way, indicates murderous attitudes toward her offspring. The idea occurs to me that she is attempting to suppress and repress thoughts about her children.

A significant portion of the session follows:

Th. I wonder if you haven't been overly concerned about thoughts of your children.

Pt. I'm frightened about them, the thoughts.

Th. You know, every mother kind of resents being forced into playing the role of housewife. This is a cramped life to many persons. Most women may resent their children and from time to time wish they weren't around. It's natural for them to feel that, *[reassuring the patient about possible hostility]*

Pt. (rapidly) That's how I feel.

Th. They may even get a feeling sometime that if the children pass away, that will liberate them. Not that they really want that, but they look at it as an escape, *[more reassurance]*

Pt. That's what I didn't want to say. I've felt that it was horrible to be like that.

Focusing on Material Being Resisted

Bringing the patient's attention to the material against which the resistance is being directed must be done in a very diplomatic way, preferably by helping the patients to make their own interpretation or by a tentative interpretation.

A patient with a problem of dependency complained of an intense headache and a general feeling of disinterest in life.

The interview was rather barren, but enough material was available to bring the

patient to an understanding of what he was trying to repudiate.

> *Pt.* My wife has been telling me that I just am not like the other husbands. I come home and read the newspaper and don't go grubbing around in the garden.

> *Th.* What does that make you feel like?

> *Pt.* I guess she's right. But as hard as I try, I know I'm being a hypocrite. I just gave that up.

> *Th.* But your wife keeps pounding away at you.

> *Pt.* Well, what are you going to do. I don't help her around the place. She resents my being as I am.

> *Th.* But what do you feel your reaction is to her pounding away at you?

> *Pt. (fists clench)* It drives me nuts. I'd like to tell her to stop, but I know she's right.

> *Th.* Is it possible that you resent her attitude, nevertheless, and would prefer her laying off you when you don't do the chores? [*a tentative interpretation of the material against which there is resistance]*

> *Pt.* God damn it. I think she is being unreasonable when she sails into me. *[The patient takes courage from my interpretation and expresses resentment.]*

> *Th.* Mm hmm.

> *Pt.* After all, I come home tired and I find no interest in planting cucumbers. Besides, it's crazy. My neighbors plant dollar tomatoes. Each tomato costs them a dollar. It's no economy. The whole thing is silly. *[The patient continues in a diatribe, venting his resentment about his wife's attitude. At the end of the session his headache had disappeared.]*

Handling Acting-out

Acting-out is a common manifestation that has been given various interpretations (Abt, 1965). Fenichel (1945) defines acting-out as "an acting which unconsciously relieves inner tension and brings a partial discharge to warded-off impulses (no matter whether these impulses express directly instinctual demands, or are reactions to original instinctual demands, i.e., guilt feelings); (the present situation, somehow associatively connected with the repressed content, is used as the occasion for the discharge of repressed energies, the cathexis is displaced from the repressed memories to the present, 'derivative,' and this displacement makes the discharge possible.") Aronson (1964a) considers the essential features of any acting-out sequence to be a reenactment of a

childish ("pregenital") memory or fantasy, of which there is no conscious recollection, precipitated by transference or resistance during psychotherapy, displacing itself to some organized "ego-syntonic" action, thus permitting a partial discharge of inner tension. At the same time there is no awareness of any relationship of the old memory or fantasy with the current action.

Prior to coming to therapy the patient, having indulged in acting-out tendencies as a way of expressing unconscious impulses and feelings, may have gotten into certain scrapes. During psychotherapy acting-out may occur even in patients who have, before treatment, shown no evidence of it in their behavior.

There are some psychotherapists who take the view that acting-out can serve a useful purpose in some patients, that it may be growth inducing and, particularly where basic problems originated in the preverbal state, they constitute a means toward assertiveness and a preliminary step toward gaining insight. Consequently, they tend to encourage and even to stimulate acting-out. Other therapists, however, regard acting-out as always detrimental to therapeutic progress since it drains off the tension that should be employed for a requisite understanding and working through of conflicts. Between these two extremes an intermediate viewpoint may be taken, acting-out being managed in accordance with whether it serves as an obstruction to or as an intermediate stage toward learning.

Some patients who were overindulged and poorly disciplined as children will engage in untoward acting-out behavior to goad the therapist into a setting of limits such as they had never experienced with their own parents. On the other hand, where parents have been too authoritarian and have cowed the patient to a point where the slightest emergence of defiant or antisocial conduct inspires fear of a counterattack, acting-out may constitute a breaking out of restraints. The handling of acting-out in these two instances will be different.

Where acting-out occurs as a resistance to therapy, it is usually inspired by the transference situation. Because patients refuse to verbalize prior to acting-out and

because they may conceal and rationalize their behavior, it may be difficult to deal with it therapeutically. For instance, a prudish female patient, shortly after starting therapy, confessed having involved herself in extramarital love affairs with several men. It was only through a dream that I was able to get a glimpse of her guilt feelings at sexual actions that were totally foreign to her personality. Confronting her with the existence of sexual guilt brought forth divulgence of the information that she had, during the past month, become so sexually aroused that she felt forced to seek satisfaction in outside affairs. Focusing on her feelings about me, the patient was soon brought to an awareness of how closely she had identified me with her father, and of how her incestuous impulses were being displaced. The establishment of the connections of her current behavior with its infantile roots enabled her to control her acting-out and to work through her fantasies within the therapeutic situation.

The therapist should consequently be alert to extraordinary behavior patterns that occur in the patient. Thus, a man who is ordinarily restrained may engage in random, multiple sexual affairs to the point of satyriasis, or involve himself in dangerous but exciting aggression-releasing situations that are potentially disastrous to him. One patient, for instance, whenever provoked by hostility toward her therapist, would get into her car and drive speedily and recklessly. Only when she narrowly escaped an accident would she slow down.

When acting-out is recognized, it is necessary to bring this to the attention of the patient. The therapist may suggest that there are reasons why the patient feels forced to engage in certain behaviors. Talking about feelings *prior* to putting them into action will help the therapeutic process. Acting compulsively the way that the patient does tends to interfere with therapy. Should the patient accept these statements and verbalize, enough energy may be drained off in the interview to forestall acting-out. Interpretation may also help to dissipate the need for unrestrained behavior. Interpretive activities will require a repeated pointing out to the patient of manifestations of acting-out conduct. At the same time attempts are made to link actions to fantasies or impulses that are preconsciously perceived. Material from free associations and dreams may be valuable here. What helps

in most instances is bringing the patient to an awareness of evidences of transference. Should any of the acting-out manifestations contain healthy elements, the therapist should attempt to reinforce these. The strategic timing of interpretations is important. Where acting-out occurs during a session as a manifestation of transference and resistance, interpretations will be particularly effective; nevertheless, a prolonged period of working through may still be required.

Should acting-out persist and should this be potentially dangerous to the patient, the therapist may direct the patient to desist from the acts on the basis of their destructive nature, while encouraging talking about impulses. Of course, in some instances, it may be impossible for the patient voluntarily to stop acting-out. Exhibitionism, voyeurism, transvestism, and masochistic sexual activities are examples. However, with persistence it may be possible to get patients to talk freely about their temptations and to help them, to an extent at least, to gain some voluntary control. Increasing the frequency of sessions and giving patients the privilege of telephoning the therapist whenever the impulse to act-out occurs are often helpful. As a last resort, if patients continue dangerous acting-out, the therapist may threaten to withdraw from the therapeutic situation unless control over impulses is exercised. Behavioral aversive conditioning techniques are sometimes employed as a means toward checking acting-out that cannot be controlled in any other way. Cooperation of the patient will, of course, be necessary. The patient may also be told, "If you want to continue in this self-destructive behavior, you can do it by yourself; you don't need me. If you want to change, I can help you."

It goes without saying that acting-out within the therapeutic session, like physical attacks on the therapist and lovemaking gestures, are to be discouraged or prohibited. Patients may be told that they can talk about anything they please, but that unrestrained actions are not permitted by rules of therapy. Experience has shown that these interfere with the therapeutic process.

Handling Transference Resistances

Where transference has developed to the point where it constitutes resistance to

treatment, it will have to be resolved. If it is not dissipated, it will seriously interfere with the working relationship. Treatment may become interminable, the patient utilizing the therapeutic relationship solely as a means of gratifying neurotic impulses at the expense of getting well. Frustrated by the absence of what the patient considers to be the proper response to reasonable demands, the patient may terminate treatment with feelings of contempt for or antagonism toward the therapist.

Superficial manifestations of transference may often be adequately handled by maintaining a steadfast attitude and manner, constantly bringing the patient back to reality. Sometimes a studied avoidance of the role that the patient wants the therapist to play, or acting in an opposite role, minimizes transference. For instance, if the patient expects the therapist to be directive and controlling, on the basis of a conviction that all authority is this way, the therapist deliberately acts permissive, tolerant, and encouraging of those activities toward assertiveness and freedom that the patient cherishes but which he or she believes the parents had prohibited. Such role playing rarely is successful because the patient will usually see it as a ruse. It is better to interpret to the patient what the therapist believes is behind the patient's reactions.

A female patient, conditioned to expect punishment for infractions by a punitive parent, appears for a session depressed and guilt-ridden. She seems to demand that the therapist scold and punish her for having drunk to excess the evening before and for having acted sexually promiscuous. Not being able to stimulate this reaction in the therapist, the patient launches into an attack, upbraiding the therapist for passivity. The therapist continues to react in a tolerant and nonjudgmental manner, but interprets the responses of the patient in terms of her desires for punishment and forgiveness to propitiate aroused guilt feelings.

Severe manifestations of transference being rooted in infantile conditionings will usually require prolonged "working through." Strategically timed interpretations of the sources of transference in childhood experiences and fantasies, and of its present functions, will be required.

Among the most disturbing of transference resistances is that of the sexual transference, which takes the form of insistence that one can be cured only in a sexual relationship. While therapy may set off a temporary sexual attraction toward the therapist, this fascination usually disappears as therapy progresses or upon the simple structuring of the therapeutic situation. However, in some patients the sexual preoccupation becomes intense and persistent. A male patient, for example, will pick out from the behavior of a female therapist minor evidences that he will enlarge to justify his belief that the therapist must be in love with him. The protestations of the patient may greatly flatter the therapist, and the urgency of the expressed demands may tempt her to respond partially by touching or holding the patient. These advances are most provoking to the patient and incite greater sexual feeling. Should the therapist engage in any kind of sex play with the patient, this can have only the most destructive effect on both participants. Once the patient has even partially seduced the therapist, he may develop contempt for her weakness and for her abandonment of ethical principles. The therapeutic situation will obviously terminate with any expressed intimacy.

It is important in handling sexual transference not to make the patient feel guilty about sexual feeling. Rather, the feeling should be accepted and an attempt made to find out what it means in terms of the patient's past sexual attitudes and behavior. For instance, sex may indicate being accepted or preferred by someone. It may perhaps have the connotation of vanquishing or humiliating others. Sometimes reassuring comments are helpful in abating the patient's reactions. Thus the patient may be told, "It is usual for persons to develop such feelings for their therapist," or "It is good that you have these feelings because they will enable you to work out important attitudes and relationships," or "The *feeling* you have toward me is a step in your ability to feel and to relate to other people," or "This will serve as a means toward better relations with others." Where the patient brings in dreams and fantasies, it may be possible to interpret, with all the precautions already mentioned, the sources of the patient's transference reactions.

Another disturbing resistance is that of the hostile transference. Here the patient will react to the therapist as if convinced of the reality of the therapist's unfriendliness,

destructiveness, ineptness, seductiveness, and maliciousness. The patient will be importunate, irrascible, and insistent that it is the therapist who misinterprets and not he or she. The patient may become retaliatory or destructive in response to the therapist's fancied hostility, or may experience panic, depression, or psychosomatic symptoms. A resolution of hostility by the introduction of reality and by interpretation is indicated, following some of the suggestions given for the management of the sexual transference.

Where transference cannot be handled in any other way, active steps will have to be taken to minimize it. Such measures include a focusing in the interview on the current life situation rather than on early childhood experiences, avoidance of dreams and fantasies, discouraging discussion of the patient's relationship to the therapist, abandonment of the couch position and free association if these have been employed, decreasing the frequency of the interviews, presenting interpretations in terms of the character structure and current life situation rather than in terms of genetic determinants, and greater activity in the interview.

THE NEED FOR WORKING THROUGH RESISTANCE

Resistance may burn up the entire energy of the patient, who may self-defensively concentrate on fighting the therapist, or proving the therapist to be wrong, or winning the therapist over with gestures of helplessness, praise, or love, or seeking various means to escape or to evade treatment. The struggle is an intense one and usually goes on below the level of awareness.

When one appreciates the purpose of resistance, one realizes that patience is a great virtue. The therapist must bear with the neurotic individual as he or she progresses and takes refuge over and over again in customary defenses. Resistance is yielded only after a great struggle, for change is a painful affair.

Since resistance has a dynamic function, an effort is made to help the patient to relinquish it slowly. Too sudden removal may produce severe anxiety and may provoke a reinforcement of the neurotic defenses intended to protect the individual. Relinquishment

of resistance will thus be blocked by a threat of repetition of the anxiety experience.

Resistance is best managed by demonstrating its presence, its purpose, its ramifications, its historical origin, and the manner of its operation in the patient's present relationships with the therapist and with people in general. As resistances are gradually analyzed and resolved, repressed material appears in consciousness in a less and less disguised form. Resistances require a constant working through. A single interpretation of a resistance is hardly effective.

The therapist should allow resistance to evolve fully before taking it back to its origins. If a second resistance develops, the therapist must handle it by returning to the first one and demonstrating to the patient the interrelationship of the two. Tackling the patient's defensive reactions inevitably causes the patient to feel threatened and to dispute interpretations of his or her resistance. This reaction is opposed by a contrary motive, that of retaining the good will of the therapist. Often the patient will attempt to satisfy both of these motivations at the same time by abandoning his or her defense in the forms recognized by the therapist and changing it to a less obvious type. The understanding of these elaborations and their continued exposure forces the patient to take a real stand against them and, finally, to abandon them entirely.

It is always essential to remember that resistance has a strong protective value. Patients will usually reject any insight that is too traumatic, perhaps toying with it for a while, then forgetting it. However, through careful handling, insight into how and why the resistance is operating may be gained. First, the patient must be made aware of the resistance. Merely calling attention to it alerts attention to a specific task. It prevents burning up energy in pursuit of maintaining the resistance, constructively diverting it toward tracing down its meaning.

Once a resistance develops, it is essential to abandon other tasks until it is resolved, because the patient will not be productive while battling the therapist. It is best at first not to probe too deeply for unconscious material, but rather to work intensively upon the immediate interpersonal relationship. To aid in the process, the patient must be

impressed with the fact that there is nothing morally bad about showing certain defensive attitudes in the form of resistance.

The dealing with transference resistances may be a prolonged affair in the personality disorders. Here the ego seems blocked in absorbing the full meaning of the oppositional behavior as it becomes apparent. The patient may acknowledge the presence of certain drives. The patient may even understand their irrational nature and historical origin, but this pseudo-insight provokes little change in the customary life adjustment. The entire therapeutic process is intellectualized, the patient perhaps using insight to fortify himself or herself against anxiety. The patient's relationship with the therapist never proceeds to a level of good feeling that is shorn of hostility and inordinate expectations.

In infantile, narcissistic character structures particularly, intellectuality serves as a defense against unconscious impulses. Habitually there is a repression of the feeling aspects of the patient's personality, and mastery is sought through intellectual control. Any experience of feeling is regarded as catastrophic. By a curious transformation the defense itself may become a vicarious means of gratifying non-permissible drives as represented in hostile and sexual impulses.

Patients, who have a tendency to isolate emotional components from emerging unconscious material, may make the latter acceptable to themselves by repressing the affective content. Frequently they strive to neutralize their panic by means of attempted foresight and reason. During therapy they give the impression of being very active and at first seem to work extraordinarily well. Even though they make a brilliant feat of minutely analyzing their inner mental processes, little change occurs. Such patients may involve the therapist in long dialectic arguments that take on the nature of debates. Words replace action and constitute a defense against feelings.

Interpretation of this type of defense is bound to create great turmoil in the patient. The patient is prone to feel attacked and criticized by the therapist. "Negative therapeutic reactions" are common, the patient responding to important interpretations not with insight or relief, but with depression and discouragement. Hostility may be directed at the

therapist in an effort to annihilate the therapeutic work.

It is essential to remind every patient not to get too distressed if cure is not immediate. Some patients are confounded and depressed when they find, in spite of therapy, that they go on reacting in their usual ways. It may be necessary to explain that reaction patterns that have become established over a long period cannot be removed in a few sessions. They are habits that call for extended working through and reeducation.

In the event the patients insist they cannot get well because they are hopeless, the therapist may say, "You can express your hopelessness, but I will not go along with it. You can spend your energies feeling hopeless, and you don't need me for this; or you can spend your energies doing something about getting well in which case I can help you."

ILLUSTRATIVE CASE MATERIAL

Example 1

In this session, a female homosexual patient with a problem of dysphoria introduces a number of different resistances that block her progress.

> *Pt.* I keep losing my keys constantly. My mind can't seem to concentrate lately. I notice that the only time I want to think about my problem is when I come here. The minute I get out I feel relieved. When I leave here I notice my hands as very cold. *[This sounds like resistance in the form of intellectual inhibition.]*

> *Th.* I see. Can you tell me more about this?

> *Pt.* When I get out of the office, in waiting for the elevator, I push myself up against the wall pretending the wall to be Helen *(the patient's homosexual love object)*. I actually kiss that wall and I say, "Who does he think *he* is, trying to pull me away from my darling Helen. I won't have it, I just won't have it." *[This device seems to be a magical way of neutralizing therapy, which she interprets as a threat to her homosexuality.]*

> *Th.* What does it remind you of when you do that?

> *Pt.* Like being united with my mother. Everything seems to be O.K. again, and I can go on living. *[Having lost her mother in childhood, the patient's homosexuality, in part, is a neurotic attempt to reunite herself with her mother.]*

> *Th.* Mm hmm.

Pt. You see. I do that.

Th. But why do you think I want to take you away from your mother?

Pt. I see that. You see, the information I get here, I feel, is going to get rid of the old regime and bring on a new regime.

Th. And the old regime is what?

Pt. Homosexuality. That's strong. It's easier to live in than the new regime.

Th. And the new regime?

Pt. Is getting rid of the mother fantasy and working it out.

Th. So that you would consider any insights that you get here in a certain way.

Pt. As dangerous to my ability to function *(pause)* for the moment.

Th. So when you come here, I upset the balance and you may want to go to the opposite extreme.

Pt. I shift to the opposite extreme so I can function.

Th. You must perhaps think of me as a terrible person to do this to you. *[probing our relationship]*

Pt. You are a horror, *(said facetiously)* I adore you, you know.

Th. You do? Why?

Pt. You know I do. *[Our relationship, though ambivalent, seems good.]*

Th. In spite of what I do?

Pt. In spite of it. (*coughs*)

Th. Maybe I better stop doing this to you. *[challenging her desire for health]*

Pt. Hell, no. I don't go wild. There is a certain amount of control.

Th. The fact that you know all the reasons that exist for your problem . . .

Pt. (*interrupting defiantly*) Doesn't do me any good.

Th. You are still the arbiter of whether you'll do anything about the situation or not. But at least you have the right to know all the facts. There is no magic about this. The whole thing is your choice. Nobody is going to take anything away from you, you don't want to let go of.

Pt. But I don't have the ability to make a choice rationally, *(yawns)*

Th. Right now your choice would be irrational?

Pt. Yes, I'd choose homosexuality. But, not really. You know, my mind is wandering. I'm trying not to listen to you. You know what I'm doing now? I'm trying to figure out my school homework. *[Patient is aware of her resistance.]*

Th. Not paying attention to what I'm saying.

Pt. Isn't that awful. First I yawn and then my mind wanders. And I wasn't even aware of what I was doing. *[Again she recognizes her resistance.]*

Th. But now you've caught yourself.

Pt. I caught myself.

Th. There must be a reason why it's dangerous for you to integrate what we talk about. *[pointing out possible reasons for her resistance]*

Pt. I just won't listen to you. *(coughs)* I'll bet this throat business has something to do with it. Obviously.

Th. You sense your own resistance. Do you want me to leave you alone?

Pt. No, no. But I do want to get well.

Th. It may take time for you to overcome this problem. It started far back in your childhood. And you have been reacting automatically since.

Pt. You know, I didn't hear a word you said. My mind keeps wandering, *[more resistance]*

Th. Do you remember anything we talked about the last session?

Pt. Nothing. My mind's a complete blank. I can't pull myself together at all. (*coughs*) And you know why I can't do this?

Th. Why?

Pt. Because you are sitting back and judging me on my little speeches.

Th. I'm judging you?

Pt. It's not true, but that's how I feel. I sort of feel I'm on trial and that I'm likely to do things wrong. The same thing happens when I get up and speak in class. It's funny that I don't remember a damn word of what you said today.

Th. How about what I said to you last time?

Pt. Oh, I remember that, but I can't put it together.

Th. Suppose you try.

Pt. It's like the only thing that can give me pleasure is my homosexuality and my torture fantasies with masturbation. I feel that you will take these from me. I say to myself that if I let you take these things away, the time will come when I'll need them and I'll be without them. Take life's last spark away.

Th. No wonder you can't concentrate here, if you think this is what really is going to happen. As if there can't be a good substitute for your present pleasures.

Pt. But it's not entirely what I feel because I do want to get well. But I can't seem to do it today. When I leave here, I suppose I'll kiss that wall to get my equilibrium back. Or I will get a hopeless desire and sexual attraction for you. I don't want to listen to what you have to say. I just want to be close to you. *[transference resistance]*

Th. In a way that's the same thing as clinging to and kissing the wall? (I am not trying to discourage her transference, but merely to control its intensity.)

Pt. It is exactly the same thing. It's the same thing I have about Helen. Intellectually I'm not interested. I want to get into bed with her. So stop talking and let's have sex. That's how I feel about you. Same kind of feeling.

Th. Sex appeases your tension? Is that what you really want exclusively?

Pt. Obviously not, but I can see how this operates. And another crazy thing I do. When I leave here and get onto the street, I imagine you are watching me from the window. I get into my car and roar off.

Th. What does that mean to you?

Pt. It's like I get my masculinity back again.

Th. Which means you feel you lose it when you come here?

Pt. (laughs) Yes, I really do. I know that's silly. I say, "I'll show him. I'll roar off. I'll show him he can't make me into a woman." I try to get my feeling of power. (*laughs*) How silly can you get?

Example 2

A patient comes in with a hoarseness so severe that she can hardly talk. This symptom came on her several hours prior to her session and was not accompanied by any other signs of a head cold. Exploration reveals the symptom to be a manifestation of various resistances.

Th. I wonder if you have been at all emotionally upset prior to this hoarseness, *[focusing on possible emotional sources of the symptom*]

Pt. I don't know what you mean.

Th. Are you aware of anything emotional that is happening right now? (*long pause*) What about your feeling about therapy?

Pt. The only thing I can say now, which is nuts, is that I'm scared to death of you. *(pause)*

Th. The way you look at me is suggestive that you are afraid of me. (*The patient has a frightened expression on her face.*)

Pt. I was always aware that I had a tenseness before, but it never was like this. (*The patient is so hoarse it is difficult to make out what she is saying.*)

Th. What do you think this is all about?

Pt. I don't know, *(pause)*

Th. Have you had any dreams?

Pt. Yes, I had one dream I can hardly remember. It's scrambled, *(pause)* I dreamed I was in some sort of clinic. It was your clinic. *(pause)* And there was a young chap there who was very attracted to me. He was there for treatment too. I liked him, and he liked me. But I was a patient at the clinic and I was working there, both. I talked to a group of people on the stairs. You were there as an onlooker in a benevolent way. And I was kidding. I said I want to go to Paris and live a couple of years. But this guy I liked and I decided we would have to take you with us. We have to take Dr. Wolberg with us because we have to finish this treatment. I looked at you and said, "That's involved for you, isn't it?" You laughed. It was all said in fun. Then this young chap and I decided to go home, and we walked and walked. And all of a sudden it occurred to me that I was walking without any trouble at all. *(Among the patient's problems are muscular pains and arthritis complaints in both legs which make it hard for her to walk.)*

Th. Mm hmm.

Pt. (pause) And then I was back in the clinic, and this young chap said he wanted me to do his analysis. I said that's impossible. And he sort of grinned at me and disappeared out of the door. That's all I can remember. *[The thoughts that come to my mind are that the patient may represent herself in the dream as her feminine component and the young man as her masculine component. She wants to return to narcissism (loving the man) and feels she can function this way (being able to walk). However, she is unwilling to give up her dependency on me (returns to the clinic) and she relinquishes her masculine component (the man disappears out of the door). Another possibility is that the young man is a disguised symbol for me toward whom the patient feels she can express an erotic feeling. In this way she can dissociate her sexual feeling for me from her therapy. Working further on the dream may disclose its meaning.]*

Th. When did this dream occur?

Pt. Last night.

Th. What are your associations to it?

Pt. (pause) I'm blocked off on associations, *(pause)* I'm blocked off on thinking. I'm in a complete state of suspension, *[intellectual resistance]*

Th. What in the dream might give you clues about your fear of me? What might you be planning or thinking of that would make you afraid of me?

Pt. Well, when I said I want to go to Paris, I might want to run away.

Th. What does Paris mean?

Pt. If I could do what I want to do, I'd go to Paris for a couple of years. I love it, just adore it. I love the French people, their relaxation and acceptance. It was wonderful.

Th. What does Paris symbolize to you?

Pt. Fun and sex. It's a sexy place.

Th. And here you wanted to go with this young man.

Pt. Yes, he was cute. (*laughs*)

Th. Was there a sexual feeling about that dream?

Pt. Oh, yes, sure. I was all for this guy. I'll tell you who he was. I never thought of it until now. He was a guy I met at Bob's party last Wednesday night. He turned out to be a young psychiatrist, and he knew you. Which is connected with you. So there you are.

Th. So you really felt attracted to him.

Pt. Yes, but had to take you along.

Th. Why do you think you had to?

Pt. Obviously you two are the same.

Th. So that you may have sexual feelings for me and project them onto another person, or you have a fear of sex and also fear disappointment. [*tentative interpretation*]

Pt. {sighs) Couldn't that be the same thing?

Th. It might. There may also be a desire to leave your therapy and run off and have fun, and wonder about my disapproval of that. There may be many things. What do you think? *[tentative interpretations]*

Pt. Consciously I'm not aware of wanting to run away from therapy. It's very painful to me as you can see. I wouldn't be happy getting out of it; I'd only be happy getting through with it. But the sexual thing troubles me.

Th. What about any sexual feelings toward me?

Pt. I think I've always had that. I block off though and can't talk about it. It's almost impossible. [*She recognizes her resistance.*]

Th. What does talking about the feelings do?

Pt. Make me scared of you. I don't want to talk about it. I'm sure that's what's happening to me now, *(pause)* I'm just preventing talking, that's all. *(pause)* And I feel silly. [*This indicates an awareness that her hoarseness may be a form of resistance against verbalizing sexual feelings toward me.*]

Th. Silly about your feelings?

Pt. Mm hmm. *I* think it does. All my life I've covered up important things, so to let it out is an almost impossible thing. I talk about sex often in a pseudosophisticated way. I can make smart cracks faster than anybody I know, but it has nothing to do with me. To talk about my sexual feelings—no, no. The minute it touches me, I clam up.

Th. Yet you haven't been too inhibited in your sex life.

Pt. I think I was a great deal, even though I didn't act it. *(pause)* I just thought of a dream I had in which you kissed me. I told you about it two months ago. From that time on I haven't been able to talk about my sexual feelings for you.

Th. Mm hmm.

Pt. When I'm lonesome I say you are very attractive to me sexually, *(pause)* I feel sexual contact with you is forbidden, like it would be with a father. *(The patient's voice is much clearer now, as if her hoarseness is vanishing.)*

Th. If it's true that you feel extremely guilty about having sexual thoughts about me, that would cause you not to want to tell me your thoughts, [*interpreting her resistance*]

Pt. That comes close to it, I think. It's silly. *(laughs)* I'm beginning to see through you. *(The patient's voice is very clear at this point, her hoarseness having subsided considerably.)*

Th. What do you mean?

Pt. You're trying to make me talk about you. All right, *(laughs)* I have varying emotions about you. First, I say, "To hell with that bastard, I won't go back to see him." Then I say, "That's what he expects me to do, so I shall go back to see him." And then I say you are trying to be my friend, trying to do something decent. Then I get contrite about having had bad thoughts. All of which is a bunch of crap. I know it as well as you know it.

Th. So you must feel resentful toward me sometime.

Pt. I feel, *(long pause)* I feel now, and I have for the last few times I've seen you, that all of the threads that have bothered me have all come together in one knot, which knot has become

you. If I can get that knot untied, then I'll be free. All the other things that bothered me are minor. I'm pulling out everything I have to resist you.

Th. Resist me in what reference?

Pt. Horribly enough I'm afraid it's a resistance to getting cured, *[recognition of resistance of normality]*

Th. You sound disgusted with yourself.

Pt. I am.

Th. What might cure do to you?

Pt. Well, it could put me back to work. It could eliminate all my excuses for not doing things. It could make me take an aggressive and active role. It could make me stop drinking and take that fun away from me. It could make me take a decisive action about George *(her husband).* I've come through the labyrinth and I'm up to the door, and I'm just resisting like hell. *[The patient elaborates her many resistances against normality.]*

Th. You must be frightened. Because that door is the door people want to reach.

Pt. That's what I've been coming here to reach.

Th. And now that you're approaching it, you are a little afraid of it.

Pt. I'm scared as hell, but I'm beginning a little to understand it.

The following is an excerpt of the very next session that brings out some interesting points:

Pt. I had a very peculiar reaction. Of course, it is almost impossible for me to say it. a very peculiar reaction last time. And I don't know what it was that was said, whether it was something I said or something you said, I don't know. But it was something in connection with our conversation, our relationship. Then all of a sudden I got a "cat-and-canary" deal, which you knew perfectly well, because you couldn't help but see it on my face. I don't see how you couldn't, and then just as I left, I said, "I feel like you're laughing at me." I knew that you weren't laughing at me in the sense of being nasty, but you knew damned well I wouldn't tell you what was on my mind. And, of course, that's the hell of the "cat-and-mouse" thing, because I'm perfectly aware that you know what's on my mind. Or at least you know very well whether I'm holding something back and won't say it or not. And I know that you know; so, therefore, I get into one of these, as I say, "cat-and-mouse" deals.

Th. What makes you feel that I can read your mind, that I know what you're holding back?

Pt. I'll bet 99 times out of 100 you do. It's very difficult, and I feel very silly. Whatever it was, whether that was a part of it or something else, I got a reaction of being very silly and ingenue, and very ridiculous, and I couldn't get over that feeling. Now what tossed me into that?

Th. When did you get this feeling?

Pt. Sometime during the last part of our conversation last time. I don't remember very much what we said, only that I think you asked me how I feel about you.

Th. How *do* you feel?

Pt. Giddy.

Th. Giddy?

Pt. Yeah. I think when I use the word "silly" I probably mean that, *(pause)*

Th. How did you feel *I* must have viewed you? Was it that you thought *I* thought you were silly?

Pt. Yeah. I imagine that's it.

Th. Well, why?

Pt. *(pause)* My reaction when I left was that I wanted to put my arms around you and kiss you. Now whether that is a little-girl reaction or not, I don't know. But that was the feeling I had.

Th. You felt affectionate?

Pt. Yeah. And then I think that's probably why I felt embarrassed. I felt I *(laughs)* wanted to go over and sit on your lap, like a little girl, and I'm probably older than you are.

Th. You think I think you're silly if you want to do that?

Pt. Probably because I had the idea that you've been trying to make me grow up. And goddamn it, I don't want to grow up.

Th. If this is what you feel, this is what you feel. Let's try to understand it. Suppose you do feel like putting your arms around me or sitting on my lap. Do you think there is something wrong with that?

Pt. Apparently I do. I don't think so, but I *feel* there is. I must or I wouldn't react that way. And when I get the "cat-and-canary," as they say, the "cat-that's-robbed-the-canary-look" on my face, I usually have something in my head, which I entertain, which I think is not in order. *(pause)*

Th. You know it is rather interesting that you find it so hard to mention to me what had happened, *[focusing on resistance]*

Pt. Sometimes I'll go for months and won't mention some things to you. And it isn't because I want to hide something. That's the goddamned mechanism of this thing. I blurted out and told you the last time, but, of course, by the time I get to talking about things, it's just when I'm putting on my coat. Like last time I kicked myself around the block when I got outside. I thought, why that's perfectly silly, why shouldn't I have said that; I've said every other

goddamned thing. It's a wonder I came back today and said it. Because sometimes I might go for months and I might talk about every subject in the world. But some little thing like that which apparently has significance for me, I can't talk about.

Th. Perhaps it had such deep significance to you for a special reason?

Pt. Well, I find you attractive, *(laughs)* It's silly, but I have a thought it would be nice ... last time what I failed to say was that I thought it would be nice to go to bed with you. But it kills me to tell you that. [*sexual transference*]

Th. Perhaps you wonder what my reaction would be.

Pt. I can remember one instance now. I don't suppose it was the type of person. It was probably the way I was feeling at the time. But usually men have approached me and I pretty much took what I wanted and left what I didn't want alone. That's always the case. A few times I thought someone was awfully cute, and I have deliberately gone after it, trying to look undeliberate. The exception was this once, and I can't remember who this man was. I think I'd read it in a novel, and I decided to try to ask a man to sleep with me, and did. And the result was disastrous. He ran like he was hit by a poisoned arrow.

Th. I see.

Pt. This guy ran. I don't think I ever did see him again. I remember now. Yeah. To show you that I'm embarrassed about it, I can't remember his name. Anyway, he was a guy that I went to Viriginia with. I was going on my business. He was going on his business. He was trying to make a business deal with me. He was very good looking, and he was my type. He was dark and not too damned tall and big, and I thought he was very attractive. I had lunch with him several times. And so I was going to Richmond. And I said at lunch one day that I was going to go to Richmond on such and such a day. And he said, "What are you taking?" And I told him the train number. And I got on the train, and he had the compartment right next to me. That I've never figured out. Maybe it was just luck. So anyway, he started making love to me. He came in to my compartment, and we were having a couple of drinks, and we were talking. And he started making love to me and all in a roundabout way, an inch at a time, an inch at a time. He put his arms around me first, and all the powwow they go through. So I thought this is going to be silly. I'd been thinking about it for weeks. That looks good. I'd like to have that when I can get a hold of it. So I just turned and looked at him. I said, "You don't have to go through all this, because I *want* to sleep with you." And it scared the hell out of him.

Th. Do you feel that maybe you're afraid of being outspoken with me too?

Pt. Goddamn it, yes. (*laughs*) I see it now. I must be afraid. You will run off and leave me if I'm too outspoken. My parents never let me speak my mind. Everything I learned I got out of being on the go with the other kids on the street. *[We continue to explore her sexual feelings toward me.]*

The Management of Untoward Attitudes in the Therapist, Including Countertransference

Two people locked up in the same room are, sooner or later, bound to find their difficulties rubbing off on each other, each personality influencing the other. The patient will regard the therapist in many ways, such as (1) an idealized parental figure, (2) a symbol of the parents and of authority, and (3) a model after whom one seeks to pattern oneself. A therapist too responds to a patient in various ways. There is a tendency to project onto the patient one's own prejudices and values as well as to identify the patient with individuals from one's own past. The therapist's reactions are bound to influence those of the patient. In recognition of the fact that a therapist cannot truly act as a blank screen, no matter how thoroughly adjusted one is, many therapists have devoted themselves to a delineation of the clinical effects of what they have called *countertransference* (Balint & Balint, 1939; Berman, L, 1949; Bonime, 1957; Cohen, M, 1952; Gitelson, 1952; Heiman, P, 1950; Little, M, 1951; Orr, 1954; Rioch, 1943; Salzman, 1962; Tauber, 1964; Winnicott, 1949; Wolstein, 1959). The importance of countertransference is that it influences all forms of psychotherapy—supportive, reeducative, or reconstructive—sometimes to their detriment, sometimes to their benefit.

The idea that countertransference is always bad has in recent years been revised (see Chapter 5, 57). Countertransference may be used in a therapeutic way. Therapists, recognizing that their own neurotic feelings are being activated, may look not only into themselves, but also into what neurotic needs and drives in their patients are activating in their personal reactions. They may then bring up these provocations as foci for exploration. They may ask, "Is the patient aware of aberrant impulses and behaviors? What does the patient want to accomplish by them?" Confronting the patient with the behavior may have a therapeutic impact.

Accepting the benefits of some countertransference reactions, we shall in the

remainder of this chapter concern ourselves with its negative effects that account for a great many failures in psychotherapy.

Conceptions about countertransference are multifaceted. These range from the traditional idea that it is exclusively confined to feelings derived from repressed unresolved parental attachments (Winnicott, 1949) to strivings provoked by anxiety (Cohen, M, 1952) to the total range of attitudes of the therapist toward the patient (Alexander F, 1948). The tendency to dilute countertransference with reactions emerging from the habitual character structure has created some confusion. Befuddement also comes from the tendency to identify all positive or negative feelings toward the patient as forms of countertransference. The therapist as a functioning human being will have a warmth toward, a liking for, and empathy with patients—more with some than with others for realistic reasons. The therapist will also be candidly angry with certain actions of patients, the display of which toward the patient may not at all be destructive. Indeed, the patient may be traumatized by the therapist's failure to respond to provocations with justified indignation or rage. However, the reactions we are concerned with most in psychotherapy are responses of the therapist not justified by reality but which issue either out of the therapist's own transference or that emerge as expressions of the neurotic character structure. Therapeutic manipulations fostered by the therapist's needs, rather than by those of the patient, are bound to create rather than to solve problems (Lorand, 1963a).

Where disciplined in self-observation, the therapist may become cognizant of troublesome attitudes and feelings toward patients before expressing them in behavior. The more insight one has into one's interpersonal operations, the more capable one is of exercising any necessary control. Where there is little understanding of one's unconscious dynamisms, the therapist is most apt to respond with unmanageable negative countertransference.

An illustration of how countertransference may act to the detriment of therapeutic competence may be cited by the case of a male therapist who, well trained and endowed

with more than the usual warmth toward people, was able to achieve good results in psychotherapy with most patients. Notably defective, however, were his results with male patients who had serious difficulties with women. The therapist himself was involved in conflict with his wife, the details of which he was not at all loath to verbalize. This was undoubtedly a manifestation of his unresolved problems with women. Whenever his male patients divulged their difficulties with their wives, the therapist would immediately respond with rancor and vehemently denounce the chicanery of scheming females. This attitude, while temporarily comforting to some patients, ultimately resulted in their distrust of the therapist, engendered by a realization that they could never work through with him some of their basic life problems.

It is rare indeed that a therapist, irrespective of how free one is from personality blemish, can respond with completely therapeutic attitudes toward all patients. With some patients one may display an adequate degree of sensitivity, flexibility, objectivity, and empathy, so helpful to good psychotherapy. With other patients one may manifest a lack of these qualities and an inability to perceive what is happening in the treatment process. There will be a failure to recognize neurotic projections in the relationship, and to remain tolerant in the face of the patient's irrational and provocative behavior. Thus, infantile requests by the patient for exclusive preference, or sexual responsiveness, or expressions of resentment and hostility, or unfounded complaints of being exploited, may bring out in the therapist attitudes that interfere with a working relationship.

> If the analyst cannot identify with the patient, he will encounter difficulties, but identification in turn leads to other difficulties ... the analyst then experiences the patients' intense anxieties fears, rages, lusts and conflicts as his own, and unless he faces these problems and deals with them directly, he may resort to controlling devices to allay the patient's anxiety and his own—such as excessive tenderness or other devices similar to those employed by the patient's parents, or he may resort to primitive defenses similar to those used by the patient, especially paranoid defenses. (Savage, 1961).

Character distortions in the therapist will inevitably have an effect on the patient. Thus, a need in the therapist to be directive and authoritarian, while advantageous in supportive approaches, tends, in insight therapy, to interfere with the individual's growing sense of self, expanding assertiveness, and independence. Authoritarian attitudes also

pander to dependency strivings in the patient and coordinately nurture rebellious tendencies. Some therapists are driven by pompousness to make too early and too deep interpretations, which they hope will impress the patient with their erudition and perceptiveness. They may also attempt to force the patient into actions before the latter is ready for them. However, this playing of a directive role with the patient to satisfy certain emotional needs in the therapist must not be confused with a deliberate extension to the patient of emotional support when this is therapeutically indicated. The former is usually based on the motivation to parade one's power and omniscience; the latter is a studied, measured giving of help that is inspired by the needs of the patient.

Tendencies toward passivity and submissiveness in the therapist may also have a detrimental effect on treatment since it is sometimes necessary to be firm with the patients, as in helping them to avoid retreat, to execute insight into action, and in offering them essential guidance and reassurance. Submissive traits in the therapist, furthermore, operate to bring out sadistic, hostile attitudes in the patients.

Impulses toward detachment may develop in the therapist as a defense against entering into close contact with some patients. This trait is particularly destructive to the therapeutic relationship. The patient may be able to establish some sort of relatedness with a domineering or a passive therapist, but is totally unable to relate to one who is detached.

A therapist who, because of personal anxiety or a depriving life situation, is thwarted in the expression of certain basic drives may attempt to live through them vicariously in the experiences of the patient. The therapist may, therefore, tend to overemphasize certain aspects of the patient's behavior. Thus, if the patient is in a position of fame, or is financially successful, or is expressing sexual or hostile impulses, the therapist, if there is the unconscious need to satisfy such strivings, will focus unduly on these perhaps to the exclusion of other vital psychic aspects. This loss of perspective is particularly pronounced where there is any overidentification with the patient.

Neurotic ambitiousness may cause the therapist to glory in the patient's

accomplishments and to push the patient inexorably into areas that are calculated to lead to success and renown. Overambitiousness may also be extended toward seeking rapid results in treatment. Here the therapist will be unable to wait for the gradual resolution of resistance. Accordingly, the exploratory process will be promoted too hurriedly at the beginning of therapy. Perturbed by the slowness with which the patient acquires insight, the therapist may interpret prematurely, and then respond with resentment at the oppositional tendencies of the patient. The therapist may also propel the patient too vigorously toward normal objectives and then become frustrated at the patient's refusal to utilize insight in the direction of change.

Due to anxiety or guilt, it may be difficult for the therapist to countenance certain needs within himself or herself. When such needs appear in the patient, the therapist may exercise attempts to inhibit their expression. Difficulties here especially relate to impulses toward sexuality, hostility, and assertiveness. Should the patient introduce these topics, the therapist may act disinterested or may focus deliberately on another area. The therapist may be unaware of these personal psychic blind spots that prevent exploring anxiety-inspiring conflicts in the patient. Thus, a therapist who has problems in dealing with hostility, may, upon encountering hostile expressions, reassure the patient compulsively or channelize verbalizations toward a less threatening topic. Fear of hostility may also cause the therapist to tarry, to lose initiative, and to evidence confusion on occasions when the patient attempts to act in an aggressive or assertive way. Fear of special aspects of the patient's unconscious may cause the therapist to circumvent the discussion of pertinent material to the detriment of reconstructive therapeutic goals.

Other limiting personality manifestations may reflect themselves in neurotic attitudes toward money with an overemphasis of fees and payments, in an inability to tolerate acting-out tendencies in the patient, and in a tremendous desire for admiration and homage. Perfectionistic impulses may cause the therapist to drive the patient compulsively toward goals in treatment that are beyond the patient's capacities. At times some therapists, under pressure of their own neurotic drives, may set up a situation in treatment that parallels closely the traumatizing environment of the patient's childhood.

When this happens, the patient's transference may become extreme and perhaps insoluble. Certain patients may mobilize in the therapist strong feelings of rejection and intolerance, which will destroy the emotional climate that is so important for personality development. Other therapists, burdened with narcissism, and needing to impress the patient constantly with their brilliance, may utilize interpretation too freely and water down the therapeutic process with intellectualizations.

It must not be assumed that all neurotic displays on the part of the therapist will have a bad effect. If they play into the patient's immediate needs, they may bring the patient to a rapid homeostasis. Thus, a sadistic therapist may be eagerly responded to by a masochistic patient. An authoritarian, domineering therapist may satisfy the dependent impulses of a depressed person. Restoration of equilibrium will not, of course, alter the basic personality structure. Important to consider also is that growth in a psychotherapeutic relationship with a neurotic therapist may occur in patients with essentially good resources. Such patients will select out of positive aspects of the therapeutic situation elements that they can utilize constructively. They may rationalize the therapist's neurotic weaknesses, or not pay attention to them, or simply blot them out of their cognitive field. It is to be expected that perceptive patients will eventually discover some neurotic patterns or traits in their therapists. This may at first result in disillusionment, anxiety, resentment, or insecurity. If the relationship is a good one, however, there need be no interference with the therapeutic process, the patients ultimately adjusting themselves to the reality of a less-than-ideal therapist image. It may actually be helpful to discard the mantle of perfection with which the therapist has been draped in the early part of therapy. The degree and kind of neurotic disturbance in the therapist is what is important.

At certain phases in treatment therapist improprieties may become more pronounced than at others. For instance, during periods of resistance the therapist may respond with aggressive or rejecting behavior. Some actions of the patient may also stimulate countertransference. A patient who is frankly seductive may stimulate sexual feelings in the therapist; one who is openly antagonistic may precipitate counterhostile

attitudes. The patient may be sensitive to the moods of the therapist and work on these for specific gains, the most insidious effect of which is a sabotaging of the treatment effort.

Because countertransference may result in therapeutic failure, it must be handled as soon as possible. Where recognized, the therapist may be able to exercise some control over it. There are therapists, who, though unanalyzed themselves, have an excellent capacity for self-analysis and an ability to restrain annoying expressions of countertransference. This permits the therapeutic process to advance unimpeded. A therapist who has undergone successful personal psychotherapy or psychoanalysis will still be subject to countertransference from time to time. Nevertheless, one should, by virtue of one's training, be capable of detecting and of managing troublesome reactions as soon as they develop.

Instead of denying a neurotic response to the patient, which is so common, some therapists, detecting their own untoward responses, admit them openly and even analyze them with the help of the patient. Alger (1964) suggests that the therapist should "deal with these feelings in no way different than he deals with any other of his reactions. By this is meant that he be willing to include all the reactions he has while he is with his patient as part of the analytic data of that particular situation. ... In this view, the analysis then becomes a joint activity in which two participants attempt by mutual effort to assemble and openly share with each other their perceptions, their concepts, and most importantly their own feelings." Such therapeutic license will call for great skill on the part of therapist, to say nothing of personal courage.

One way of acquiring this skill is to examine oneself honestly rather than defensively when attacked or criticized by a patient. To be sure, it is impossible for a therapist to maintain a consistent attitude toward or interest in patients at all times. Names and events may be forgotten, indicating to the patient lack of rapport; appointments may be broken or confused, connoting unconcern; irrelevant comments may be made, pointing to "noncaring-ness"; tension and anxiety may be expressed, suggesting instability. Irrespective of the reasons for the therapist's reactions, awareness of what one is doing

and willingness to admit one's failings when they are discerned by the patient is of paramount importance. There is nothing so undermining to a patient as to have an observation, predicated on fact, dismissed as fanciful, or to have an obvious error on the part of the therapist converted into a gesture for which the patient is held responsible. Where the therapist is capable of admitting a blunder and of conveying to the patient that this does not vitiate respect and interest, the liability may actually be converted into an asset.

Certain therapists have taken this as license to articulate every aberrant thought and impulse to the patient, and even to act out with the patient. While this may be accepted by some patients as indications of the therapist's genuineness, it is destructive for most patients who expect the therapist to function as a rational authority. Therapists who are basically detached, and who are obsessively preoccupied with neurotic impulses, may, nevertheless, come through to the patient more sincerely as people when they engage in such random and undisciplined behavior than when they assume the straitjacket of a "therapeutic" attitude. From this experience of unrestraint, however, they may devise a theory and formulate methodologies, predicated on being free and abandoned in the therapeutic relationship, a stance that for most professionals will prove to be antitherapeutic.

Detection of countertransference and character distortions may not be possible where deep unconscious needs are pressing. It is this unawareness of their inner drives that so frequently causes therapists to rationalize them. Indeed, the very selection of certain methodologies and kinds of therapeutic practice are often determined by unconscious motivations. Thus, a therapist, basically passive, who fears human contacts and has evolved a detached manner as a defense, may be attuned to schools in which extreme passivity and nondirectiveness are the accepted modes. Or, if by personality domineering and aggressive, a therapist may be inclined toward endorsing the doctrines of those schools that advocate directive or coercive techniques.

MANAGEMENT OF COUNTERTRANSFERENCE

Those aspects of countertransference that reflect the projection of a patient's unconscious process may enable a sensitive therapist to detect unverbalized needs and conflicts. How to deal with countertransferential feelings constructively will depend on how skillful the therapist is in making interpretations and the readiness of the patient to accept such interpretations. It is essential that confirmation of the therapist's intuitive hunches be obtained from other sources of information such as the patient's nonverbal behavior, dreams, slips of speech, free associations, and acting out episodes. The therapist may have to delay interpretations until a strategic time presents itself. The manner in which interpretations are made will also determine how they will be accepted (see Chapter 45).

Some of the patient's actions may stir up realistic angry feelings in the patient that have nothing to do with countertransference. Here it is necessary to judge how propitious a disclosure of such feelings may be. It is sometimes important to verbalize one's angry feelings toward a patient who is behaving in a self-defeating and provocative manner, especially when there is no need to build up a transference neurosis. Such verbalization is not done in a punitive way, but rather as a means of bringing the patient to an awareness of how the patient comes through with people and why reactions toward him or her are less than congenial. Where the patient is in a negative transference toward the therapist or the transference is acting as resistance to therapy, the therapist must control angry feelings and work on the interpretation of the transference to get therapy "back on the tracks."

Since some negative countertransferential reactions are unavoidable, most likely breaking through when the therapist's emotional reserve is taxed or when the therapist is distraught and upset, the question arises as to what one can do to neutralize their antitherapeutic effect. Signs of countertransference include impatience with the length of a session or resentment at having to terminate it, doing special out-of-the-ordinary things for select patients, dreaming about a patient, making opportunities to socialize with the patient, sexual fantasies about the patient, unexplained anger at the patient, boredom with the patient, impulses to act out with the patient, and refusal to terminate when planned

goals have been achieved.

In order to become sensitized to one's own neurotic manifestations when they appear, all therapists should subject themselves to self-examination throughout the course of therapy. Such questions as the following are appropriate:

1. How do I feel about the patient?

2. Do I anticipate seeing the patient?

3. Do I overidentify with, or feel sorry for the patient?

4. Do I feel any resentment or jealousy toward the patient?

5. Do I get extreme pleasure out of seeing the patient?

6. Do I feel bored with the patient?

7. Am I fearful of the patient?

8. Do I want to protect, reject, or punish the patient?

9. Am I impressed by the patient?

Should answers to any of the above point to problems, the therapist may ask why such attitudes and feelings exist. Is the patient doing anything to stir up such feelings? Does the patient resemble anybody the therapist knows or has known, and, if so, are any attitudes being transferred to the patient that are related to another person? What other impulses are being mobilized in the therapist that account for these feelings? What role does the therapist want to play with the patient? Mere verbalization to oneself of answers to these queries, permits of a better control of unreasonable feelings. Cognizance of the fact that one feels angry, displeased, disgusted, irritated, provoked, uninterested, unduly attentive, upset, or overly attracted may suffice to bring these emotions under control. In the event untoward attitudes continue, more self-searching is indicated. Of course, it may be difficult to act accepting, non-critical, and nonjudgmental toward a patient who is provocatively hostile and destructive in attitudes toward people, and who possesses

disagreeable traits that the therapist in everyday life would criticize.

The ability to maintain an objective attitude toward the patient does not mean that the therapist will not, on occasion, temporarily dislike many of the things the patient does or says. Indeed, one may become somewhat irritated with any patient on certain occasions, especially when being subjected to a barrage of unjust accusations, criticisms, and demands. The stubborn resistances of the patient to acquiring insight and to translating insight into action, and the clinging of the patient to attitudes and action patterns that are maladaptive and destructive, will tax the endurance of any therapist, no matter how well integrated one's personality may be. But the capacity to understand one's own feelings will help the therapist better to tolerate the neurotic strivings of the patient and to maintain a working relationship.

To illustrate how a therapist may control countertransference, we may consider the case of a patient who is having an affair with the wife of his best friend and feels exultant about this situation. The therapist, repulsed by the enthusiasm and sexual abandon displayed by the patient, may, therefore, have a temptation to interpret the situation as a disgraceful one, with the object of putting pressure on the patient to give up his paramour. With this in mind, the therapist may enjoin, order, or suggest that the patient stop seeing the woman in question or desist from having sexual relations with her. Should the therapist step in boldly in this way, the interference will probably be resented by the patient. Indeed, transference may be mobilized, the patient regarding the therapist as a cruel, depriving, dangerous mother or father who prohibits sex or freedom. An artificial note will thus be injected into the relationship, the patient utilizing his affair as a means of defying the therapist. Not only will the patient continue in his infatuation, but the therapeutic situation may deteriorate. Or the patient may yield to the therapist's suggestion and give up the relationship with the woman and then become depressed and detached, as if he has been forced to relinquish something precious. He will feel that his independence has been violated.

In attempting to control one's responses, the therapist may indulge in self-searching.

Realizing moralistic attitudes, the therapist is better capable of keeping in the forefront the general principle that, right or wrong, the patient is the one who must make the decision about continuing in the affair or giving it up. Accordingly, instead of suggesting to the patient that he stop the illicit relationship, the therapist may say:

"Now here is a situation that seems to have a good deal of value for you. You get fun out of seeing your friend's wife, but you also see that there are difficulties in the situation. Now suppose we discuss the good and bad sides of your predicament." The patient then will verbalize his feelings about the virtues as opposed to the liabilities of his intrigue. Thereupon, the therapist may remark: "Here, you see, there are values as well as liabilities in the situation. It is important for you to consider all the facts and then decide the course of action you want to take." In this way the therapist strives to keep personal feelings from influencing the patient. The patient is then better equipped to evaluate what is happening and to plan his own course of action.

It is unnecessary for therapists to feel that they must strap themselves into an emotional straitjacket to avoid upsetting the patient. Nor is it essential that they be paragons of personality virtues to do good psychotherapy. As long as one is reasonably flexible, objective, and empathic, and provided that a working relationship exists, one may indulge a variety of spontaneous emotional responses, even some that are neurotically nurtured, without hurting the patient or the therapeutic situation. Actually, the patient will adjust to the therapist's specific personality, if it is sensed that the therapist is a capable, honest, non-hostile person who is interested in helping the patient get well.

For example, a therapist may be inclined to be active and somewhat domineering. The patient may then exhibit toward the therapist the usual attitudes toward domineering and authoritative people: the patient may become fearful, or hostile, or submissive, or detached. As the therapist interprets these reactions without rancor, the patient may challenge the therapist's overbearing manner. The therapist, if not threatened by this stand, will acknowledge the operation of some domineering tendencies. The very fact that the therapist admits responsibility, may give the patient a feeling that he or she is not

dealing with the image of imperious authority. The patient may then question the facades and defenses that automatically are employed with authority, and may countenance a new kind of relationship. In working out this aspect of the problem, the patient will undoubtedly see connections with other personality facets and begin working on these also.

If, on the other hand, the therapist acts in a passive, retiring way, basic attitudes toward passive people may emerge. Thus, the same patient may become disappointed, sadistic, or depressed. The therapist, observing such reactions, will be able to bring the patient to an awareness of why these tendencies are being manifested. The patient will learn by this that the therapist is really not an inconsequential person, in spite of a quiet manner. Indeed, the patient may discover personal qualities of need for a godlike authority as well as contempt for any lesser kind of human being. An important aspect of the problem will then be resolved. With this resolution other aspects will come up for consideration, such as the patient's attitudes toward domineering people. Thus, even though the patient deals with two entirely different reactions on the part of the therapist, basic difficulties will have been managed and hopefully worked out.

What is important, therefore, is not whether the therapist has an impeccable personality that admits no negative countertransference, but rather that prevailing distortions can be sufficiently reduced, controlled, or explicated to provide the patient with a suitable medium in which to work through neurotic patterns.

A basic assumption in insight approaches is one made originally by Freud that was to the effect that once the individual becomes aware of unconscious motivations, one can then alter one's behavior and get well. That this fortunate consequence does not always follow (a circumstance also recognized by Freud) is the disillusioning experience of many young therapists, who have predicated their futures on the premise that analysis of resistances will inevitably bring forth insight and cure like a sunbeam breaking through a cloud.

The fact that a patient acquires a basic understanding of the problems and delves into their origins as far back as childhood, does not in the least guarantee being able to do anything about them. Even if an incentive to change is present, there are some patterns that cling to a person obstinately as if they derive from a world beyond the reach of reason and common sense. The patient is somewhat in the position of the inveterate smoker who has been warned by the physician to give up tobacco at the risk of an early demise, or of the obese hypertensive who pursues gluttony with avidity while reviling his or her weakness and lamenting an inevitable doom. Chided by the physician to reduce weight to avert the threat of a coronary attack, the patient is unable to avoid overstuffing with the foods marked taboo on the reducing chart, irrespective of how thoroughly the patient appreciates the folly of intemperance. In the same way, repetitive compulsive patterns lead an existence of their own seemingly impervious to entreaty or logic.

Complicating this enigma further is the fact that the acquisition of even inaccurate insights may register themselves with beneficial effect, particularly if the therapist interprets with conviction and the patient accepts those pronouncements on faith. Marmor (1962) has implied that "insight" usually means the confirmation by the patient of the hypotheses of the therapist that have been communicated by various verbal and nonverbal cues. Having arrived at a presumably crucial understanding as indicated by

approving responses from the therapist, the patient experiences what is essentially a placebo effect. The restoration of the sense of mastery reinforces further belief in the validity of the supposition, and encourages the patient to search for further validations, which most certainly is bound to be found by the patient in the suggestive pronouncements of the therapist.

One of my patients reported to me what he considered a significant flashback that almost immediately resolved his anxiety: "This," he avowed, "was a cock-sucking experience I reconstructed from what must have happened to me in childhood. It involved an affair with a Chinaman. My father gave me shirts to take to the Chinaman who had a laundry nearby. I got the slip, but when I brought my father along to collect the laundry, I took him by mistake to another Chinese laundry. My father had a fight with the Chinaman over the slip. Then I remembered and brought my father to the right laundry. We lived in Cleveland at the time. That's why I know it happened before I was 6. Seems young to be running errands, but I had a dream that convinced me that the Chinaman sucked my cock. I remember he gave me lychee nuts."

This memory served to convince the patient that he now had the key to his fear of wandering away from home and his sexual problems. It required no extensive work to reveal this bit of insight as false, although it had a most astonishing effect on the patient.

This does not mean that some of the insights patients arrive at may not be correct. But not too much wisdom is needed to recognize that, with all of the doctrines of psychodynamics current among contemporary schools of psychotherapy, each one of which finds its theories confirmed in work with patients, factors other than their precepts, reflected as insights, must be responsible for at least some of the cure. The nonspecific windfalls of insight do not invalidate the specific profits that can accrue from a true understanding of the forces that are undermining security, vitiating self-esteem, and provoking actions inimical to the interests of the individual.

In opening up areas for exploration, a therapist should, in the effort to minimize false insight, confine oneself as closely as possible to observable facts, avoiding speculations as

to theory so as to reduce the suggestive component. The more experienced one is, the more capable one will be of collating pertinent material from the patient's verbal content and associations, gestures, facial expressions, hesitations, silences, emotional outbursts, dreams, and interpersonal reactions toward assumptions that, interpreted to the patient, permit the latter to acknowledge, deny, or resist these offerings. Dealing with the patient's resistances, the therapist studies the patient's behavior and continues to reexamine original assumptions and to revise them in terms of any new data that come forth.

The collaborative effort between patient and therapist made in quest of insight is in itself a learning experience that has an emotional impact on the patient that is at least as strong as any sudden cognitive illumination (Bonime, 1961). Malvina Kramer (1959) has pointed out that "what appears from the patient-analyst viewpoint to be a matter of insight and intrapsychic rearrangement turns out to be a far more complex process which depends on fields of multiple interaction on many levels."

Improvement or cure in psychotherapy may be posited on the following propositions:

1. The patient successfully acquires an understanding of the nature of the problem by developing the capacity to conceive of it in terms that are meaningful.

2. On the basis of this understanding, the patient begins to organize a campaign of positive action, acquiring symbolic controls, replacing destructive with adaptive goals, and pursuing these in a productive way.

True insight is helpful in this process. It acts as a liberating and an enabling force; it upsets the balance between the repressed and repressing psychic elements; it creates motivations to test the reality of one's attitudes and values; it gives the person an opportunity to challenge the very philosophies with which one's life is governed. But insight is not equivalent to cure; by itself it is insufficient to arrest the neurotic process and to promote new and constructive patterns.

Indeed, the development of insight may surprisingly produce not relief from distress, but an accentuation of anxiety. The ensuing challenge to change one's modus

operandi, and the sloughing off of neurotic protective devices make the possibility of exposure to hurt all the more real. No longer is one capable of hiding behind one's defense mechanisms. One must tear down one's facades and proceed to tackle life on assertive terms. Prior to acquiring insight, one may have envisaged "normality" in fantasy as a desirable quality, but the approaching new way of life fills the individual with a sense of foreboding.

Thus a man with an impotency problem may learn in therapy that his impotence is a defense against a fear of being mutilated by destructive, castrating women. Realizing that his defense is realistically unfounded, he must still expose himself to intercourse. This will continue to be extremely frightening to him until he convinces himself,. through action, that the imagined dangers will not come to pass. A woman, working in an advertising agency, may discover that a fear of competition with men is associated with her repudiation, on the basis of anxiety, of a desire for masculinity. Her knowledge then opens up the possibility of her being able to stand up to men. Specifically, she may practice her new insight on a man in her office who has advanced himself professionally over her, because she had assumed a retiring and passive attitude. The understanding that she is playing a role with men akin to the subordinate role she had assumed as a child with her brother does not ameliorate the anxiety that she feels at having to compete with her office associate.

To protect themselves from facing the threatened perils of action, patients may throw up a smokescreen of resistance. They may reinforce old and employ new defensive mechanisms. They may devaluate strivings for health even though these had constituted strong incentives for starting therapy. The original motivations may be submerged under the anxiety of impending fulfillment and the patients may then interrupt treatment.

It is an unfortunate fact that only too often does therapy grind to a halt at a point where insight must be converted into action. The impediment encountered by the patient is complicated by resistance against releasing intolerable unconscious fantasies associated with action. In psychoanalysis action inhibition may symbolically be repeated in

transference, and analysis of the resistance may liberate the patient. The therapist, while permitting the verbal expression of the unconscious fantasy in the relationship, does not participate in it; nor does the therapist encourage its sexual or hostile acting-out. Any interventions are predicated on the patient's need, not the countertransferential demands of the therapist. But even under those circumstances translation of insight into action may fail.

MODERN LEARNING THEORY AND PSYCHOTHERAPY

The difficulties that invest the resolution of old patterns and the elaboration of new ones make it necessary for therapists to use every stratagem at their disposal. Since psychotherapy involves a learning process in which the patient acquires abilities to abandon neurotic adjustment in favor of an adaptation consonant with reality, it may be interesting to consider the therapeutic situation in the light of a theory of learning. A number of attempts have been made to coordinate psychotherapy with the principles of modern learning theory. None of these has proven successful since the various propounded theories—including the stimulus-response and cognitive theories—are unable to account for the complexities of ego functioning, both normal and pathological. The ego seems to operate under laws of its own that have scarcely been embraced by any of the learning theories. Furthermore, there are various kinds of learning to which different postulates may be applied. The unsolved problems of learning would seem too diffuse to permit of any real application of learning theory to the phenomena of psychotherapy.

It may be helpful, nevertheless, to consider a number of well-known learning principles and to attempt to apply them to psychotherapeutic situations.

Learning is most effective where the individual participates directly in the learning experience. For this reason, the greatest impact on a patient is registered by patterns that come out during the encounter with the therapist—patterns that are a product of the collaborative relationship. Such a learning experience gives the patient a basis on which to reconstitute ideas of reality. It permits the patient to experiment with

the therapist as a new kind of authority in association with whom the patient can evolve a more wholesome image of the self.

This eventuality, however, does not always develop in therapy, and when it happens, it does not guarantee an integration of understanding toward productive behavioral change. First, the patient may have an investment in the maladaptive patterns that subserve spurious security needs. To give them up exposes the individual to fantasied dangers or to deprivations. For example, a homosexual man may learn that he seeks in the homosexual relationship a virile image to repair his own damaged genitalia. He learns also that avoidance of women is both a safety measure to withdraw him from competition with other men and a way of preventing his being overwhelmed and infantilized by a mother figure. These insights do not subdue his intense sexual interest in males nor stop him from seeking men as a source of gratification. They do not lessen his disgust toward women, with whom he continues to maintain a casual, detached, demanding, or hostile relationship.

A second factor that may hinder the occurrence of a meaningful learning experience in therapy is the fact that a patient's reactions may have become so automatic and conditioned that knowledge of their unreasonableness does not suffice to inhibit them; they continue in an almost reflex way. One patient as a boy was constantly being taken to physicians by a hypochondriacal mother. Threats of operations were used as measures to exact the cooperation of the boy for various injections and diagnostic procedures. In later life, the patient developed a profound fear of doctors to a point where he refused to expose himself to essential medical contacts. An understanding of the sources of these fears, and an attempt to control them, did not inhibit explosive physiological reactions at the sight of a physician.

A third instance in which the learning experience in therapy may not be effective occurs when the attitudes and behavior of the therapist do not provide the conditions most conducive to change; because patterns, perhaps inspired by countertransference, may reinforce the patient's neurotic expectations. A woman patient, burdened in her work

by damaging competitiveness with other women and constantly involved in winning the attentions of her male associates through her seductive manner, realizes during therapy the origin of these drives in her competitiveness with her mother for her father's favors. Yet she may cleverly maneuver the therapist into acting overprotective and reassuring toward her by playing on the therapist's personal interest in attractive women.

Repeated attempts to execute healthy responses may lead to their reinforcement. Nevertheless, repeated practice of rational reactions does not necessarily inhibit neurotic responses. The power of the repetition compulsion often neutralizes effective learning. Thus, a man who compulsively fails as soon as success becomes imminent may, on the basis of insight into this distortion, force himself diligently to take advantage of any emoluments his life situation yields. Yet the impulse to fail will become so overbearing that he may yield to failure even while trying to succeed. Learning, nevertheless, goes on in the medium of neurotic relapse, provided that the individual is aware of what is happening and has ideas of why he needs to foster his failure. This working through is helped by the therapist who is in a position to be objective. It may be achieved by the person alone if he has the motivation to examine and to correct his behavior.

Learning is facilitated through satisfaction of important needs, such as gaining of rewards and an avoidance of punishment. However, in the light of our experiences in psychotherapy, we have to recast our ideas about rewards and punishments due to the disordered values of the patient. Rewards to a neurotic person may most keenly be the expressed residues of surviving infantile needs, such as dependency or defiance, which are more or less unconscious. They may be organized around maintenance of various neurotic mechanisms of defense that reduce anxiety. In the latter case the individual will develop not health-oriented behavior but more sophisticated methods of supporting defenses. Thus, a married man, pursuing at the sacrifice of his safety and economic security, a disturbed young woman, who constitutes for him a maternal symbol, is suffused with pleasure whenever the woman favors him with her attention. Due to her narcissism, immaturity, and fears of men, she rejects his advances, yet she demands that he protect

and support her. Fearful that he will lose her affection, the man yields to the unsatisfactory arrangement of financing the irresponsible expenditures of the young woman in the hope that she will eventually bestow her favors on him. His hostility and anxiety mount as he becomes more and more trapped by his dependence. In therapy what the man seeks is freedom from his symptoms and, covertly, expert stratagems of breaking down the young woman's resistance to loving him unstintingly. After a period in treatment, he learns the meaning of his involvement. The rewards that he obtains in integrating this learning is the immediate approval of the therapist and the promised reward that his symptoms will be relieved if he extricates himself from his untenable situation. These satisfactions threaten the rewards he really seeks in terms of overcoming the young woman's rejection of him and of establishing himself as her favorite "son" and lover. What he does then is to utilize his psychological insights to understand the reactions of his desired mistress in order to outmaneuver her. Momentary sexual yieldings are followed by her executing violent scenes and threats of separation, which, precipitating anxiety in the man, binds him more firmly in his enslavement. The punishment that he receives is really no deterrent to his continued acting-out of this drama. Indeed, it fulfills an insidious need to appease his guilt feeling. Thus, as in many psychological problems, punishment becomes a masochistic reward.

We cannot, therefore, apply the same criteria of rewards and punishments to the complex problems of learning in psychotherapy as we do to some other forms of learning. This is why conditioning techniques that are utilized in behavior therapy fail to influence certain kinds of neurotic disturbance. As the working-through process continues in treatment, the patient may, however, eventually rearrange his value systems. He may then approximate healthy goals as rewards and conventional pain and suffering as punishments. Conditioning under these circumstances may then prove successful.

Rational understanding is a *sine qua non* of learning. Rational understanding in itself, as has repeatedly been emphasized, does not seem to help many emotional problems. This is because behavioral change is predicated on complex rearrangements of thinking, feeling, and acting that are bound together in tangled disorder. We attempt a

disentwining of this complex yarn by plucking away at the surface strands. There may be no other way of getting at the disorganized psychosociophysiological structure. Hopefully, our efforts will be rewarded. Even from superficial intellectual unravelings behavioral, and even physiological, readjustments may ensue. As S. Freud (1928) once said, "The voice of the intellect is a soft one, but it does not rest until it has gained a hearing." Ultimately our therapeutic operations may overcome the tumultuous emotions of the psychologically ill individual. Unfortunately, patterns and values acquired early in life may obstruct meaningful adult learning. The most obstructive interferences are systems that have been repressed and yet obtrude themselves in devious ways. For example, sexual education as it is now being taught in high schools and colleges may have little impact on a young woman who has developed, as a result of childhood anxieties, the practice of shunting sexual material out of her mind. Defiance of authority, developed to preserve autonomy and to neutralize overprotective and interfering parental figures, may subtly block the incorporation of factual data. Perfectionistic tendencies and fear of failure, residues of a damaged self-image, may interfere with effective recall in situations where performance is a measure of self-worth. The powerful imprint of early impressions and experiences on the total behavior of the individual cannot be overemphasized, and learning may be blocked until some resolution of inner conflict has been instituted.

Is it completely hopeless, then, to try to take advantage of any basic learning propositions in order to expedite psychotherapy? Let us attempt to answer this question by considering some of the positive learning factors that Hilgard (1956) has described so well.

Motivation is important in learning. Individuals who are motivated to learn will apply themselves to the learning task and more readily overcome their resistances. Rewards are much more effective learning stimulants than are punishments. In psychotherapy, rewards may be offered to patients in the form of encouragement and approval when they have come to important understandings or have engaged in constructive actions. The benefits of their activities may be pointed out in terms of what progress will do for them.

When learning failures occur, the person may be helped to tolerate them by pointing out previous successes. In psychotherapy failures are inevitable, partly due to resistance and partly to the repetitive nature of neurotic drives. Reassurance of the patients when they become discouraged by failure and helping them to see why the failure occurred may encourage them to try again. The therapist may accent the patient's constructive activities that were initiated in the past.

Setting realistic goals during learning is an important step. Individuals may be unable to achieve success where their objectives are beyond their capacities or opportunities. Where their goals are too modest, also, they will not make the effort that would be most rewarding. In psychotherapy, where the therapist senses that the patient is overly ambitious and that his or her plans are unrealistic, it is essential that the therapist bring the patient back to earth. There are some memories the patient may be unable to recover, some patterns so imbedded in the past that they cannot be overcome. Pointing some of these facts out may prevent the individual from engaging in frustrating efforts that discourage productive learning. On the other hand, when the individual's targets are too limited, for instance, where one insists that one is so seriously and irretrievably ill that one cannot achieve certain gains or execute essential actions, the therapist has a responsibility in stimulating the patient toward more ambitious aims.

Learning is most effective where there is a good relationship with the teaching authority and where mutual respect prevails. This is, of course, the essence of good psychotherapy. Where habitual contacts with authority are predicated on fear, hostility, or excessive dependence, the patient will probably display these patterns, which will then inhibit learning. The patient may be diverted from the task of learning toward fulfillment of regressive needs in the association with the therapist. The therapist must be alert to these maneuvers and must constantly keep the working relationship at the proper pitch, devoting efforts to this above all other tasks.

Active participation by individuals in the learning process is more effective than a passive feeding of materials to them. If the learner is able to figure out facts and to apply

these to a variety of situations, he or she will learn most readily. In therapy problem-solving tasks are given to the patients; questions are directed at them; a thinking through of solutions is encouraged. The motto is "Let's figure this thing out together" rather than "Here are the answers." The patients are constantly encouraged to enter into new situations and to observe their reactions to these challenges.

Where learning materials and tasks are understood by individuals, they will integrate knowledge better than where these are meaningless. Knowledge of how to perform well in the learning task, recognition of errors in operation, and the understanding of what constitutes effective performance are most helpful. In therapy the treatment situation is structured for the patient; the purpose of different techniques is presented to the patient in terms that can be understood. There are a number of routines that may seem mysterious to the patient, for instance, the refraining from advice given and the employment of dreams. A careful explanation of their rationale is conducive to greater cooperation.

Repetition makes for the greatest success in learning. Where recall can be spaced over an expanded span, material will be better retained. In psychotherapy the patient is continuously engaged in examining neurotic behavior; the patient acquires an increasing understanding of why one acts in certain ways. Repetition of successful behavioral responses is encouraged. The working-through process constitutes a continuous learning experience.

BUILDING MOTIVATION FOR ACTIVITY

If empirically we are to pay credence to these concepts of learning, we have to abide by the rule that the first step in helping patients to translate insight into action is to build adequate incentives toward the abandoning of old patterns of living. A constant analysis of the significance of the individual's habitual drives—their purpose, origins, contradictions, and resultant conflicts—casts doubt on the value of such drives. Gradually patients realize that their strivings do them more harm than they do them good, that they are responsible for much of their maladjustment, and that they promote many of their own symptoms.

Eventually they understand that the pleasures that they derive from the fulfillment of their patterns are minute, indeed, compared to the devastation that are created in their lives. They then become willing to challenge the validity of their customary modes of adjustment. Whether they will change their behavior is a choice they themselves have to make.

For example, a woman with a strong dependency drive discovers that her need for dependence dominates every aspect of her thinking and feeling. Finding an omnipotent person on whom to lean fills her with a sense of goodness and security. Life than becomes a bountiful place; she is suffused with vitality, imagination, and creativeness. But not long after this metamorphosis a curious change takes place in the way that she feels. Fear and panic begin to overwhelm her; she becomes sleepless and she feels depressed; headaches, dyspepsia, and muscle tension develop. To her consternation she seems to invite suffering, masochistically assuming the manner of a martyr, and then undermining the person who acts as her host. She appears also to want to capitalize on her plight, by holding forth physical weakness and infirmity as reasons for her avoidance of responsibility.

These patterns become apparent to her during psychotherapy in relation to her husband who she variantly adores, fears, and despises, making for a tumultuous marriage. She learns that while she is driven to submit herself to him as a powerful parental agency, this crushes her assertiveness and fosters feelings of helplessness. Exploration of the genesis of her patterns may show her how her dependency resulted from subjugation by an overprotecting mother, who stifled her independent emotional growth. This knowledge gives impetus to her desires for freedom. She sees how continued pursuit of dependency since childhood causes reflex helplessness and crushing of independence. Such insights are fostered in a nonjudgmental and tolerant treatment atmosphere, the therapist never is represented as an authority who orders the patient to change her way of life.

On the basis of her new understanding much dissatisfaction may be created in the patient with her present life situation. She will also be motivated to experiment with different modes of adjustment. The desire to give up dependency as a primary adaptive

technique may, however, be blocked by a fear of, and a contempt for, normal life goals. Anxiety here may mask itself as anhedonia—an indifference to or boredom with pleasures and impulses accepted as valuable by the average person—for, compared with the ecstatic, albeit spurious, joys of neurotic fulfillment, customary routines seem uninspiring indeed. The therapist accordingly engages in a constant analysis of misconceptions about normality in terms of their anxiety-avoidance components.

When our patient, for instance, manifests disinterest in certain people, it may be possible to show her that she harbors contempt for any individual who does not possess glamorous strength and omniscience. She may actually classify people into two categories: those who are superior and who potentially can serve as parental substitutes and those who are inferior and, therefore, are utter bores. The immense narcissism and grandiosity inherent in her attitudes about herself may become apparent to the patient as she realizes how she strives to gain omnipotence through passive identification with a godlike figure. At this point the patient may become aware of why she refuses to have children. She realizes that she does not want to be replaced as the favorite child of her husband. She does not want to "give" and be a parent to a child, since she herself wants to be that child. She conceives it her right to take from others.

This analysis of anxieties and expectations, and the continued verbalization by the patient of fears and anticipated pleasures, provides increased motivation to attempt a different life expression. But no new patterns can be learned unless the motivation to acquire them is greater than the motivation that promotes the survival of the existing neurotic habits. Therapist activities, therefore, must embrace encouragement of any desires that the patient voices for mental health, emotional growth, and freedom from suffering. The therapist must attempt to undermine the pleasure and security values that the patient seeks from the prosecution of her neurosis. Thus, the therapist may show the patient that the rationale of her dependency need is inescapable if one accepts the premise that she is incorrigibly helpless. While it is true that conditions in her childhood made dependency and related patterns necessary, she now continues to operate under assumptions that are no longer true. Her expectations of injury approximate those of a

child. If she analyzes her situation today, she will see that conditions no longer necessitate anachronistic reactions that are so destructive to her adjustment. She is challenged to revise her assumption of life as a repetitive phenomenon that is blackened by shadows of her need for parenting.

PROVIDING A FAVORABLE ENVIRONMENT FOR ACTION

With expanding insights the patient tends to affiliate neurotic strivings with suffering and maladjustment. Their operation and even their appearance begin to evoke discomfort. This provides motivation for their inhibition. Involved in the inhibitory response are incidental stimuli or cues that are associated with the neurotic patterns and that once could initiate them. More and more the patient becomes capable of controlling reactions and of engaging in productive responses.

It may be necessary for the therapist to prepare the patient in advance for any foreseen disappointments that may occur in the course of executing a new response. Thus, if our dependent patient decides that she must assert herself with her husband, she may resolve to do this by asking him for a regular allowance weekly, from which she can budget her household expenses, purchase her clothing, and provide for certain luxuries. Hitherto her husband has doled out funds whenever she needed to make a purchase, requesting an itemized accounting in order to check on her spending. He has considered his wife irresponsible—an attitude the patient has sponsored, partly out of need to avoid responsibility and partly out of hostility—because she has made many unnecessary purchases. He has for this reason restricted her spending. We may, therefore, anticipate that he will react negatively to her suggestion that he provide her with a weekly sum and that she be entrusted with the family purchasing. Because she has chosen this area as a test for her assertiveness, a negative or violent reception of her assertive gesture will probably mobilize anxiety and result in defeat. She may then suffer a decisive setback in her therapy and perhaps never again dare to approach her husband assertively.

To forestall this contingency, the therapist may ask her to anticipate her husband's reaction when the patient presents her plan. The patient may be fully expectant that her

husband's response will be negative. She may then be asked to anticipate her own reaction should he refuse to cooperate. The therapist may even predict for the patient a violent response on the part of her husband and get her to verbalize how she would feel if he became recalcitrant and punitive. Once the patient accepts the possibility that her request may bring forth hostility and once she recognizes that her husband may, on the basis of her past performance, perhaps be justified in his refusal to trust her management, the therapist may encourage her to approach her husband on a different basis. Discussing with him the need for practice in making herself more independent, she may suggest that he allow her to assume greater responsibility in the handling of finances. However, since even this prudent method of presentation may be rejected, the patient should be prepared for a disappointment. What is accomplished by this tactic is that the patient is desensitized to failure and musters the strength to cope with an absence of rewards for her new responses.

In many patients insight is translated into action without too great activity on the part of the therapist. In some patients, however, considerable activity may be required before therapeutic movement becomes perceptible. Although the therapist may have been more or less passive during the first two phases of therapy, this phase necessitates more energetic measures, and greater pressure and confrontation because of the patient's reluctance to face anxiety.

PSYCHODRAMATIC TECHNIQUES

In occasional instances role playing may be efficacious, the therapist taking the role of the individual with whom the patient seeks to relate on different terms. Or the therapist may suggest that the patient assume the role of that individual, while the therapist takes the part of the patient. The patient, in addition to building up immunity to rebuffs, enjoys in this technique an opportunity for emotional catharsis. The therapist is, in turn, possessed of a means of making the patient aware of one's undercurrent feelings and responses. If the therapist does group psychodrama, the patient may be introduced into the group while continuing to be seen on an individual basis too.

Conferences with Family Members

An element often overlooked in the resistance to getting well is the impact of the reactions on the patient of significant other persons. The patient's interpersonal relationships are bound to change as the shackles of the neurosis are broken by the patient. The threat to the existing family balance will mobilize defensive attack and withdrawal maneuvers on the part of those with whom the patient is in close bond and who are threatened by change. Often this creates such turmoil that the patient will block off progress and perhaps retreat to former patterns of interaction, only to be rewarded by a return of symptoms. The therapist may imagine that it is the therapy that is ineffective, an unhappy thought that the patient may well instigate and sustain. By being constantly on the lookout for possibilities of retrenchment into former behavioral patterns, the therapist will best be able to explain failure of progress as a form of resistance. This phenomenon is most clearly apparent in children, adolescents, and young people who live closely with their families, particularly those who are withdrawn and schizoid. Therapy in releasing independent or rebellious activities in the identified patient may create a crisis in the family homeostasis.

Family therapy with the significant others present may be very successful where the related persons are not too emotionally disturbed. Where an adult patient lives in a close relationship with another person, like a spouse, the person is bound to react with anxiety when the patient threatens to upset present routines. Thus, the mate of our female patient with the dependency problem will probably regard any change in the patient in her striving for freedom as an assault on his own rights. He may then attempt to undermine the patient's treatment.

Surmising such a contingency, we might find it expedient to arrange for a talk with the spouse. The consultation will have to be secured with the knowledge and even cooperation of the patient. One or several conferences with the spouse can often make the difference between success or failure in the patient's initial effort at a new response. Once the spouse sees the rationale of the new plan of action (and senses that he is not being blamed by the therapist), and he realizes that his own problems and needs are being taken

into account, he may voluntarily cooperate. Even hostile reactions of the patient may be tolerated by him, if he is alerted to the possibilities of such reactions. In our dependent patient, for example, an interview may be geared around the discussion with the husband of what he has noticed about his wife. Any troublesome attitudes and behavior mentioned may then be pointed out as manifestations of her problem of lack of assertiveness. In order for her to overcome this problem, which is so crippling to her adjustment, including her marital adjustment, it will be necessary to give her an opportunity to grow. Even though she may make mistakes, the husband is enjoined to exercise tolerance, since this is how people learn and grow. It would be better for her to make a few mistakes, for instance, in the way that she budgets her allowance, and to help her to learn through her mistakes, than to let her continue in her present state of turmoil.

Obviously, in order for the husband to adjust to the patient's assertiveness, it will be necessary for him to master some of his own needs that are being satisfied by the patient's passivity and dependence. A fear for his own masculinity, and/or a compulsive striving for superiority and power may demand that his wife relate to him as a subordinate. Consequently, the husband may have to experience a therapeutic change himself in order to allow his wife to exercise assertiveness in the relationship. He may go through an emotional crisis before this happens, even though he appreciates the purpose behind the plan as explained to him by the therapist. Naturally the husband's dynamics would not be thrown at him during an interview because he would most certainly reject the interpretations. Rather he may be told: "I know this is asking a good deal from you to let your wife experiment. You may not be able to do it, many people can't." This challenge may be enough to get his cooperation.

The following excerpt from a session with a woman whose dependency problem resembled that of the hypothetic patient we are considering as an example illustrates this point:

> *Pt.* And Sunday morning I was in church and I got a little nervous. Then when I came home, my husband started acting funny, wanting to go here, wanting to go there. I told him I thought he didn't really want to go anywhere. He brought up a lot of things. All of a sudden I looked at him and saw hatred on his face, and my mind stopped working. He said, "You care more

about the doctor than you do me." He acted very jealous, and I got upset.

Th. I see.

Pt. And in the last few months we had been getting along so well. You know I just am never going to go back again to what I was. I got upset at his attitude and wanted to throw something at him, but instead I turned it on me. I cried and tore my hair. He got me so angry, I lost control. I don't want to live with a man I have to appease. I told him he is a mean man and that I would leave him.

Th. And then what happened?

Pt. He got upset and cried. He told me it was his fault. He said he always was this way and that he could see he was wrong. Then I started feeling sorry for him. Then I got mad at him. I don't think I can stand him. He's brutal and mean. He isn't happy until he sees me groveling on my knees. Then he's happy. Maybe I'm not the woman for him. *(pause)*

Th. But you *could* assert your rights. You *could* define what you feel your rights to be.

Pt. But I have. I don't see what I did to aggravate him. I know he has a problem in wanting to treat me like a slave. Maybe someone else could stand it, but I can't. And I told him and threatened to walk out. *(pause)*

Th. So what happened then?

Pt. Surprising. He broke down and cried. Then he said it was all his fault. He said he could see how he treated me, that it was all his fault. He said he didn't know how I could stand it so long. He said he would try to treat me more like an equal.

There are many instances in which improvement in therapy of one marital partner results in increasing emotional disturbance of the mate. Indeed, a disturbed adaptation of the patient may be a condition necessary for the equilibrium of the mate. Thus, a husband, domineered by a power-driven wife, may satisfy masochistic needs under a domain of tyranny. He may be unwilling to give up his masochistic indulgences and adjust to an atmosphere of cooperative equality brought about by the wife's improvement through psychotherapy. Or a frigid woman, receiving treatment, may make sexual demands on her impotent husband who will then develop strong anxiety. Where the mate of the patient has good ego strength, he or she may possibly be able to adapt spontaneously adjusting to the new demands presented by the patient toward a healthier adjustment. The outcome of psychotherapy in one partner then will be emotional improvement in both members. However, it may be necessary for the mate of the patient to receive psychotherapy also

where spontaneous improvement does not occur. Conjoint marital therapy and even family therapy, including as many involved members of the family as possible, may be in order.

Adjusting the Patient's Environment

Where the patient's environment is disturbed, it may have to be altered before insight can adequately be translated into action. Thus, if there is undernourishment, shabby physical attire, bad housing, and other consequences of a subminimal budget standard, which are outside of the patient's control, a community or private agency may have to render assistance. An individual who is living with a brutal or neurotic parent or marital partner may be unable to achieve adequate mental health until an actual separation from the home is brought about. Domineering parents who resent their offspring's self-sufficiency may cause a patient to feel hopeless since compliance seems to be a condition for security.

The majority of patients are capable of modifying their environment through their own actions, once the disturbance is clearly identified and the proper resources are made available to them. Occasionally the adjunctive series of a trained social worker may be required, especially with children and patients with weak ego structures. The therapist, with the help of a social worker, may materially alleviate certain problems by simple environmental manipulation. This is particularly the case where the people with whom the patient lives are capable of gaining insight into existing defects in the family relationship. Such factors as favoritism displayed toward another sibling, lack of appropriate disciplines and proper habit routines, the competitive pitting of a child against older siblings, overprotective and domineering influences of the patient's parents or mate my sometimes be eliminated by proper psychoeducation. Correction of sources of discord and tension frequently is rewarded by alleviation or disappearance of symptoms.

Such situational treatment, while admittedly superficial, can have definite therapeutic value and may permit an individual to proceed to more favorable development. Often family members become so subjectively involved with the problems

of the patient, so defensive and indignant about them that they are unable to see many destructive influences that exist in the household. An honest and frank presentation of the facts may permit intelligent people to alter the situation sufficiently to take the strain off the patient.

It must not be assumed, however, that all situational therapy will be successful, even when gross disturbances exist in the household. Frequently the family is unable or unwilling to alter inimical conditions because of severe neurotic problems in members other than the patient or because of physical factors in the home over which they have no control. Here the social worker, through repeated home visits, may start interpersonal therapy that may bring the family around toward accepting the recommendations of the therapist. The worker may, in specific instances, render material aid to the family, or may assist in the planning of a budget or a home routine. Direct contact of the social worker with the family may reveal that others need attention or therapy.

Another function that the social worker can fulfill is to make available to the individual the various church, school, and neighborhood recreational facilities. Persons with emotional problems frequently become so rooted to their homes, out of a sense of insecurity, that they fear outside contacts. Establishing a relationship with and introducing the patient to groups outside the home may start a social experience that becomes increasingly meaningful for helping to release forces that make for self-development. A day hospital, day-care center, or rehabilitation unit are often of great value.

In cases where the destructive elements within the family are irremediable or where the individual is rejected with little chance of eventual acceptance, it may be necessary to encourage the individual to take up residence elsewhere. Temporary or permanent placement in a foster family or rest home may be essential. Although there is evidence that such change of environment rarely has an effect on deeper problems, residence in a home with kindly and sympathetic adults may serve to stabilize and to give the individual an opportunity to execute in action the insight learned. The most significant factor in changes

of residence is the meaning that it has to the patient. If the patient regards it as another evidence of rejection, it can have an undermining rather than a constructive influence. Instead of getting better, the patient may regress to more immature patterns of behavior. Above all, the patient must be adequately prepared for residence change or placement and should look forward to it as a therapeutic experience rather than as a form of punishment.

Caution must, however, be exercised in effecting drastic and permanent changes in the work or home situation, and thorough study of the patient is essential before one is justified in advising anything that may recast the patient's entire life. This applies particularly to problems of divorce and separation.

Many married patients seek therapeutic help while on the crest of a wave of resentment that compels them to desire separation or divorce. Mere encouragement on the part of the therapist serves to translate these desires into action. The therapist should, therefore, always be chary of giving advice that will break up a marriage unless completely convinced that there is nothing in the marital situation that is worthy of saving or until certain that the relationship is dangerously destructive to the patient and that there is no hope of abatement. This precaution is essential because the patient may completely bury, under the tide of anger, positive qualities of the mate to win sympathy from the therapist or to justify the resentment felt toward the mate.

When the therapist is swept away by the patient's emotion and encourages a breakup of the home, many patients will be plunged into despair and anxiety. They will blame the therapist for having taken them so seriously as to destroy their hopes for a reconciliation. It is advisable in all cases, even when the marital situation appears hopeless, to enjoin the patient to attempt the working through of problems in the present setting, pointing out that the spouse may also suffer from emotional difficulties for which treatment will be required. The patient will, in this way, not only be helped, but also the spouse, and constructive features of the relationship will be preserved. It is wise to get the patient to talk about positive qualities possessed by the spouse instead of completely being absorbed by the latter's negative characteristics.

On the other hand, it is undesirable, indeed manifestly impossible, to restrict every patient from making fundamental changes during therapy. Conversion of understanding into action presupposes that the life situation must be altered. The rule that no changes be made during the period of therapy is more honored in its breach than its observance. The important thing is that the patient discuss with the therapist plans to effectuate change *before* making them in order to lessen the possibilities of a neurotic decision, for instance one that may be in service of masochistic self-defeating impulses.

Learning New Patterns within the Therapeutic Relationship

The reexperiencing by the patient, within the therapeutic situation, of early unresolved fears, attitudes, and needs and the proper management by the therapist of these strivings are important means of learning. The patient has an opportunity to work out, in a more favorable setting, problems that could not be resolved in relationships with early authorities. The new patterns resulting are gradually absorbed and become a part of the patient's personality.

For this to happen, the therapeutic situation must serve as a corrective experience and must not repeat early disappointments and mishandlings. The patient while motivated to grow and to develop within the relationship, is hampered by anxiety, residual in expectations of hurt from domineering, rejecting, overprotecting, and punitive authority. This is why the therapist must not be tempted by the patient's unprovoked attitudes and behavior to repeat the prohibitions, penalties, and retribution of authoritative figures in the patient's past. Should the therapist respond in this way, the patient's convictions that authority is not to be trusted will be reinforced. No modifications of attitudes can occur under these circumstances.

Realizing that the patient must verbalize or act out unreasonable strivings in order to get well, the therapist will have an opportunity to react to these in an entirely different way from that anticipated by the patient. The therapist acts in a warm, accepting, and nonjudgmental manner. These attitudes inspire the patient to retest the original traumatic situation. The patient does this anticipating hurt. If the therapist, by virtue of

understanding and the ability to remain objective, can avoid repeating the punitive and rejecting threats, the patient may be helped to live through in a new setting crucial experiences that should have been resolved as a child. The therapist will constantly have to interpret to the patient the latter's expectation of hurt, and to help the patient to realize that the circumstances under which one failed to develop security and self-esteem were peculiar to a disturbed childhood.

This will call for a high degree of mental health on the part of the therapist, whose own value system is bound to incorporate many of the judgments and arbitrary attitudes residual in the culture, which, incorporated in the parent's attitudes, have crushed the patient's growth.

Within the therapeutic relationship itself, therefore, the patient is helped to find a new and healthier means of adjustment. A virtue of the working alliance is that it acts as a prototype of better interpersonal relationships. It fosters the patient's faith in other people and ultimately in the self.

One way that the working relationship is utilized is to battle resistances to action. It is sometimes necessary to encourage patients to face certain situations that have paralyzed them with fear. Utilizing the relationship as a fulcrum, the patients may be urged to experiment with new patterns while observing their responses. A program sometimes may be planned cooperatively with the patients, the therapist occasionally making positive suggestions. While advice giving is best eschewed, the advantages and disadvantages of alternative courses of action may be presented, the patients being encouraged to make a final choice for themselves. Thus, if a patient wants the therapist to make the decision on an issue, the therapist may ask, "What do *you* feel about this?" Possibilities of failure, as well as anticipated reactions to entering into new situations may be explored. The patient may be cautioned- by such statements as, "It isn't easy to do this" or "This may be hard for you." A method of stimulating action is to confront the patient with the question, "What are you doing about this situation?" whenever dissatisfaction is expressed by the patient on his or her progress.

Even with these promptings the patient may shy away from executing actions that threaten to promote old anxieties. If the initiative is put in the patient's hands, a stalemate may result. Although an analysis of resistances may encourage a cautious step into dangerous territory, the patient may need a gently firm push by the therapist before boldly approaching a new activity. In phobias, for instance, the patient may have to be strongly urged to face the phobic situation, on the basis that it is necessary to learn to master a certain amount of anxiety before one can get well. Where the relationship with the therapist is good, the patient will be motivated to approach the situation that seems dangerous with greater courage.

Success and pleasure in constructive action constitute the greatest possible rewards for the patient. Occasionally the therapist may indicate approval in nonverbal or in cautiously phrased verbal terms. Conversely, whenever the patient fails in an attempted action, sympathy, reassurance, encouragement, and active analysis of the reasons for the failure are indicated. The patient may be reminded that the difficulty has been present a long time and that one need not be discouraged if one does not conquer one's trouble abruptly. The patient may be given an explanation such as the following: "You know, an emotional problem is often like a hard rock. You can pound on it with a hammer one hundred times without making any visible impression. The hundred-and-first time, however, it may crumble to pieces. The same thing happens in therapy. For months no visible change is present, but the neurotic structure is constantly being altered under the surface. Eventually in therapy, and even after therapy, signs of crumbling of the neurosis occur."

Eventually the rewards of positive achievement and enjoyment issue out of the new and healthy patterns themselves. Surcease from suffering, reinforced by joys of productive interpersonal relationships, enable the patient to consolidate gains.

Adjunctive devices are often helpful during the action phase of therapy. These include the prescription of tranquilizing drugs, to help master anxiety associated with attempting new tasks, as well as hypnosis, self-hypnosis, and behavior therapy. (See

Chapters <u>56</u> and <u>51</u>.)

ILLUSTRATIVE CASE MATERIAL

The following is a portion of a session in which a man with a personality problem of dependency, submissiveness, passivity, and detachment indicates how he has put his insight into action and asserted himself.

Pt. There has been a great change in me. I haven't felt this way in my whole life. And it has been going on for weeks.

Th. Is that so?

Pt. Yes. Of course, I used to have spurts of good feeling for different reasons. Once I felt as happy as a lark when I was about 13. I had had eczema for years and x-ray treatments took it away. I felt grand for a short time. And then I felt wonderful when I met my wife, but it lasted only a short while. But all these things came from external causes. The way I feel now seems to be coming from inside of me. All my life I seem to have been a zombie, really dead, because I carried inside of me all sorts of standards of other people. I was like an automaton. If you would press a button, I would react in a certain way. I never had a sense of myself.

Th. Mm hmm.

Pt. Things have happened these weeks, which I think I handled well, and my reactions were good too. I have never had a prolonged period like this. Several times I'd say to myself, "I wonder if I can keep this up?" People mean different things to me now, you know. They are not powerful and threatening. My daughter was operated on at the hospital, for example. I regarded it in a sensible way. I said, "It's a minor operation. I'm concerned about her, but it's a simple thing and nothing to be upset about." I used to have a whole string of emotional responses that go along with illness. Now my wife has this worrying but that was instilled in her by her mother. So I had to go along handling various things with her feelings which used to suck me into a trap before and arouse guilt feelings in me.

Th. I see.

Pt. So she started to hammer at me a few days before the operation to see to it that the room in the hospital was a good one, that there was a television set there, and so on. Now this is a good hospital, I know, but their policy is annoying. I know they have a program, and you could stand on your ear and get nowhere by ordering them around. So I said to my wife, "I'm not going to follow out your directions and do this and do that because I don't think it's right. Everything will go smoothly." So I did it my way, and everything went smoothly.

Th. Previously how would you have done it?

Pt. To tell you this is a revolution is an understatement. I'd always appease my wife like I did my mother. I'd do what she said without questioning it. This time I did what *I* wanted, and I felt

no guilt. I had a sense of power. Everything went smoothly. When I got to the hospital, my wife was frantic because they gave my daughter a rectal sedative and she expelled it. The nurse was all confused and didn't know what to do. Then they called for her to go to the operation. I said, "I won't let her out of the room until she is properly sedated. I don't care if they get the whole hospital on my head; I'm just not going to do it." And I did this with ease. There was nothing to it. Before this I would say, "Look, I'm making these people wait, and so forth, and so forth." So the intern came up and gave her a sedative. They called the surgeon who agreed that the child shouldn't come down until she was sedated. (*laughs*) Everyone was chewing their nails, but I stuck to my guns. Not that I was unreasonable, but I did stick to what I felt was right.

Th. And things came out well?

Pt. Better than well. It's like a miracle. To think how fearful I was, before therapy, to take a stand with anybody. Especially, I wasn't able to be firm with my wife. When I got home, though, my wife started on me and said that I should have acted more cooperative. That burned me up because that questioned my stand. I told her calmly (*laughs*) that I had sized up the situation and felt this is what had to be done, and the proof was that things turned out well. Even if they didn't, I was sure I was doing the right thing.

Th. I see.

Pt. I then realized that my wife was under a strain, and I told her I was sorry if I talked rough to her. And then she said, "Yes, you're sorry," sarcastically. I said to her, "Look, I said I was sorry. I'm not going to crawl; I'm not going to stand on my head or any goddamn thing." And I didn't feel any anxiety or any guilt or anything. This morning my wife was as happy as a lark, as if nothing had happened.

Th. That made you feel you could take a stand and nothing bad would happen.

Pt. I just brought that up to show that I wasn't drawn in; I felt I was right and I wasn't going to try to dope out my wife's neurotic reactions to things and turn myself inside out trying to please her. I felt wonderful about this. So that was that.

Th. Yes.

Pt. I get a lot of resentment now at certain women mostly, and say, "Why did I have to knock myself out for years? What's so great about them? They are just people, and there are plenty of them around. Why were women so important to me?" I know what it springs from, and it seems so crazy to me now. (*laughs*)

Th. What *did* it spring from actually? *[testing his insight]*

Pt. Well, I would say that there were many factors involved and the picture becomes clearer; my whole life becomes clearer all the time. I would say it all started out, leaving psychologic terms out, with getting a terrible deal with my mother—she killed me. She must have acted in such a way that I was terribly uncertain of her love, and I must have gotten the feeling that if I didn't do exactly as she wanted me to do, she wouldn't love me anymore. And there was no approbation given to me as a person. I became a thing. I became something that was used as a ground for other people's neurotic problems. My mother, on the one hand, being

defeated in her life, used me to a point of smothering me with affection, which, I have a feeling now, covered a lot of repressed hostility and a lot of rebellion against being a mother. My father, on the other hand, showered on me his own lack of confidence as a man. He impressed me with what a man should be, that when he was with people, he wouldn't let them get away with anything. If a cab driver said anything to him, he'd beat him up. He had a tremendous temper. He'd say, "You got to fight; don't take anything from anybody." He never gave me any affection. He couldn't. I think he has a lot more qualities than my mother, but he is very compulsive in the matter, as shown by the fact that he couldn't be warm. He was compulsive about his own work and emphasized to me not to procrastinate or put off tomorrow what could be done today. The approbation came from getting good marks in school. That was the big thing.

Th. Yes.

Pt. So, I grew up with two big areas that were involved—the love area with my mother and the work area with my father. And then, in addition to that, my mother presenting the picture of what a bastard an aggressive man is. My father was a bastard, she said. "I love you," she said, "so don't be a bastard to me. If you do certain things that I don't like, then you are a bastard to me." So I grew up that way with no confidence in myself, no feeling about myself as having worth. The only worth I had was getting good marks to please my father and giving in to please my mother. So with one thing and another I started to crack up.

Th. What happened with your wife?

Pt. She became a mother, and the same thing would have happened with every woman. No matter what the woman was, she was irreplaceable because I had no confidence I could get another woman.

Th. How would you say your attitudes are now in that respect?

Pt. Well, I would say, number one, I know they are not irreplaceable. I think I use sex in an abnormal way. First, it was to prove being a man and to get this feeling of being approved and accepted by a woman like my wife, which after a while stopped working because it proved nothing. So I feel now they are not irreplaceable. I know they have problems, and I don't have to get involved in their problems. I don't have to be sucked in again into being an automaton who is prey to their whims. Pleasing a woman, no matter what her problems, is good as long as it is a reciprocal thing; but doing it just to please her becomes detrimental to the relationship. I suppose in our culture women are more insecure than men and have problems; but I don't have to get involved in their problems. I also have learned that making a woman insecure by making her feel uncertain about you is not the answer. Because, while it works temporarily to incite her interest, it breaks up the relationship after a while.

Th. So that you feel your attitudes are altogether more wholesome.

Pt. My, yes. I realized that my feelings and my needs are just as important as the woman's. All this time I've been making an intellectual exercise about resolving conflict. Instead, the drives I feel now are healthy and good. After all, if it's a fifty-fifty proposition; you can't be too submissive and you can't be too aggressive. I feel a lot more strength within myself. I feel more alive and more vital. The reactions of other people don't matter as much as my own, or I'd say better that my reactions are equally important as the opinions of other people.

49
The "Working-through" Process

Mental health is won only after a long and painful fight. Even in supportive therapy, where goals are minimal, the person clings to symptoms with a surprising tenacity. In reeducative therapy the patient returns repetitively to old modes of living while making tentative thrusts in a new and more adaptive direction. In reconstructive therapy the struggle is even more intense, the patient shuttling back and forth, for what seems to be an interminable period, between sick and healthy strivings.

The initial chink in the patient's neurotic armor is made by penetrations of insight. The patient tries stubbornly to resist these onslaughts. The implementation of any acquired insight in the direction of change is resisted even more vigorously. Only gradually, as anxieties are mastered, does the patient begin to divest neurotic encumbrances.

Change is never in a consistently forward direction. Progress takes hold, and the patient improves. This improvement is momentary, and the patient goes backward with an intensified resistance, retrenching with all previous defenses as the problem is investigated more deeply. Anxiety forces a reverse swing toward familiar modes of coping with fear and danger. This is not a setback in the true sense because the individual integrates what has happened into the framework of rational understanding. With the gain achieved from this experience another step forward takes place. Again, anxiety forces a return to old methods of dealing with stress or resorting to disguised adaptations of one's defenses. In association with this there may be discouragement and a feeling of helplessness. But this time, the reintrenchment is more easily overcome. With the development of greater mastery there is further progress; and there may again be a regression to old defenses. The curve of improvement is jerky, but with each relapse the patient learns an important lesson. The neurotic way of adaptation is used less and less, and as patients gain strength through what is happening to them, they are rewarded with

greater and greater progress.

It is discouraging to some therapists to encounter such curious reluctances in their patients toward moving ahead in treatment. The therapist is bound to respond with discouragement or resentment when, after having made an estimable gain, the patient experiences a recrudescence of the symptoms. Should the therapist communicate dismay to the patient, the latter is apt to regard this as a sign of hopelessness or of having failed the therapist. Actually, there is no need for despondency or pessimism should the patient fumble along, repeat the same mistakes, or backslide when logic dictates that one forge ahead.

One way the therapist may maintain control of personal feelings is to anticipate setbacks in all patients. No patient will be able to acquire new patterns overnight. Each patient has a personal rate of learning, which may not be accelerated by any technical tricks.

Before structural psychic change can take place, it is necessary for patients to amalgamate changes that they have achieved in one area with other areas of their personalities. Analogically, it is as if in a business institution that is failing specific enlightenment comes to one department of the organization. After a new policy is accepted and incorporated by this department, it is presented to the other organizational divisions for consideration. Resistance against changing the status quo will inevitably be encountered, with eventual painful yielding by department heads, executives, and other administrative personnel. Many months may go by before the recommended reforms are generally accepted and put into practice. Not until then will the influence on the business be felt. In emotional illness, too, enlightenment produced by understanding of one facet of the individual's behavior will have little effect on the total behavior until it is reconciled with the various aspects of the patient's personality.

This process of *working through* is usually extremely slow, particularly where basic character patterns are being challenged. One may painstakingly work at a problem with little surface change. Then, after a number of months something seems to "give," and the

patients begin responding in a different way to their environment. Gaining satisfaction from the new response, they integrate it within their personalities. The old patterns continue to appear from time to time, but these become increasingly susceptible to influence and replacement with new more adaptive reactions. Having achieved a partial goal, one is motivated to tackle more ambitious aims. The investigative operation is extended toward these new objectives, and the working-through exercise then goes on with retreats and advances until constructive and established action eventuates.

Thus, a patient with a disturbing personality problem came to therapy because of the symptom of impotence. Understanding of his sexual misconception, with a working through of his fear of performance, opened up the possibility of more advanced objectives. A portion of an important session with this patient follows:

Pt. I saw Jane after I spoke to you. Sexually we got along better than we ever had. She had a good orgasm, and it was really the first time. We've been seeing each other for about 5 months, so it was sort of a milestone as far as I was concerned. And yet, I wasn't, I didn't feel as though I'd done a great thing, as though I'd "arrived" or anything like that.

Th. Previously you had felt—I can even recapture your own words—that if an occasion ever occurred with a person like Jane where you could really function to your own satisfaction and to hers, it would really mean you had achieved your goal. Now that it's come about, it hasn't proved to be anything like you anticipated.

Pt. I said to myself that something seems to be stopping me almost from thinking about it. I said, "Now, let's think about this thing because this is supposedly very important." And I just didn't grasp it, as though there's something you want so much, and you get it, and it doesn't mean anything. I said this ought to give you a wonderful feeling; this should be good for you, that this happened. It was good, but it didn't solve all my problems like I imagined it would. And I don't know whether it's because it's become less important to me. It continually demonstrates this business of I could do such-and-such, if only this were the case. How foolish that is because I thought to myself, "Well, really it's just once. Maybe it should be another time. Maybe I should prove myself again. Once really isn't enough." But I feel I could do it three or four times, or a hundred, and it still wouldn't be enough. *[The patient is apparently aware of the fact that sexual success will not solve all of his problems.]*

Th. As a matter of fact, it is possible that the reason you weren't functioning well sexually with her is that you weren't permitting yourself to enjoy sex for the pleasure value but rather for its value in building you up. *[interpreting his neurotic use of*

Pt. I would guess that I have certainly changed in that respect. It bothered me though that it didn't mean more to me than it did. I thought, "Well maybe that's why it happened," because it didn't mean so much to me. So that we're still really on the same basis, as far as this business is concerned.

Th. Mm hmm.

Pt. I say to myself, "Well, there's three women, Barbara, Martha, and Jane, that I'm sleeping with. I have now reached a point where I, they've all been able to have orgasms. It made me feel comfortable, but not. . . maybe I could be better off if I could think, 'Jesus, I'm terrific, or what a great man I am now'." But I don't feel that way.

Th. It would be a very neurotic thing to build up your self-esteem solely and completely, or largely, on the basis of how you function sexually. That's a facade that will cross you up.

Pt. It would be like evaluating a man on the basis of his appetite. If I would be with a woman and I could only have one orgasm, I would think to myself, "Well, you're not as much of a man as if you had two or three orgasms." And yet, it would be like saying, "If a man eats a plate of oysters, if he eats only one plate, he's not as much a man as if he'd eaten two or three plates." I realize my attitude is ridiculous.

Th. But still you seem to think one way and feel the other way.

Pt. It really is a tough situation. This sort of thing seems to be pretty much the kernel of my difficulty. It radiates in all actions and all spheres. I mean the sexual element now seems to, right now, this week anyhow, seems to be receding somewhat into the background and other aspects becoming important. I see where it's necessary to do more, to alter your personality and your attitudes. A whole new set of values have to be evolved, what's good and what's bad, what's right and what's wrong, the sort of life you want to live and what you want to do about it, which, I presume most people never really figure out. I have toyed with the idea before, but now I want to get into myself more.

Another patient with sexual fears and problems in his marital life was, with continued working through, able to make good progress. His relationship with his wife improved. Sexuality became less compulsive a function; he began to achieve greater assertiveness and a feeling of increased self-esteem. These changes are illustrated in the following fragment of the session that follows:

Pt. Tuesday night I decided to bring some flowers home. It was like a miracle, a tremendous response. In fact my wife's face was so overjoyed that I really felt a little sorry that—well, she'd been so miserable—it just required little things like that, not much to make her happy. I talked to her last night about my work, and she interpreted my actions as rejection. But it wasn't so, I told her. I said the things you really want are the important ones. She said that it's true. I explained to her about my work and eventually I thought I'd be able to spend more time with the children, and I was working toward that end. I feel much more comfortable in the situation. I was afraid that I'd have a compulsion to want to do as many things as possible along these lines, so that she'd know I was thinking of her. And the result would be that I'd have a conflict between wanting to do those things and other things like my work. But I find it's not so. I feel very comfortable, much more comfortable in the situation. I feel that I can do those things if I want to. If I think of something to make her know that I'm thinking of her, it's not an effort really on my part. I don't feel a compulsion to want to do them. In fact, when I got the flowers, I really enjoyed getting them. I would say

right now that my situation, therefore, on the whole is a little better. These other things aren't important to me. My wife is enjoyable. I'm more in control of the situation.

Th. You'll be able to make even further progress if you can think objectively about your situation and not act impulsively as you once did.

Pt. Yes, I guess so. I guess being tied up in a situation makes you lose your perspective, but I was so interested in the things that she was actually finding fault with me for, I felt that I concentrated on those, taking them as a personal affront, instead of realizing what they were. I suppose that the situation will change again in some way, but right now I guess things are fairly peaceful, considering everything. I have a great deal of work to do, but I think I'm less neurotic about it; for the first time, I would say, since I've been in business, I am willing and eager to strip myself of as much detail work as possible. Before I was just holding on to it. I made up my mind that this work has to be done and that until I do it, I won't be able to take it easy. The work has to be done before I can take it easy. So I said to myself, "Well, it's really awful because if I had three days like Saturday, where no one bothered me, in a row, I could do it all." So I told my wife that I'm going to have to work a few nights and she said O.K. In fact, last night, I did one of the things that she complained about, I came home late again. But it was wonderful; she didn't complain about it. She greeted me with a smile and said nothing about it. So I could see that that wasn't the important thing. I would say that I feel on the whole that I sort of climbed a little and reached a little plateau, if such a thing is possible.

Th. Well, let us examine that plateau, and see what incentives there are to move ahead. Because virtually, in terms of your goals that you came to see me for originally, you've pretty much achieved those, haven't you?

Pt. I suppose so. The physical symptoms that I had, I don't have them any more. I assume they'll just fade away, because I never think of them. Sexually, I'm functioning much better than I ever did before. So I guess on those two counts I've come a long way. That's true.

Th. In your assertiveness, in your capacity to stand up for your own rights, what about that?

Pt. Well, I'd say there is probably less progress made on that score. We haven't been working on it as much as the other thing.

Th. Well, do you feel that it's been a problem? Do you feel that that constitutes a problem for you?

Pt. Yes, definitely, but now I feel more like a person with rights and things like that, more of an individual than I felt before. But I think I still have a long way to go to feel really an assertive person, I would say. And this may be just a temporary peace that I've achieved. All the elements that caused me anxiety for the past few months have reached the point of equilibrium.

Therapeutic progress is gauged by the ability of the patient to apply what has been learned toward a more constructive life adaptation. The recognition of disturbing drives and the realization that they are operating compulsively do not guarantee that any

modification will occur. Nor do they mean that the patient has the capacity for change. The ability to progress depends upon many factors. Foremost is the desire for change. Among the motivating influences here are a sense of frustration induced by an inability to fulfill normal needs and growing awareness that neurotic strivings are associated with suffering far in excess of compensatory gratifications.

The detection of contradictions in the personality structure also acts as a powerful incentive to change. It is, however merely the first step in the reintegrative process. Thus, if a patient exhibits a pattern of compulsive dependency, the mere recognition of dependency and its consequences will not alter the need to cling tenaciously to others. While it may point the way to the more basic problem of inner helplessness and devaluated self-esteem, there is still a need to examine the meaning of the patient's impaired self-esteem as well as to determine its source. Furthermore, there is required an appreciation of the motivating factors in the individual's present life that perpetuate feelings of helplessness. Understanding the origins of one's dependency trend and tracing it to determining experiences with early authorities are important steps, but these too are usually insufficient for cure. As long as basic helplessness continues, dependency has subjective values the individual cannot and will not relinquish. While the irrationality of one's drives may be recognized as well as the unfortunate consequences, one will desperately cling to them, at the same time rationalizing prevailing motives. Partial insight regarding deep dependency promptings will not eradicate them nor dim their acceptance the remainder of one's life.

Working through, as has been previously indicated, is especially difficult in reconstructive therapy and a description of the process may at this point be helpful. The releasing of the self from the restraint and tyranny of an archaic conscience, freeing it from paralyzing threats of inner fears and conflicts, is an extremely slow process. Ego growth gradually emerges, with the development of self-respect, assertiveness, self-esteem, and self-confidence. It is associated with liberation of the individual from a sense of helplessness and from fears of imminent rejection and hurt from a hostile world.

The process of ego growth is complex and merits a more elaborate description. Fundamentally to encourage such growth it is necessary to cajole the ego into yielding some of its defenses. Within the self the individual feels to weak to do this and too terrified to face inner conflicts. Unconscious material is invested with such anxiety that its very acknowledgment is more than the patient can bear. Rooted in past conditionings, this anxiety possesses a fantastic quality, since it is usually unmodified by later experiences. It is as if the anxiety had been split off and were functioning outside the domain of the ego. In therapy it is essential to reunite the conscious ego with the repressed material and its attendant anxiety, but resistance constantly hampers this process. Promoting resistance is the hypertrophied set of standards and prohibitions that developed out of the individual's relationships with early authorities. These standards oppose not only the uncovering of unconscious material, but also the expression of the most legitimate personal needs.

Working through in reconstructive therapy must be accompanied by a strengthening of the ego to a point where it can recognize the disparity between what is felt and what is actually true, where it can divest the present of unconscious fears and injuries related to the past, where it can dissociate present relationships with people from attitudes rooted in early interpersonal experiences and conditionings. Ego growth is nurtured chiefly through a gratifying relationship with the therapist. The exact mechanism that produces change is not entirely clear. However, the therapist-patient relationship acts to upset the balance of power between the patient's ego, conscience, and repressed inner drives. The ultimate result is a liberation of the self and a replacement of the tyrannical conscience by a more tolerant conscience patterned around an identification with the therapist.

The relationship with the therapist may, however, light up the individual's fears of injury, as well as inordinate expectations, drives, and forbidden erotic and hostile desires. Despite the lenity of the therapist, the patient will keep subjecting the therapist to tests in order to justify a returning to the old way of life. If the therapist is too expressive in tolerance of the patient's deepest impulses, the patient will look upon treatment as a seduction for which one will pay grievous penalties later on. On the other hand, a repressive attitude expressed by the therapist will play in with the patient's residual

concept of authority as restrictive and, therefore, deserving of customary evasions and chicaneries. At all times the patient will exploit usual characterologic defenses to prevent relating the self too intimately to the therapist. The patient has been hurt so frequently in previous interpersonal relationships that there is the conviction that danger lurks in the present one. Under the latter circumstance the working-through experiences may take place within the transference relationship itself particularly when the patient is in long-term therapy and the therapist encourages the development of a transference neurosis. Obviously the therapist must have had psychoanalytic training to lead the patient through the rigors of the neurotic transference experience.

Many months may be spent in dealing with resistances that ward off the threat of a close relationship with, and the acknowledgment of certain irrational feelings toward, the therapist. The therapist acts to dissolve these facades by direct attack. Perhaps for the first time patients permit themselves to feel, to talk, and to act without restraint. This freedom is encouraged by the therapist's attitude, which neither condones nor condemns destructive impulses. The patients sense that the therapist is benevolently neutral toward their impulses and will not retaliate with counterhostility in response to aggression. Gradually the patients develop reactions to the therapist that are of a unique quality, drawing upon emotions and strivings that have hitherto been repressed. The release of these submerged drives may be extremely distressing to the patients. Because they conflict so outrageous with standards, bound to reject them as wholly fantastic or to justify them with rationalizations. There is an almost psychotic quality in projected inner feelings and attitudes, and the patients may fight desperately to vindicate themselves by presenting imagined or actual happenings that put the therapist in a bad light.

As the patients experience hostility toward the therapist and as they find that the dreaded counterhostility does not arise, they feel more and more capable of tolerating the anxiety inevitable to the release of their unconscious drives. They find that they can bear frustration and discomfort and that such tolerance is rewarded by many positive gains. Finally, they become sufficiently strong to unleash their deepest unconscious drives and feelings, which previously they had never dared to express. Projecting these onto the

person of the therapist, the patients may live through infantile traumatic emotional events with the therapist that duplicate the experiences initially responsible for their disorders. The latter phase occurs when the patients have developed sufficient trust and confidence in the therapist to feel that they are protected against the consequences of their inner destructive impulses.

Sexual wishes, hostile strivings, and other drives may also suddenly overwhelm the patients and cause them to react compulsively, against their better judgment. The patients almost always will exhibit behavior patterns, both inside and outside the therapeutic situation, that serve either to drain off their aroused emotions or to inhibit them. They may, for instance, in response to feelings of rage, have a desire to frustrate and hurt the therapist. Accordingly, they will probably have but tend to suppress imprecations and derisive feelings about the therapist, minimizing the latter's intelligence, or emphasizing any shortcomings. They may become sullen, or mute, or negativistic.

These reactions do not always appear openly and may be manifested only in dreams and fantasies. Sometimes hostility is expressed more surreptitiously in the form of a sexual impulse toward the therapist, which may have its basis in the desire to undermine or to depreciate. At the same time the patients realize that they need the love and help of the therapist, and they may feel that expression of hostility will eventuate in rejection. They may then try to solve their conflict by maintaining a detached attitude toward the therapist, by refusing to verbalize freely, by forgetting appointments, or by terminating treatment.

A danger during this working-through process is that the patients may act out inner impulses and feelings and fail to verbalize them. This is particularly the case where the patients are given no chance to express everything that comes to mind. Such acting-out has a temporary cathartic effect, but it is not conducive to change. If the patients do not know what they are reliving, they will think that their reactions are completely justified by reality. If acting-out goes on unchecked, it may halt the therapeutic process. The most important task of the therapist here is to demonstrate to the patients what in the

therapeutic relationship is being avoided by acting-out.

As the patients realize that their emotions and impulses are directly a product of their relationship with the therapist, they will attempt to justify themselves by searching for factors in the therapist's manner or approach that may explain the reactions. Inwardly they are in terror lest the therapist call a halt to therapy and thus bring to an end the possibility of ever establishing an unambivalent relationship with another human being. Yet they continue to respond with contradictory attitudes. On the one hand, they seek praise and love from the therapist, and, on the other, they try to repudiate and minimize the therapist. They resent the tender emotions that keep cropping up within themselves. The battle with the therapist rages back and forth, to the dismay of both participants.

One of the effects of this phase of the therapy is to mobilize ideas and fantasies related to past experiences and conditionings. The transference relationship is the most potent catalyst the therapist can employ to liberate repressed memories and experiences. As the patients express irrational impulses toward the therapist, they become tremendously productive, verbalizing fantasies and ideas of which they were only partially aware.

Sooner or later the patients discover that their attitudes and feelings toward the therapist are rooted in experiences and conditionings that date to the past; they realize that these have little to do with the therapist as a real person. This has a twofold effect: first, it shows them why exaggerated expectations and resentments develop automatically in their relationships with others; second, it permits them to see that they are able to approach people from a different point of view.

The transference is a dynamic, living experience that can be intensely meaningful to the patient. Recovery of repressed material is in itself insufficient. The material has to be understood, integrated, and accepted. During reconstructive therapy much material of an unconscious nature may come to the surface, but the patients will, at first, be unable to assimilate this material because it lies outside the scope of their understanding. In the transference relationship the patients are able to feel their unconscious impulses in actual

operation. They realize them not as cold intellectual facts but as real experiences. The learning process is accelerated under such circumstances.

The transference not only mobilizes the deepest trends and impulses, but also it teaches the patients that they can express these without incurring hurt. This is unlike the ordinary authority-subject relationship, in which the person feels obligated to hold back irrational feelings. Because of the therapist's tolerance, the patients become capable of countenancing certain attitudes consciously for the first time. They appreciate that when they express destructive attitudes toward the therapist, these do not call forth retaliatory rejection, condemnation, or punishment. They gradually develop a more tolerant attitude toward their inner drives, and they learn to reevaluate them in the light of existing reality rather than in terms of unconscious fantasies and traumatic events in the past. As they undergo the unique experience of expressing their deepest strivings without retaliation, they also begin to permit healthy attitudes to filter through their defenses. The therapist becomes an individual who fits into a special category, as less authority and more the friend.

The tolerant and understanding attitude of the therapist provides a peculiar attribute of protectiveness; for the patients alone are unable to accept inner conflicts and impulses and use the therapist as a refuge from danger. The conviction that they have a protector enables them to divulge their most repulsive dreams, impulses, emotions, memories, and fantasies, with an associated release of affect. Along with growing awareness of their unconscious drives with placement in the time frame of earliest childhood, the patients sooner or later discover that there is a difference between what they feel and what it actually going on in reality; they find that their guilt feeling and anxiety actually have no basis in fact.

The patients may bring up more and more painful material. Encouraged to express themselves, they begin to regard the therapist as one who bears only good will toward their repressed drives. They will continue to exhibit all of their customary interpersonal attitudes and defenses in their relationship with the therapist, but they can clarify these to

themselves under a unique set of conditions—conditions in which they feel accepted and in which there is no condemnation or retaliatory resentment.

The reorientation in their feelings toward the therapist makes it possible for them to regard the therapist as a person toward whom they need nurture no ambivalent attitudes. Their acceptance of the therapist as a real friend has an important effect on their resistances. These are genetically related to the hurt that they experienced in their relationships with early authorities. The lowering of resistances is dynamically associated with an alteration in their internalized system of restraints, for, if they are to yield their defenses, they must be assured that the old punishments and retributions will not overtake them. It is here that their experiences with the therapist play so vital a role because in it they have gained an entirely new attitude toward authority. Their own conscience is modified by adoption of a more lenient set of credos.

One of the chief aims of reconstructive therapy is to render the conscience less tyrannical and to modify it so as to permit the expression of impulses essential for mental health. Perhaps the most important means toward this alteration is through acceptance of the therapist as a new authority whose standards subdue and ultimately replace the old and intolerable ones. In the course of the therapeutic relationship the patients tend to identify themselves with the therapist and to incorporate the therapist's more temperate values. The ultimate result is a rearrangement of the dynamic forces of the personality and a reduction in the harshness of the superego.

Identification with the therapist also has a remarkable effect on a patient's ego. Progress in reconstructive therapy is registered by the increasing capacity of the reasonable ego to discern the irrationality of its actions, feelings, and defenses. The rebuilding of ego strength promotes a review of old repressions, some of which are lifted, while others are accepted but reconstructed with more solid material, so that they will not give way so easily to unconscious fears. Growth in the rational power and judgment of the ego makes it possible to identify these destructive strivings, which, rooted in past experiences, are automatically operative in the present.

Ego strength, consequently, results both from liberation of the self from the repressive and intolerant standards of the tyrannical conscience, and also identification with the accepting, non-hostile figure of the therapist. Ultimately, ego growth involves an identification with a healthy group. This is, of course, the final aim in therapy, and a good relation with the group eventually must supplement and partly replace the personal identification.

The undermining of the superego and the strengthening of the ego give the patients courage to face their fearsome impulses, such as hate. They become increasingly more capable of expressing rage openly. The possibility of their being physically or verbally attacked by the therapist becomes less and less real to them. As they resolve their hate and fear, they are likely to experience an onrush of loving emotions. Particularly where a transference neurosis has been allowed to develop, these may burst forth in a violent form, as in a compulsive desire for sexual contact. In this guise feelings may be loathsome and terrifying and may become promptly repressed. Sexuality, to the mind of the patients, may mean unconditional love or surrender or a desire to attack or to merge with another person. Inextricably bound up with such destructive feelings are healthful ones, but because the patients have been hurt so frequently in expressing tender impulses, they have customarily been forced to keep feelings under control. In their relationships with the therapist they learn that normal demands for understanding and affection will not be frustrated and that these have nothing to do with hateful and sexual attitudes.

As the therapist comes to be accepted as an understanding person, the unconscious impulses come out in greater force, and the patients discover that they are better able to tolerate the anxiety that is created by such expression. In contrast to what occurs in real life, resistance to one's divulgence is not reinforced by actual or implied threats of retaliation or loss of love. The patients then become conscious of the fact that their terror has its source within themselves rather than in an implied threat of hurt from the therapist. This insight does not help much at first, but gradually it permits the patients to experiment in tolerating increased doses of anxiety.

The development of the capacity to withstand pain makes it possible for the patients to work out more mature solutions for their problems, instead of taking refuge in repression, a defense hitherto necessitated by an inability to tolerate anxiety. The discovery that they have not been destroyed by their impulses and the realization that they have not destroyed the therapist, whom they both love and hate, are tremendous revelations, lessening the inclination to feel guilty and to need punishment, and contributing to their security and self-respect.

At this stage in therapy the patients become more critical of the therapist and more capable of injecting reality into the relationship. They attempt to test out their new insights in real life. They do this with considerable trepidation, always anticipating the same kind of hurt that initially fostered their repression. As they discover that they can express themselves and take a stand with the therapist, a new era of trust in the therapist is ushered in with a definite growth of self-confidence. Over and over they work through with the therapist their own characterologic strivings, reexperiencing their unconscious impulses and the accompanying reactions of defense against them. Gradually they become aware of the meaning of their emotional turmoil, as well as of the futility of their various defenses. The continuous analysis of the transference enables them to understand how their neurotic drives have isolated them from people and have prevented expression of their healthy needs.

A new phase in their relationships with the therapist ensues. Realizing that the therapist means more to them than does anyone else, they seek to claim this new ally for themselves. They may wish to continue the relationship indefinitely, and they may look upon the completion of therapy as a threat. Clinging to their illness may then have positive values. However, they soon begin to understand that there are reality limitations in their present relationship, and they begin to realize that they do not get out of it the things that they are beginning to demand of life, that the outside world is the only milieu in which they can gratify their needs. They find the relationship with the therapist gratifying, but not gratifying enough; their reality sense becomes stronger, and their ability to cope with frustration is enhanced. Finally, they set out in the world to gain those satisfactions that

they have never before felt were available to them.

The working-through process is not always accompanied by the intensive transference manifestations such as have been described. Indeed, the relationship with the therapist may be maintained on a more or less equable level, the working through of attitudes, feelings, and conflicts being accomplished exclusively in relation to persons and situations outside of therapy. This is particularly the case in supportive, reeducative, and psychoanalytically oriented psychotherapies in which a transference neurosis is more or less discouraged. But even in the latter therapies it may not be possible to keep direct transference from erupting; if this occurs, some of the working through will have to be focused on the patient-therapist relationship.

Again it must be emphasized that circumvention and avoidance of a transference neurosis do not necessarily limit the extent of reconstructive change that may be achieved by skilled therapists with less intensive therapies than classical analysis. Nevertheless there are some patients in whom repression is so extreme that only a transference neurosis will serve in its resolution. (See also Chapter 42)

EXPEDITING WORKING THROUGH

It is salutary to avoid reinforcing the patient's concept that one is a laboratory of pathological traits. Our focus on symptoms, conflicts, defenses, and personality distortions may divert us from accenting the sound, constructive, and healthy elements that coexist. Patients are sufficiently alarmed by their difficulties not to need constant reminders of the various ways that these obtrude themselves in their lives. In a subtle way they perceive that the therapist is more interested in their pathological traits than in other aspects, and they may respond to this reinforcement by concentrating on them at the same time that they build a shell of hopelessness around themselves. As they repetitively indulge their neuroses, and the therapist keeps pointing this out to them, they may begin to feel out of control. Ultimately, they may give up and assume the attitude that if they are unavoidably neurotic, they might as well act like heroes in a Greek legend, marching with head up to their inevitable doom.

Neurotic trends are tenacious things and do not yield by constant exposure of their existence or source. They must gradually be neutralized through replacement with more effective and adaptive substitutes. This process will require that the therapist mobilize all positive resources at the disposal of the patients. While one should not avoid acquainting the patients with what they are doing to sabotage their adjustment, and perhaps the reason why, one should at the same time point out what constructive elements are present simultaneously. For example, a saleswoman in therapy who is burdened by a need to fail, destroys again the opportunity of advancement by insulting the vice president of the company, who is in charge of her operations and who is considering her and a colleague for a post that is more interesting, better paying, and more prestigious. The patient eager to have this new job, to her own consternation finds herself engaging angrily in complaints and recriminations about the company's policies and operations charging that the vice president must in some way be involved. The patient reports to her therapist.

> *Pt.* I did it again. I was so furious with myself. I even realized what I was doing while I was letting off steam. I'm just a mess.

Improper Response

> *Th.* You aren't, but what you're doing to your life is. You shouldn't have allowed yourself to criticize your superior directly.

Proper Response

> *Th.* It's obvious to me that you care enough about yourself to be disturbed by what happened. When a similar situation presents itself that invites you to fail, you will most likely be able to anticipate your response in advance and alert yourself to any sabotage talk.

The patient should be apprised of her active need for cooperation. She must be told that one cannot change without experimenting with certain new actions. Like any experiments she must take some risks, and she must be prepared to face some failure and disappointments, even a few hurts. Successes cannot occur without some failures. The therapist should extend as much help and encouragement as is necessary— but no more. It is important that the patient assume as much responsibility as possible. Role playing here can be helpful.

To summarize, the following principles may be found helpful:

1. Patients must proceed at a pace unique for themselves and contingent on their readiness for change and on their learning abilities.

2. Reinforcement for progress is needed in the form of therapist verbal approval whenever the patient takes a reasonable step forward.

3. If resistances to movement develop, the focus on therapy must be concentrated on understanding and interpreting the patient's resistances.

4. Adjuncts, like assigning homework practice sessions, for the gradual mastery of certain problems may help deal with obdurate resistances.

5. Encouraging the patient to generalize from the immediate situation one aspect of experience, or the control of a symptom, to other experiences may be important. This eventually enables a view of the immediate disturbance in the light of the total personality structure.

6. Adjuncts like role playing may be indispensable.

ILLUSTRATIVE CASE MATERIAL

Illustrative of the working through of transference is the case of a young divorcee with a personality problem of detachment, whose marriage had broken up largely because of her general apathy. Sexually frigid and with little affectionate feeling for people, she had never been able to establish a relationship in which she could feel deep emotion. After a prolonged period of working on her resistances, she began to evince positive transference feelings toward me, as manifested in the following fragment of a session:

> *Pt.* I had a dream yesterday. We were dancing together, and then you make love to me. Then the scene changes, and there is a fellow sitting on a bench, and you kiss me and in jest ask him to leave. And then you sit down, and I lie down with my head against you. You put your arms around me. And then the scene shifts again, and you and I are in the kitchen. And my daughter, Georgia, is climbing over the sink toward the window, and I pull her in. Then I'm standing there with my son, John, in the hallway and you very professionally ask if there is anyone else I am waiting for. You came to find out about John. You forget the fact that you asked me for dinner, and I'm very let down and wake up with that let-down feeling.

> *Th.* What are your associations to this dream?

Pt. I awoke with the feeling that I'm very much in love with you. I want you to love me very much. It's a desperate feeling that I can't control.

Th. How long has this feeling been with you?

Pt. It's been accumulating over a time, but it suddenly hit me last night, and when I awoke this morning, I knew, *(pause)* This is a funny thing to ask you, but I feel sexually attracted to you. Is it ever permissible to . . .to. . . I mean *(blushes)*

Th. You mean to have an affair?

Pt. Yes.

Th. Well, I appreciate your feeling very much. It often happens that in therapy the patient falls in love with the therapist. This is understandable because the patient takes the therapist into her confidence and tells him things she wouldn't dare tell herself. But in therapy for the therapist to respond to the patient by making love would destroy therapy completely.

Pt. I can understand perfectly. But I felt that you responded to me, *(laughs)* that *you* were in love with me. I think you are the most wonderful man in the world.

Th. You may possibly feel I reject you. It is important though to explore your feelings for me, no matter what these may be.

Pt. I agree, agree with you, of course. I can't see how this happened to me though. It never happened before. It's a hell of a note, but as you say, it must inevitably happen.

There ensued a prolonged period of strife in which the patient veered from sexual to hostile and destructive feelings toward me. The following session, for example, reflects negative impulses.

Pt. I'm furious at you. I don't, didn't want to come today.

Th. Can you tell me why?

Pt. Because you've gotten, gotten me to feel like a human being again instead of a piece of wood, and there's nothing to do about it. You know very well there's nothing to do about it.

Th. You mean, now you're able to feel about people and there's nothing you can do about expressing yourself?

Pt. (angrily) Oh, please be quiet will you. *(pause)* Here you went and got me all stirred up for absolutely nothing. It's like you want to torture and hurt me.

Th. What makes you think that I want to torture you and hurt you?

Pt. I didn't say you wanted to. I don't believe I've reproached you at all. I never reproach anybody

for anything, I never have.

Th. But . . .

Pt. Have I ever implied or said one word of reproach to you? I don't believe I have.

Th. No.

Pt. No. I don't think so. I don't reproach anybody for anything. I don't want you to do anything at all, except just let me walk out of that door.

Th. Do you really want to walk out of that door?

Pt. I'm going to walk out of that door. You see, what you don't know about me yet is that I've a very, very strong will, *(pause)* You sit there in that chair, and I sit here opposite you, and you've got that lovely warm darn way of speaking, and before I reach that door, you'll freeze like an icicle. And I can do exactly the same thing, exactly the same thing.

Th. You mean just to get even with me?

Pt. Have you ever seen me try to get even with anybody? I don't think you have. I'm not a very vindictive person.

Th. Do you think I really act icy to you?

Pt. But you do.

Th. When?

Pt. I went out of here the last time ashamed of myself. I went down that street crying. I was crying. I felt you rejected me, cold to me.

Th. You felt that I rejected you? You felt that I acted cold toward you? When did I act cold toward you?

Pt. Let's drop that rejection business, shall we? It isn't a question of being rejected. It has nothing to do with it at all. And if we get right down to it, what difference does it make whether you do or you don't?

Th. It makes this difference, that I am very much interested in helping you.

Pt. If I walked out of this room, you'd never think of me again.

Th. You feel that if you walk out of this room, I'll never even think of you again.

Pt. That's exactly how I feel! Exactly what I feel. Yes. Suppose you had to do the same thing for every patient. You couldn't last, any more than any other doctor could last, any more than any trained nurse could last. They can't. *(pause)* Well, I'm feeling a lot better getting that off my chest.

Th. I'm glad you're feeling better.

Pt. Yes. I'm sure. I think you owe me quite a little time. I don't believe I've ever stayed here 45 minutes, have I? I don't think so. I've always looked at that clock and I've gone. I've gone to the second at 40 minutes after I got here. *[This is not exactly correct, but I decide not to challenge it.]*

Th. Why?

Pt. Because I don't want anything from anybody. Because I don't want one minute of anybody's time.

Th. You just want to be completely independent?

Pt. Yes, I do.

Th. I wonder if you trust me?

Pt. I've always trusted you. What do you think I'm coming here for? There isn't anybody that is forcing me to come. Who is it that drags me any place on a chain? If I didn't want to come, there isn't anybody that could make me come.

Th. Indeed. You know, too, that it's good that there's nobody that forces you to be here. It has to be completely a free-thing with you, a voluntary thing with you, a thing that you really believe in.

Pt. I don't know what I'm going to do when I have to leave you, when I'm through with this.

Th. Why?

Pt. I can't depend on anybody, see?

Th. You're afraid to get dependent on me?

Pt. I'm afraid to get dependent on any human being, because there isn't a living human being that I can trust. Not even you. I can't trust anybody on earth. And that's the truth.

Th. I can't force you to trust me, but I hope you will. I'll do everything in my power to be worthy of that trust. But I can appreciate the suffering and torment that you must go through as you begin to feel feelings for me.

Pt. But you do torment me.

Th. How do I torment you?

Pt. I think you resent me, even despise me.

Th. Did I ever do anything to give you that impression?

Pt. No, but ... I guess I must *think* you reject me. But you really don't.

The brief samples of the interviews contained here do not permit the detailed and painful elucidations of the genetic origins of the patient's problem. This was rooted in relationship to her early parenting figures. Her mother was a vain, rejecting, narcissistic woman and her father a cold, detached individual to whom she could never get close. She was made to feel that human beings should at all times control their emotions. Her dreams in therapy left no doubt in my mind that she was transferring her repressed feelings related to her father toward me. The working through of her feelings toward a more constructive solution is shown in this portion of an interview that occurred several months after the initial onset of transference:

> *Pt.* When I came to you, you were exactly what I needed at that moment, and you comforted me when I came, and for the first few weeks—it was no more than that—then I began to like you. I liked you more and more, and it was interesting to me that I could feel that way about a person because I had not up to that point. You were the first person that I felt anything for since many, many years ago. So I reasoned it out, and I felt that you were probably ... I didn't know what you were like as a man. I knew you only from a professional standpoint, what you were like. Maybe I would not feel that way if I did know you, I don't know. I was trying to tell myself I didn't know enough about you to feel that way. It wasn't anything sound. And another thing I felt was that you were probably a symbol of what I would like to have or feel for someone, that you just were a symbol. Actually, I didn't know enough about you to feel that way, and I kept telling myself that, and, during your vacation when I left I thought I didn't know how I was going to get along without seeing you. It was really the high point of my week when I came to see you. I looked forward to it, and I really enjoyed that more than anything else that I did. So, during the summer, I thought, "Well, I am going to miss him. How will I get along?" I sort of leaned on you, and I had gotten so much comfort. Then, something began to happen to me, and I felt that even if I felt that way, maybe you did like me very much, maybe you didn't. I don't know whether what you say is all professional. I felt that as far as you were concerned, even if you did like me, and I liked you as you said, which was what I had figured out for myself, that any sort of very close friendship was not possible and isn't practical. I felt that I needed you much more as a doctor than a man at that point and that I should forget about it. So it was something that I was putting on. I probably needed something, maybe it wasn't necessarily you. So I sort of started to look around at men. I was aware more of the attention they paid me. I responded more, which I had never done. I found that I was giving them a little more encouragement because I never radiated any encouragement. I felt that if I were to find someone, I was very happy that I could feel that way about someone. I really was because I didn't think I could any more, I just didn't. I missed seeing you, which was very unusual for me, because I hadn't felt that way about anyone in many years. So I started to look around; as I say I have responded, but I haven't found anyone that I do feel that way about. Of course, I haven't had the opportunity.

> *Th.* At least you are not running away and are not guilt-ridden. You may feel that if the right sort of person came along, there may be a possibility for a relationship. But what about me right

now?

Pt. Well, I'll tell you how I feel about that. When I first came here, not the first few weeks, but a little later, I felt that you did like me personally. I don't know how justified I was, but I did feel that.

Th. You mean that I was in love with you?

Pt. Not that you were in love with me, but that you were attracted to me, that you did like me. But, of course, again I said that maybe I was so keyed up; I thought maybe I had sort of colored it, which was unusual for me, because I have never in all my life responded to any man or made the first steps without his feeling a great interest in me. I have never, so that if it was so, it was different than it had ever been because that was never so before. I have never made the first move or picked someone and said I liked him and want to know him, and I'd like to be in love with him. I never felt that way.

Th. It was always as a result of somebody else's actions first.

Pt. Of somebody radiating more than the usual amount of interest. So that I felt that it was different and I was rarely wrong, I mean, I was always right, but, of course, as I say, I was in a different state of mind than I am today. I am much calmer, probably see things a little clearer. So that I felt that you didn't love me, and I hoped that you didn't. In a way I wanted it, and yet I realized that I hoped you didn't because I might respond. I just felt it was wrong because you were the wrong person, because you are my doctor. "So, find somebody else," I said to myself. (*laughs*) As a matter of fact a very funny thing happened. I ran into my uncle who referred me to you shortly after first starting with you. I was beginning to feel that way about you, and I was curious about you. I met him in a restaurant. We talked for a few minutes. He asked me how I was getting along. I said I was making progress. He asked me how I liked you, and I said very much indeed, you were grand. He said he thought so too. You were practical, and he recommended you because he thought you would be what I needed. So I said, "Is he married?" And I was blushing. So he said, "He has an awfully nice wife and some lovely children." I realized then that probably I had radiated something that I hadn't intended to. I must have radiated some interest.

Th. Your reaction to me was one that occurs commonly in psychotherapy.

Pt. I realize this.

Th. Sometimes it's necessary to have such a reaction to get well.

Pt. That's the thing, that's the reason I bring it up.

Th. You might never get well if you didn't have a positive attitude toward me. That attitude we can use as a bridge to better relationships with men. There is a possibility that you may not find a man right away. There is a possibility of that, but at least you will know that it's not because of any block in you; it's not because you have no capacity to love.

Pt. Well, it's been, and I'll tell you it's been an amazing thing. I used to wonder at it myself because I certainly am not cold. I used to wonder at myself because it didn't seem to concern me. I mean sex. That's the truth of it. But I'm getting myself interested now.

50
Supportive and Reeducative Techniques during Middle Treatment Phase

With the accent on cost-effectiveness demanded by third party payers, short-term therapy has been coming into prominence, and this has tilted the scales toward goals of symptom control and problem-solving. These necessitate supportive and reeducative interventions. There are still a substantial number of therapists who believe methods aimed at symptom control, while rapidly palliating suffering and perhaps even reinstating the previous psychological equilibrium, operate like a two-edged sword. Justifiable as symptom control may seem, these skeptics insist that it fails to resolve the *underlying* problems and difficulties that nurture the current crisis. Irreconcilable unconscious needs and conflicts continue to press for fulfillment, and, therefore, they insist, we may anticipate a recrudescence or substitution of symptoms. These assumptions are based on an erroneous closed-symptom theory of personality dynamics. Symptoms once removed may actually result in productive feedback that may remove barriers to constructive shifts within the personality system itself. Even though these facts have been known for years (Alexander, F, 1944; Alexander et al, 1946; Avnet, 1962; Wolberg, LR, 1965; Marmor, 1971) and have been corroborated in the therapeutic results brought about by active psychotherapeutic methods, the time-honored credo branding symptom removal as worthless persists and feeds lack of enthusiasm for symptom-oriented techniques. The supportive process, however, may become more than palliative where, as a result of the relationship with the helping agency, the person gains strength and freedom from tension, and substitutes for maladaptive attitudes and patterns those that enable one to deal productively with environmental pressures and internal conflicts. This change, brought about most effectively through the instrumentality of a relationship either with a trained professional in individual therapy or with group members and the leader in group therapy, may come about also as a result of spontaneous relearning in any helping situation. Some dependency is, of course, inevitable in this kind of a therapeutic

interaction, the adequate handling of which constitutes the difference between the success or failure of the therapeutic relationship in scoring a true psychotherapeutic effect. Dependency of this kind, however, can be managed therapeutically and constitutes a problem only in patients who feel within themselves a pathological sense of helplessness. The sicker and more immature the patient, the stronger the dependency is apt to be. It is essential that the helping agency be able to accept the patient's dependency without resentment, grading the degree of support that is extended and the responsibilities imposed on the patient in accordance with the strength of the patient's defenses.

The evidence is thus overwhelming that symptom-oriented therapy does not necessarily circumscribe the goal. The active therapist still has a responsibility to resolve as much of the patient's residual personality difficulties as is possible within the confines of the available time, the existing motivations of the patient, and the basic ego strengths that may be relied on to sustain new and better defenses. It is true that most patients who apply for help only when a crisis cripples their adaptation are motivated merely to return to the dubiously happy days of their neurotic homeostasis. Motivation, however, can be changed if the therapist clearly demonstrates to the patient what really went on behind the scenes of the crisis that were responsible for the upset.

Supportive approaches are employed during the middle phases of treatment under the following conditions:

As a Principal Form of Therapy

1. Where the patient possesses a fairly well-integrated personality but has temporarily collapsed under severe stress, a short period of palliative psychotherapy may suffice to restore the habitual stability. Supportive techniques may also be efficacious where the problem has not yet been structuralized, as in behavior disorders in children. Actually, supportive therapy under these circumstances may be the treatment of choice in a sizable number of patients who consult a psychotherapist.

2. Patients who require more intensive psychotherapy, but are temporarily too ill to utilize reconstructive therapy, may benefit from supportive

approaches as an interim measure.

3. Supportive therapy is often mandatory in patients whose symptoms interfere drastically with proper functioning or constitute sources of danger to themselves and to others. Among such symptoms are severe depression, suicidal impulses, homicidal or destructive tendencies, panic reactions, compulsive acting-out of perverse sexual strivings, severe alcoholism, drug addiction, and disabling physical symptoms of psychologic origin.

4. Where motivation for extensive therapeutic goals is lacking in patients who seek no more than symptom relief or problem-solving, supportive treatment may prove sufficient. After such partial goals have been achieved, it may be possible to motivate the patient to work toward reconstructive goals.

5. Where the personality has been severely damaged during the formative years so that there is little on which to build, the objective may be to stabilize the individual through supportive measures. Some patients with severe infantile, dependent personality disorders, and with borderline and psychotic reactions, may be unable to tolerate the anxieties of exploration and challenge.

6. Supportive treatment may be indicated where the available time and finances are limited, or where there is extreme character rigidity, or where the personality is so constituted that the patient can respond only to commanding authoritative injunctions. Even though manifest neurotic difficulties continue in force following therapy, life may become more tolerable and the individual may adopt a more constructive attitude toward reality.

As an Adjunctive Form of Treatment during Reeducative and Reconstructive Therapy

1. Where the coping resources of the ego are failing, as evidenced in feelings of extreme helplessness, severe depression, intense anxiety, and disabling psychosomatic symptoms, extension of support is usually necessary.

2. In cases where the environment is grossly disturbed so as to impede progress, supportive techniques like environmental manipulation may be required.

MODE OF ACTION OF SUPPORTIVE THERAPY

Supportive therapy owes its efficacy to a number of factors:

1. A correction or modification of a disturbed environment or other stress source may serve to strengthen coping resources.

2. The improvement that results may permit the individual to exact gratifications essential to one's well-being.

3. The patient may fulfill, in the supportive relationship with the therapist, important interpersonal needs, the deprivation of which has created tension. The supplying of emotional needs in the relationship constitutes what is sometimes known as *transference cure*. For instance, the patient, feeling helpless, may desire the protection and security of a stronger individual on whom one may become dependent. Finding this with the therapist, the patient feels the comfort akin to a child who is being cared for by a loving and powerful parental agency. The patient is thus relieved of responsibility and filled with a sense of comfort and security. Reinforcing these effects are the influences of the placebo element and of suggestion.

4. In the medium of the therapeutic relationship, the patient may verbalize freely and gain a cathartic release for fears, guilt feelings, damaging memories, and misconceptions that have been suppressed or repressed, having no opportunity for such discharge in the customary life setting. The draining off of tension, which has been converted into symptoms, brings about relief and usually a temporary abatement of symptomatic complaints.

5. The patient may rebuild shattered old defenses or erect new ones that serve to repress more effectively offending conflicts. Supportive therapy is suppressive in nature, helping to keep conflicts from awareness or modifying attitudes toward the elements of conflict.

6. Under the protective aegis of the therapist, the patient is enabled to face and to master life problems that were hitherto baffling. Greater capacity to deal with these problems not only helps to rectify current sources of stress, but also gives the patient confidence in the ability to adjust to other difficult aspects of the environment. The resultant expansion of security may eliminate the patient's need to exploit inadequate defense mechanisms.

7. There may be alleviation of guilt and fear through reassurance or through

prohibitions and restrictions, which, imposed by the therapist, are interpreted as necessary disciplines by the patient.

8. Certain measures, like drugs and relaxing exercises, may remove tension or moderate its effects.

9. An outlet for excessive energy and tension may be supplied through prescribed physical exercises, hobbies, recreations, and occupational therapy.

THE THERAPIST-PATIENT RELATIONSHIP IN SUPPORTIVE THERAPY

The different techniques employed in supportive therapy presuppose a relationship of therapist to patient that varies from strong directiveness to a more passive permissiveness. In most cases the therapist is essentially authoritarian.

Success in treatment usually is contingent on acceptance of the therapist as a wise or benevolent authority. A consistent effort is made to establish and maintain a congenial atmosphere. Because hostile attitudes oppose the incorporation of therapeutic suggestions, it is essential to try to avoid a negative transference. An attempt is made to win the patient over to a conviction that the therapist is a helpful friend. Whenever the patient manifests attitudes that interfere with the relationship, therapy is focused on discussion and clarification in the attempt to restore the original rapport. Much skill may be required to halt negative feelings as soon as they start developing; but unless this is done, the therapist may encounter resistance that cannot be controlled.

Forcefulness of personality, and an ability to inspire confidence are important qualities in the therapist for this type of therapy. The ideal attitude toward the patient is sympathetic, kindly, but firm. The most successful therapists never derive sadistic pleasure from the patient's submission nor resent the latter's display of aggression or hostility. They do not succumb to blandishments of praise or admiration. A non-condemning, accepting attitude, shorn of blame or contempt, secures best results.

The neurotic patient may, of course, display provocative impulses and attitudes; but if the therapist is incapable of controlling his or her resentment, this practitioner will

probably be unable to do productive work with the patient. The irritation cannot usually be concealed by a judicious choice of words.

The attitudes of the therapist are important because some of the patient's responses have been conditioned by antagonistic reactions of other people. At the start of therapy the patient will expect similar displays from the therapist, especially rejection or condemnation. When such responses do not appear even under badgering, the patient's attitude toward the therapist hopefully will change. Different from how he or she acts in other relationships, the patient may begin to feel accepted as is, and genuine warmth toward the therapist may begin to trickle through. The patient may then recognize the therapist as an ally with whom one can identify and whose values one may respect.

There are therapists who attempt, in a supportive framework, to deal boldly with pathogenic conflicts by manipulating the therapeutic relationship. Here they deliberately play a role with their patients in order to reinforce or subdue the parental image or to introduce themselves as idealized parental substitutes. Transference responses are deliberately cultivated by employing permissiveness or by enforcing prohibitions graded to a desire effect. Acting a "good" parental figure is considered helpful with patients who need an accepting "giving" situation. Deprived in childhood of an understanding maternal relationship, certain patients are presumed to require a "living through" with another human being of an experience in which they are protected and loved without stint. Another role assumed by the therapist is that of a commanding, stern authoritarian figure. This is believed to be helpful in patients whose superegos are relatively undeveloped, who still demand control and discipline from the outside.

Sometimes role playing is arranged so that it simulates early patterns of parents, on the theory that it is essential for the patient to live through with the therapist emotional incidents identical in type with the traumatizing experiences of childhood. Only by dramatizing one's problems, it is alleged, can the patient be prodded out of the rigid and circumscribed patterns through which one avoids coming to grips with life. In order to mobilize activity and to release inner drives, the therapist attempts to create a

relationship that is charged with tension. The ensuing struggle between patient and therapist is said to catalyze the breaking down of the neurosis.

One may rightfully criticize this technique on the grounds that the patient may actually experience too much frustration as a direct result of the therapeutic situation. The tension and hostility that are mobilized may eventually become sufficiently strong to break through repression, with an acting-out of impulses that are destructive to the patient and to the therapeutic relationship.

A misdirected positive use of role playing is also to be impugned. Even though open demonstrations of affection may seem logical in making the patient feel loved and lovable, such gestures are usually ineffective because of the patient's ambivalence. Love is so fused with hate that the patient may completely misinterpret affectionate tokens. This does not mean that the therapist must be cold and withdrawn, for a refrigerated attitude will even more drastically reinforce the patient's feelings of rejection.

Manipulations of the relationship call for a great deal of skill and stamina on the part of the therapist. They are responded to best by relatively healthy persons. Borderline patients, schizophrenics, paranoiacs, and profoundly dependent individuals may react badly to such active gestures, and perceptive patients easily see through the play acting as not genuine.

GUIDANCE

In the supportive technique of guidance the therapist acts as a mentor, helping the patient to evolve better ways of adjusting to the reality situation. Therapeutic interviews are focused around immediate situational problems. While the therapist may formulate an hypothesis of the operative dynamics, this is not interpreted to the patient unless the dynamics are clearly manifest and the interpretation stands a chance of being accepted by the patient without too great resistance. The employment of guidance requires that the therapist encourage the patient toward a better understanding and evaluation of the reality situation, toward a recognition of measures that will correct the patient's difficulty,

and toward the taking of active steps in effectuating a proposed plan. The patient is usually required to make the choices, although the therapist may clarify issues, outline the problem more succinctly, present operational possibilities, suggest available resources, and prompt the patient to action. Reassurance is utilized in proportion to the existing need, while as much responsibility is put on the patient as one can take.

Guidance suggestions must always be made in such a manner that the patients accept them as the most expedient and logical course of action. It may be essential to spend some time explaining the rationale of a tendered plan until the patients develop a conviction that they really wish to execute it. In this choice the patients should always be led to feel that their wishes and resistances will be respected by the therapist.

There are, however, a few patients whose personalities are so constituted that they resent a kindly and understanding authority. Rather they are inclined to demand a scolding and commanding attitude without which they seem lost. Such patients appear to need punitive reinforcement of their conscience out of fear of yielding to inner impulses over which they have little control. At the start of therapy it may sometimes be tempting to respect the needs and demand of such personalities, but an effort must always be made later on to transfer the disciplinary restraints to the individual. Unless such an incorporation of prohibitions is achieved and becomes an integral part of the individual's conscience, one will demand greater and greater displays of punitive efforts on the part of the therapist. To complicate this, when one has responded to dictatorial demands, one will burn inwardly with resentment toward the therapist, and will feel self-contempt for being so weak as to need authoritative pressure.

One way of conducting the guidance interview is to try to avoid, as much as possible, the giving of direct advice. Rather, the therapist may couch ideas and suggestions in a way that patients participate in the making of decisions. Furthermore, advice should be proffered in a non-dictatorial manner so that patients feel they may accept or reject it in accordance with their own judgment.

The sicker the individuals, the more likely they will make erratic choices, and the

more they will need active guidance and direction. How long the supportive relationship will have to be maintained will depend on the strength of the patient's ego. Usually, as patients gain security and freedom from symptoms, they will want to take more and more responsibility for their own destiny. Even those persons who offer resistance to assertiveness and independence may be aided in developing incentive toward greater independence. This may require considerable time and patience, but in many instances such constructive motivation can be achieved.

ENVIRONMENTAL MANIPULATION

The special environment in which the individual lives may sponsor conditions inimical to mental health. This does not mean that mental health will be guaranteed by a genial atmosphere because personal conflicts will continue to upset the individual even under the most propitious circumstances. One may be burdened with blocks that obstruct taking advantage of available opportunities. One may initiate and foster a disturbance of the environment where none has existed in order to satisfy inner needs. Be this as it may, the therapist has a responsibility to help rectify discordant living conditions so as to give the patient the best opportunities for growth. Though the effort may be palliative, the relief the patient experiences, even temporarily, will provide the most optimal conditions for psychotherapy. It is obviously best for patients to execute necessary changes in the environment for themselves. The therapist, however, may have to interfere directly or through an assistant by doing for the patients what they cannot do for themselves.

Conditions for which environmental manipulation may be required are the following:

1. *Economic situation.*

      a. Location of resources for financial aid.

      b. Budgeting and managing of income.

      c. Home planning and home economics.

2. *Work situation.*

    a. Testing for vocational interests and aptitudes. (Referral to a clinical psychologist may be required.)

    b. Vocational guidance and vocational rehabilitation. (Referral to a clinical psychologist or rehabilitation resource may be required.)

3. *Housing situation.*

    a. Locating new quarters.

    b. Adjusting to the present housing situation.

4. *Neighborhood situation.*

    a. Moving to a new neighborhood.

    b. Locating and utilizing neighborhood social, recreational, or educational resources.

    c. Adjusting to the present neighborhood.

5. *Cultural standards.*

    a. Interpreting meaning of current cultural patterns.

    b. Clarifying personal standards that do not conform with community standards.

    c. Clarifying legality of actions.

6. *Family and other interpersonal relations.*

    a. Consulting with parents, siblings, relatives, mate, child, or friend of patient.

    b. Promoting education in such matters as sexual relations, child rearing, and parenthood.

    c. Helping in the selection of a nursery school, grade school, camp, or recreational facilities for the patient's children.

d. Referring patient to legal resources in critical family or interpersonal situations.

7. *Daily habits, recreations, and routines.*

　　　a. Referring patient to resources for correction of defects in dress, personal hygiene, and grooming.

　　　b. Referring patient to appropriate recreational, social, and hobby resources.

8. *Health.*

　　　a. Clarifying health problems to patient or relative.

　　　b. Referring patient to hospital or institution.

　　　c. Referring patient to resources for correction of remediable physical disabilities.

The therapist may have to interfere actively where the environmental situation is grossly inimical to the best interests of the patient. This usually implies work with the patient's family, since it is rare that a patient's difficulties are limited to himself or herself. Various family members may require psychotherapy before the patient shows a maximal response to treatment. Indeed, the cooperation of the family is not only desirable, but in many instances unavoidable. A good social worker can render invaluable service to the therapist here. In some cases family therapy may be required.

Where the immediate environment does not offer good opportunities for rehabilitation, the patient may be referred to resources that will reinforce the therapist's efforts, such as day-and-night hospitals, halfway houses, sheltered workshops, rehabilitation centers, and social therapy clubs. For instance, day-and-night hospitals manage even moderately disturbed patients in the community and help support their work capacities. Halfway houses serve as a sheltered social environment in which the patient's deviant behavior is better tolerated than elsewhere. The patient is capable of experimenting there with new roles while being subject to the modifying pressures of

group norms. Discarding of disapproved patterns and adoption of new attitudes may become generalized to the social environment (Wechsler, H, 1960b, 1961). Sheltered work programs have been shown to help patients make a slow adjustment to conditions and conflicts at work (Olshansky, 1960). Tolerating an individual's reactions allows the individual to restructure defenses at his or her own pace without countenancing violent or rejecting responses on the part of supervisors and employers. A reconditioning process that prepares the patient for a regular occupation in the community may in this way be initiated. Rehabilitation centers, such as Altro Health and Rehabilitation Services, provide a variety of benefits that are made available to patients and that permit them to achieve the best adjustment within the limitations of their handicaps. At such centers the following may be accomplished:

1. Handling the patient's lack of motivation and resistance to work.

2. Helping patients in their efforts at reality testing.

3. Educating patients in methods of coping with daily problems as well as in developing working skills.

4. Aiding patients in recognizing early signs of emotional upset and suggesting means of removing themselves from sources that upset them before they go to extremes.

5. Working with the patient's family to secure their cooperation and manage problems within the family structure.

6. Providing aftercare services to prevent relapses (Benney et al, 1962; Fisher & Beard, 1962).

Social therapy clubs provide an extraordinary medium for a variety of experiences, either in themselves or as part of a therapeutic community (Bierer, 1948, 1958; Ropschitz, 1959; Lerner, 1960; Fleischl, 1962, 1964; Waxenberg & Fleischl, 1965).

EXTERNALIZATION OF INTERESTS

The turning of the patient's interests away from the self may be considered

important in planning a supportive program. Hobbies, occupational therapy, and recreational activities may be considered here.

A most effective hobby is one that provides an acceptable outlet for impulses that the person cannot express directly. The need to experience companionship, to give and to receive affection, to be part of a group, to gain recognition, to live up to certain creative abilities, and to develop latent talents may be satisfied by an absorbing hobby interest.

External activities can provide compensations that help the individual to allay some inferiority feelings. Instead of concentrating on failings, patients are encouraged to develop whatever talents and abilities they possess. For instance, if they are proficient as tennis players or have good singing voices, these aptitudes are encouraged so that the patients feel that they excel in one particular field. Whatever assets the individual has may thus be promoted. Calisthenics and gymnastics, even setting-up exercises, act as excellent outlets for tensions that have no other way of being drained off.

Some patients harbor within themselves strong hostilities with needs to vanquish, defeat, and overwhelm others. These drives may have to be repressed as a result of fear of retaliatory rejection or punishment. Sometimes even ordinary forms of self-assertiveness may be regarded as aggression. The device of detachment may be used in order to avoid giving expression to what are considered forbidden impulses. For such patients hobbies that do not involve competition will be most acceptable, at first. The ultimate object is to evoke interest in a hobby that has some competitive element. The patients may come around to this themselves. For example, one patient chose photography as an outlet principally because it involved no contact with other people. Gradually, as she became more expert, she exhibited her work to friends, and, finally, she entered pictures in various photographic contests. Later on, with encouragement she learned to play bridge, which acted as a spur to an interest in active competitive games and sports.

The ability to relieve tension through activities that involve the larger muscle groups permits of an effective way of helping disquieting aggression. Boxing, wrestling, hunting, archery, marksmanship, fencing, and such work as carpentry and stone building can burn

up a tremendous amount of energy. In some individuals the mere attendance at games and competitive sports, such as baseball, football, and boxing, has an aggression-releasing effect. It must be remembered, however, that this release is merely palliative; it does not touch upon difficulties in the life adjustment of the person that are responsible for the generation of hostility.

Many other impulses may be satisfied through occupational or diversional activities. Hobbies may foster a sense of achievement and can help the individual to satisfy a need for approval. Energy resulting from inhibited sexual strivings may gain expression sometimes in an interest in pets or naturalistic studies. Frustrated parental yearnings may be appeased by work with children at children's clubs or camps.

One must expect that patients will try to employ hobbies as a means of reinforcing the neurotic patterns that rule their lives. If they have a character structure oriented around perfectionism, they will pursue their hobbies with the goal of mastering intricate details. If they are compulsively ambitious, they will strive to use their interest as a way to fame or fortune. The same driving need holds true for any other prevailing character traits.

Most patients gain some temporary surcease from neurotic difficulties during the period when they are working at a new interest; however, their troubles escalate when the hobby fails to come up to their expectations. In spite of this, diversions may open up avenues for contact with others that neutralize this reversal.

Neurotic difficulties often cause individuals to isolate themselves from the group. Pleasures derived from social activities do not lessen the tensions and anxieties incurred in mingling with people. Occupational therapy, hobbies, and recreations give the person an opportunity to regulate the degree of participation with others in a project of mutual enjoyment. Pleasure feelings to some extent help lessen defenses against people. They may even lead to the discovery of new values in relating to a group. Once the patient has established a group contact, sufficient pleasures may sustain interest. It is to be expected, nevertheless, that customary withdrawal defenses may create tension. But the benefits

derived from the group may more than make up for the discomfiture.

In some instances it may be possible to convince the patient to engage in activities or work that contribute to the general welfare of the community. This can stimulate a feeling of active participation with others and a conviction of social usefulness.

<div align="center">REASSURANCE</div>

Reassurance may be necessary at certain phases of psychotherapy. This is sometimes given in verbal form; more commonly it is indicated through nonverbal behavior, as by maintenance of a calm and objective attitude toward the patient's feelings of crisis whenever they burst out.

Verbal reassurance, when used, should not be started too early, since the patient at first may not have sufficient faith in the therapist to be convinced of the latter's sincerity. The patient may imagine that the therapist is secretly ridiculing him or her, or does not know how serious the situation really is, or is merely delivering therapeutic doses of solace without deep conviction.

In practicing reassurance, the therapist must listen to the patient with sincerity and respect, pointing out that the difficulties may perhaps seem overwhelming at present, but that there are undoubtedly more solutions than appear on the surface. Under no circumstances should the patient be disparaged for illogical fears. The patient often appreciates that worries are senseless, but is unable to control them.

One of the most common fears expressed by the neurotic person is that of going insane. Panicky feelings, bizarre impulses, and a sense of unreality lead to this assumption. There is great fear of losing control and perhaps inflicting injury on oneself or others. Fear of insanity may be justified by revelations of a mentally ill relative from whom a taint was believed inherited. It is essential to accent the facts that fear of insanity is a common neurotic symptom and that there is scarcely a family in which one cannot find cases of mental illness. A presentation may be made of the facts of heredity, with an explanation

that insanity is not inevitable even in families that have a history of mental illness. Further reassurance may be given that the patient's examination fails to reveal evidence of insanity.

Another ubiquitous fear relates to the possession of a grave physical disease or abnormality. Patients may believe that through physical excesses, or masturbation, or faulty hygiene they have procured some irremediable illness. A physical examination with x-ray and laboratory tests should be prescribed if necessary, even though negative findings may not convince the patients that their fears are founded on emotional factors. Assurance may be given to the patients that anxiety and worry can produce physical symptoms of a reversible nature. Where fears are not too integral a part of the patient's neurosis, these explanations may suffice. Even where fears are deep, as in obsessional patients, and where patients do not accept the results of the physical examination, their more rational self will toy with the idea that they may be wrong. At any rate, the absence of manifest physical illness will give the therapist the opportunity to demonstrate to the patients that their problems are not really just a physical one and that feelings of being ill or damaged may serve an important psychologic function.

Masturbatory fears are often deep-seated and operate outside the awareness of the person. Patients may, through reading and discussions with enlightened people, rationalize their fears, or they may conceal them under an intellectual coating. Either because of actual threats on the part of early authorities, or through their own faulty deductions, they may believe that their past indulgences have injured them irreparably. They may shy away from masturbatory practices in the present or else engage in them with conscious or unconscious foreboding. Assurance that they have misinterpreted the supposedly evil effects of masturbation, coupled with assigned reading of books that present scientific facts on the subject, have remarkably little effect on their qualms. They are unable to rid themselves of childish misapprehensions that seem invulnerable to reason. Nevertheless, the therapist's point of view should be presented in a sincere and forthright manner, with the statement that the patients, for emotional reasons, may not now be able to accept the explanation. Eventually, as they realize the depth of their fears,

they may be able to understand how victimized they have been all their lives by faulty ideas about masturbation absorbed during their childhood.

Reassurance may also be needed in regard to other aspects of the individual's sexual life. Frigidity, for instance, is the concern of many women who often expect that it will disappear automatically with marriage. Projecting their disappointment, some women tend to blame their mates for sexual incompetence. In therapy misconceptions will have to be clarified carefully with a focusing on possible causes of guilt and other provocative conflicts.

In men, reassurance may be required in conditions of temporary impotence. Many males are excessively concerned with their sexual prowess and have exorbitant expectations of themselves in sexual performance. Discussions may be organized around the theme that episodes of impotence are quite natural in the lives of most men. Temporary feelings of resentment toward a marital partner or attempts at intercourse during a state of exhaustion, or without any real desire, will normally inhibit the erective ability. On the basis of several such failures, the individual may become panicky, and his tension may then interfere with proper sexual function thereafter. The patient may be shown the necessity for a different attitude toward sex, treating it less as a means of performance and more as a pleasure pursuit. Reassurance that his impotence is temporary and will rectify itself with the proper attitude may suffice to restore adequate functioning.

Another concern shown by patients is that of homosexuality. Fears of homosexuality may be disturbing. It is helpful sometimes to reassure the patient regarding homosexual fears or impulses which are equated with a devalued self-image. Elucidation that a liking for people of the same sex may occasionally be associated with sexual stimulation, that this impulse is not a sign that one is evil or depraved, and that it need not be yielded to, may be reassuring. An effort may be made to explain how, in the development of a child, sexual curiosities and sex play are universal and may lead to homosexual explorations. Usually this interest is later transferred to members of the opposite sex, but in some

persons, for certain reasons, an arrest in development occurs. The patient may be informed that when homosexuality represents a basic attitude toward people as part of a neurotic problem, it need not be considered any more significant than any other problem that requires psychological treatment.

Reassurance is often necessary in the event of infidelity of one's marital partner. Where a man or woman is extremely upset because a spouse has been unfaithful, one may feel not only a threat to security, but, more importantly, a shattering of self-esteem. The therapist may affirm that infidelity on the part of one's marital partner is indeed hard to bear, but that it is far from a unique experience in our culture. The patient must be urged not to be stampeded into a rash divorce simply because of feelings of outrage. It is natural that knowledge of a spouse's infidelity does justify indignation, but in one's own interest, one must not act precipitously, even though encouraged by friends, family, and public opinion to hate and cut off from the erring spouse. There is good logic in resisting a dramatic act and not precipitating a divorce over an affair that is in all probability quite insignificant. Such reassurance may convince the patient to try to work out a better relationship with the spouse and perhaps discover why a drift from each other had occurred.

One use of reassurance practiced by some therapists is toward helping the process of ego building. Patients become so preoccupied with their defects that they are apt to lose sight of constructive aspects of their personality. The therapist here selects for emphasis positive aspects of the individual's life adjustment and personality that the patient has underestimated. Qualities of the patient may be highlighted with emphasis on how these have been sabotaged by the patient's preoccupation with troubles. Reassurance in response to inferiority feelings, however, is generally futile. One of the most common symptoms of neurosis is devaluated self-esteem, which fosters inhibitions in action, perfectionistic strivings, and feelings of worthlessness, inadequacy, and self-condemnation. Any attempt here to inflate the patient's ego by reassurance accomplishes little.

Self-devaluation may be a symptom that serves a useful purpose for the patients, protecting them from having to live up to the expectations of other people or of their own ego ideal. Rebuilding their self-esteem by reassurance, therefore, threatens to remove an important coping mechanism. Many persons who devaluate themselves insidiously do penance for forbidden strivings and desires. Reassurance here may actually plunge the person into anxiety. If patients have sufficient ego resources, reassurance even though necessary should be tempered, the patients being apprised that responsibility for investigating their patterns has to be borne by themselves. If this precaution is not taken, the patients will lose initiative in getting at the source of their difficulties, and they will tend to seek more and more reassurance from the therapist.

PERSUASION

Persuasive techniques are sometimes helpful as supportive measures, particularly in obsessive-compulsive personalities. The object is to try to master conflict by forces of will power, self-control, and powers of reasoning. Positive results are contingent on accepting the therapist as a wise benevolent authority whose mandates must be followed, (see also Chapter 9).

Persuasive suggestions have arbitrarily been subdivided into several categories. They represent a point of view and a slant on life that may not always be accurate but that, *if accepted by the patient,* may help alleviate distress. In genera}, suggestions tend toward a redirection of goals, an overcoming of physical suffering and disease, a dissipation of the "worry habit," "thought control" and "emotion control," a correcting of tension and fear, and a facing of adversity. These suggestions consist of home-spun bromides, slogans, and clichés. But their pursuit is considered justified by some therapists as a means of helping the patient control symptoms. The following suggestions are a summary of a number of different "systems" of persuasion. Superficial as they sound they are sometimes eagerly accepted by patients, who are not amenable to other approaches and seem to need a wise authority to structure their lives.

Redirection of Goals

If the patient's goals in life are obviously distorted, the patient is instructed that the most important aim in living is inner peace rather than fame, fortune, or any other expedient that might be confused with real happiness. In order to gain serenity, one may have to abandon hopes of becoming rich, famous, or successful. One may be causing oneself much harm by being overambitious. If one is content to give up certain ambitions, and to make an objective in life that of mental serenity and enjoyment, one should try living on a more simple scale. It is important to give up struggling for success. Health and freedom from suffering are well worth this sacrifice.

One can attain happiness and health by learning to live life as it should be lived, by taking the good with the bad, the moments of joy with the episodes of pain. One must expect hard knocks from life and learn to steel oneself against them. It is always best to avoid fearsome anticipations of what might happen in the future. Rather one should strive for a freer, more spontaneous existence in the present. One should take advantage of the experiences of the moment and live for every bit of pleasure that one can get out of each day. The place to enjoy life is here. The time is now. By being happy oneself, one can also make others happy.

It is profitable to concern oneself with the problems of other people. Many persons who have suffered pain, disappointment, and frustration have helped themselves by throwing their personal interests aside and living to make others happy. We are social creatures and need to give to others, even if we must force ourselves to do so. Thus, we can take a little time out each day to talk to our neighbors, to do little things for them. We can seek out a person who is in misery and encourage one to face life. In giving we will feel a unity with people.

A person may be enjoined to avoid the acting-out of a sense of despair. A pitfall into which most "nervous" people fall is a hopeless feeling that paralyzes any constructive efforts. One must not permit oneself to yield to feelings of hopelessness, for life is always forward moving. Hopelessness and despair are a negation of life. If we stop holding ourselves back, we will automatically go forward, since development and growth are

essential parts of the life process.

Overcoming Physical Suffering and Disease

The patient, who may be suffering from ailments of a physical nature, may be told that physical symptoms are very frequently caused by emotional distress. Studies have shown that painful thoughts can affect the entire body through the autonomic nervous system. For instance, if we observe an individual's intestines by means of a fluoroscope, we can see that when the person thinks fearful or painful thoughts, the stomach and intestines contract, interfering with digestion. On the other hand, peaceful, happy thoughts produce a relaxation of the intestines and a restoration of Perlstaltic movements, thus facilitating digestion. The same holds true for other organs.

Understanding the powerful effect that the mind has over the body lucidly demonstrates that physical suffering can be mastered by a change in attitudes. By directing one's thoughts along constructive lines, by keeping before the mind's eye visions of peace and health, a great many persons who have been handicapped by physical ailments, and by even incurable diseases, have conquered their suffering and even have outlived healthy people. This is because a healthy mind fosters a healthy body and can neutralize many effects of a disabling malady.

Physical aches and pains, and even physical disease, may be produced by misguided thoughts and emotions. The body organs and the mind are a unity; they mutually interact. Physical illness can influence the mind, producing depression, confusion, and disturbed thought process. On the other hand, the psyche can also influence the body, causing an assortment of ailments. In the latter instance the institution of proper thought habits can dispel physical distress.

It is natural for persons who are suffering from physical symptoms to imagine that there is something organically wrong with them. They cannot be blamed if they seek the traditional kinds of relief. But palliation is not found in medicines or operations. Relief is found in determining the cause of their troubles and correcting the cause. Worry, tension,

and dissatisfaction are causes for many physical complaints; the treatment here lies in abolishing destructive thoughts.

The first step in getting relief from physical suffering is to convince oneself that one's troubles are not necessarily organic. The difficulties may lie in one's environment, but usually they are due to improper thinking habits. If there is a remediable environmental factor, this must, of course, be remedied. Where it cannot be altered, the person must learn to change oneself so that one can live comfortably in one's difficult environment. In the latter case one has to reorganize one's patterns of thinking.

Where patients actually have an organic ailment that is not amenable to medical or surgical correction, an attempt may be made to get the patients not only to accept the illness, but also to change their attitudes toward it. It is essential to help the patients reorganize their philosophy so that they can find satisfactions in life consistent with their limited capacities.

In physical conditions of a progressive nature, such as coronary disease, cancer, or malignant hypertension, the patients may be in a constant state of anxiety, anticipating death at any moment. Here it is wise to emphasize the fact that death is as much a part of living as is life and that the horrors attached to it are those that come from a misinterpretation of nature. Life must go on. Babies are born, and people pass on to a peaceful sleep that is death. The chances are that the one still has a long useful life ahead that can be prolonged by adopting a proper attitude toward one's condition. If suffering and pain do not exist, this should be pointed out as a fortunate occurrence. The person should think about the present and avoid dwelling too much on the future. No one can anticipate what the future may bring. Accidents can happen to anyone, and even a young person in the best of health does not know when an illness or accident will strike. The only rational philosophy is to glean whatever pleasure one can from the moment and to leave the future to take care of itself. Hypnosis and self-hypnosis may be employed as aids for the alleviation of tension, pain, and physical distress.

The patients are encouraged to develop hobbies and to engage in activities that will

divert their thinking from themselves. A list of diversions that the patients can pursue may be prepared and the patients guided into adopting new interests.

Dissipating the "Worry Habit"

Patients who are obsessed with worrying about themselves may be urged to remember that much energy is expended ruminating about one's problems and fears instead of doing something positive about a solution. Worry tends to magnify the importance of petty difficulties; it usually paralyzes initiative. The worrier is constantly preoccupied with ideas of fear, dread, and morbid unpleasantness. These thoughts have a disastrous effect on the motor system, the glands, and other organs.

In order to overcome the "worry habit," it is first necessary to formulate in one's mind the chief problem with which one is concerned. To do this it will be necessary to push apprehensions boldly aside. In a seemingly insurmountable problem, one should attempt to reformulate the situation to bring clearly to mind the existing difficulty. If one is honest with oneself, one will realize that most of one's energy has been spent in hopeless despair, in anxiety, or in resentful frustration rather than in logical and unemotional thinking that can bring about tranquility.

First, it is necessary to review all possible answers to the problem at hand. Next, the best solution is chosen, even though this may seem inadequate in coping with all aspects of the problem. A plan of action must then be decided on. It is necessary to proceed with this design immediately and to abandon all worry until the plan is carried out as completely as possible. Above all the person must stick to the project, even if it is distasteful.

If the person cannot formulate a scheme, the therapist may help to do so. The patient should be told that it is better to be concerned about a constructive partial plan than to get tangled up in the hopelessness of completely resolving an apparently insoluble problem. Until the patient can work out something better, it is best to adjust to the present situation, striving always to externalize energy in a constructive way.

The patient may be urged to stop thinking painful thoughts. He or she may be told that forgetting is a process that goes on of its own accord if one does not interfere with it. Worry is a process that has been learned. One can, therefore, help oneself by controlling one's thoughts and avoiding painful ideas. If action is impossible for the moment, one can try to crowd out apprehensions by simply resolving to stop worrying.

Discussing painful topics with other people should also be avoided. If the patient must ventilate disturbing feelings, this should be done with the therapist. "Blowing off steam" and relating troubles to friends often does more harm than good because the suggestions offered are usually unsound. It is better for the patient to understand one's difficulties than to become too emotional about them. It may be necessary to ask friends and relatives to stop talking about the patient's personal problems, if such discussions are aggravating. It is understandable that people close to one will be much concerned with the patient's illness, but they must be reminded that their solicitude may aggravate the patient's condition. Trouble may often be forestalled by insisting that one "feels fine" when questioned by others about one's health.

"Thought Control" and "Emotion Control"

Patients who seem to be at the mercy of painful thoughts and emotions may be enjoined never to permit their minds to wander like flotsam, yielding to every passing thought and emotion. It is necessary to try to choose deliberately the kinds of thoughts to think and the kinds of emotions to feel. It is essential to eschew ruminating about resentments, hatreds, and disappointments, about "aches and pains," and about misery in general.

One must think thoughts that nourish the ego and permit it to expand to a better growth. A woman with multiple complaints unresponsive to various types of psychotherapy was told by her therapist that if she wants to be without pain, she must fill her mind with painless ideas. If she wants to be happy, she must smile. If she wants to be well, she must act as if she *were* well. She must straighten her shoulders, walk more resolutely, talk with energy and verve. She must face the world with confidence. She must

look life in the face and never falter. She must stand up to adversity and glory in the struggle. She must never permit herself to sink into the quagmire of helplessness or give herself up to random worries, thus feeling sorry for herself. She must replace thoughts of doubt and fear with those of courage and confidence. She must think firmly of how she can accomplish the most in life, with whatever resources she has. She must feel those emotions that lead to inner harmony.

She must picture herself as above petty recriminations, avoiding the centering of her interest around herself. Even if she suffers from pain and unhappiness, she must stop thinking about her daily discomforts. She must give to others and learn to find comfort in the joys of giving. She must become self-reliant and creative. Emancipation from tension and fear can come by training one's mind to think joyous and peaceful thoughts. But new thought habits do not come immediately. One must show persistence and be steadfast in one's application. One must never permit oneself to be discouraged. One must practice, more and more. Only through persistent practice can perfection be obtained so that the mind shuts out painful thoughts automatically.

It is not necessary to force oneself impetuously to stop worrying or feeling pain. Will power used this way will not crowd out the painful emotions. One must instead substitute different thoughts or more appropriate actions. If one starts feeling unhappy or depressed, one should determine to rise above this emotion. One should talk cheerfully to others, try to do someone a good turn; or one may lie down for a short while, relax the body and then practice thinking about something peaceful and pleasant. As soon as this occurs, unhappy thoughts will be eradicated. A good practice is to think of a period in one's life when one was happiest. This may have been in the immediate past or during childhood. One may think of people one knew, the pleasant times one had with them. This substitution of pleasant for unpleasant thoughts may take several weeks before new thinking habits eventuate.

These injunctions had an almost immediate effect on the patient. Instead of preoccupying herself with her symptoms she concentrated on putting into practice the

suggestions of her therapist, with a resultant dramatic cessation of complaints.

Correcting Tension and Fear

Where undifferentiated tension and fear exist, the patient may be told that difficulties may come from without, but that one's reactions to these difficulties are purely personal and come from within. By changing these reactions, one can avoid many of the consequences of stress. If one is confronted with tension, anxiety, or feelings of inner restlessness, it is best to start analyzing the causes. Are these emotions due to disappointment or failure? Or are they the product of a sense of hopelessness? Once the cause is found, it is necessary to face the facts squarely and take corrective steps. It is urgent to plan a course to follow and to execute this immediately. If facts cannot be altered, one must change attitudes toward them. It is essential to stop thinking about the painful side of things and to find instead something constructive on which to concentrate.

One may be unable to prevent anxious thoughts from coming into one's mind, but they can be prevented from staying there. The person must stop saying, "I can't," and think in terms of "I can." As long as one says, "I can't," one is defeated. Being resolute and persistent in saying "I can" will eventually bring results.

The first step in overcoming tension is to stop indulging oneself in self-pity. Tension will drag one's life down if not interrupted. It is necessary to learn to love life for the living. One must learn not to exaggerate troubles. One must let other people live *their* lives, and one should live one's own.

Many people suffering from tension and fear have helped themselves by saying, "Go ahead and hurt all you want; you will not get me down." Fears are best faced by courageously admitting them. They can be conquered by stopping to fight them or by refraining from trying to master them by sheer will power. Acknowledging that one is afraid is the first step. Thereafter one must determine to rid oneself of fear by developing the conviction that one will overcome it. A sense of humor is of unparalleled help here. If one laughs at one's fears instead of cringing before them, one will not be helpless and at

the mercy of forces one cannot control.

Practicing relaxation sometimes is useful. Each day one may lie on one's back, on the floor or on a hard surface, for 20 minutes, consciously loosening up every muscle from forehead to feet, even fingers and toes. The individual may then start breathing deeply, with slow, deep exhalations through pursed lips. At the same time the individual may think of a peaceful scene at the mountains or seashore. Mental and muscular relaxation are of tremendous aid in overcoming states of tension, (see also Chapter 56).

Facing Adversity

In the event patients have an irremediable environmental difficulty, they may be reminded that there are many dire conditions in one's environment that cannot be changed no matter how diligently one tries. Poor financial circumstances, an unstable mate, overactive youngsters who make noise and tax one's patience, a physical handicap, or an incurable physical illness can create a great deal of worry, tension, and anxiety. It is not so much these difficult conditions that are important as it is the reaction of the person to them. Life is usually full of struggle; but individuals need not permit themselves to get embroiled in the turmoil and misery of the world. There are many persons who are deformed, or deprived of sight, hearing, and of vital parts of their body, who live happily and courageously because they have learned to accept their limitations and to follow the rule to live life as it is right now. There are many persons who, forced to exist under the most miserable conditions of poverty, with no resources or education, are not distressed by worry or nervousness because they have not yielded themselves to their emotions.

It is a human tendency to exaggerate one's plight. If one compares oneself with many other people, however, one will discover that one is not so badly off. Individuals may not be able to achieve all of the ambitions that they have in life. They may not be as intellectual as they want to be, or as strong, or successful, or rich, or famous. They may have to earn a living at work they detest. As bad as they imagine their state to be, if they were to be faced with the possibility of changing places with some other persons, they would probably refuse to do so. They might be dissatisfied with their appearance, and may long for

features that would make them look more handsome and distinguished or beautiful and sophisticated. If this were possible, they might instead find their health had become impaired or their intellect was not up to its present level.

It is necessary to make the most out of the little one has. Every person possesses weaknesses and must learn to live with them. Each of us must pattern our life so as to make our weaknesses as little manifest as possible. We must expand all of our good qualities to the limit. One's facial appearance may not be handsome, but one may have nicer hair and teeth than many other people. These may be emphasized in hair style or proper facial expression. One can appear well groomed with well-tailored clothing. If one's voice is good, one should cultivate it. In this way one may take advantage of every good feature one possesses.

Instead of resigning oneself to a sense of hopelessness, it is wise to turn one's mind toward creative activities and outlets. It will take much perseverance to conquer feelings of helplessness and frustration, but this can be done, particularly by living honestly and courageously. The wealthiest person is one who has not riches but strength of spirit. If individuals are dissatisfied with themselves, they may try to imagine themselves as the kind of person who they would like to be. They may then find that they can do those things that they have hitherto felt were impossible. They must never yield to despair or discouragement. Crippled persons have learned to walk by sheer perseverance of will. On the other hand, one should not set goals for oneself that are impossible of fulfillment. Thwarted ambition can give rise to bitterness and greed.

A sign of character is to change those conditions that can be remedied and to accept those that cannot be changed. To accomplish this one must face the problem squarely. What is to be done about a difficult situation? What can be done? How will one go about accomplishing the change? This calls for a plan of action that, once made, must be pursued diligently without discouragement.

There are always, of course, situations one must accept. Unalterable facts must be faced. If one cannot change things as they are, one can change one's own attitude so that

one will not overreact to one's difficulties. As soon as a person has decided to make the best of things, his or her condition will improve immediately. If one is unable to possess the whole loaf, one must learn to content oneself with part of a loaf. One must disregard minor discomforts, and pay less and less attention to them. One's symptoms may be annoying, but they are not fatal. Keeping two written lists, outlining on one side the things that have troubled one, on the other side the things that have gone in one's favor, will often convince the person, after a while, that the balance is on the positive side.

It is particularly important to train oneself to overcome the effects of frustration and disappointment. These may be expressed in the form of quarreling, or holding grudges against others, or by depression or physical symptoms. There are many dangers associated with permitting oneself to become too discouraged. It is best here to forestall despair before it develops, by adopting the attitude that one will not allow oneself to get too upset if things go wrong. One must force oneself to regard all adversity dispassionately, with the idea of modifying the cause if possible, or changing one's point of view, if the cause cannot be removed.

The above persuasive suggestions do not represent a scientific point of view. However, their use is believed, especially by nondynamicalty oriented therapists, to be consonant with a pragmatic approach to therapy in certain patients who do not respond well to insight of other more sophisticated approaches.

EMOTIONAL CATHARSIS AND DESENSITIZATION

Release of painful feelings and desensitization to their effects constitutes an important supportive technique. Patients are encouraged to talk about those things in their past life or in their present-day relationships that bother them most. Their responsiveness will depend on the confidence and trust they have in the therapist.

The patient may be told that most people have bottled up within themselves memories and experiences that, though seemingly under control, continue to have a disturbing effect on them. The attempt to obliterate emotional experiences by banishing

them from the mind is not ordinarily successful. Disturbing ideas keep obtruding themselves into the stream of thought. Even when will power triumphs and suppression succeeds, casual everyday happenings may remind one of one's conflict. In addition to memories, there are also impulses and desires of which one is thoroughly ashamed and which one dares not permit oneself to think about. Among these are desires for extramarital sexual gratification, homosexual interests, hostile strivings, and impulses of a fantastic and infantile nature.

Emotional catharsis must never be foisted on patients. To force them to reveal inner fears of a traumatic nature prematurely may cause them such panic that their resistance to further revelations will be increased. Actually, the patients have built up so hard a crust of repression that it keeps them from admitting their deepest fears even to themselves. It is essential to let them feel their own way and choose their own pace with casual encouragement.

In continued discussions with the patients it may be emphasized that every individual has difficulties and problems to be ashamed of, that they also probably are no exception and may have had experiences that make them feel that they are wicked. Discussing the patient's problem in this roundabout way makes it possible to talk about worries more openly. For instance, where it is obvious that the patient has a suppressed homosexual wish, the therapist may weave into the discussions the fact that every person, at certain times in life, develops friendships with and crushes on people of the same sex. This is by no means abnormal; it is merely a developmental phase in the life of the individual. Some persons, for certain reasons, continue to have ideas that were normal at an earlier phase of growth. As a matter of fact, most people have fears of homosexuality. The patient may be told that it would be unusual not to have such ideas at one time. The patient may then casually be asked whether or not this is so. In opening up discussions about latent tendencies there are certain risks that must be countenanced. Sometimes patients prevent themselves from acting-out their desires by not thinking about or exposing them. Such persons may interpret the therapist's interest as condonation of their suppressed impulses, particularly where the therapist relieves them too freely of their

guilt. Guilt, of course, is, not too trustworthy an opposing force, but it may be the only deterrent to rebellious tendencies that the patient has. An effort to supply the patient with rational deterrents should be made where cravings may involve the patient in unforeseen dangers.

The ability of the patient to discuss impulses, fears, and experiences openly, without encountering condemnation, enables the patient to tolerate the implications of the suppressed material.

In the event patients confess to a truly reprehensible incident in their lives, the ventilation of these facts may have to be followed by active reassurance. They may be reminded that the incidents they have revealed do not necessarily pollute them, that many persons are compelled, for neurotic reasons, to do things that they regret later, and that their subsequent actions can fully neutralize what they have done. Patients may be urged to spend their energy doing something positive in the present rather than to wear themselves out regretting the past. They may, if they desire, make some restitution to any person who has been injured by their acts, or to society in general.

In cases where individuals have irrational feelings that issue out of their relationships with people or where they have phobias, they repeatedly may be urged, for purposes of desensitization, to talk about if not to expose themselves to those situations that incite painful emotions. Their experiences are then subjected to discussion, and the patients are trained to face those situations gradually, without quaking. For instance, if patients have a fear of closed spaces, they may be instructed to lock the door of their rooms for a brief instance for the first day, to increase the interval to the count of 10 the next day, then to one-half minute, extending the time period daily, until they discover through actual experience that they can tolerate the phobic situation. Other phobias may be treated in a similar way with selected pertinent suggestions. The therapist must appreciate, of course, that the patient's fears may be rooted in established conditionings and may not yield to such desensitization techniques until a behavioral analysis is instituted and tactics sensibly organized. These tactics actually are reeducative and

therefore will be discussed in the next chapter on Behavior Therapy.

MISCELLANEOUS SUPPORTIVE MEASURES

See also Chapter 56 "Adjunctive Aids in Psychotherapy"

Relaxation exercises and massage may be prescribed for muscle tension, spasms, contractures, and tremors, the patient being referred to a physiotherapist when this is necessary. Enforced rest is sometimes advised for fatigue and exhaustion in the form of a prolonged vacation or a sojourn in a spa or country place. Subcoma insulin therapy is sometimes prescribed for unyielding anxiety states, delirium tremens, and confusional syndromes. Electrical (convulsive) therapy is helpful in bipolar disorders, endogenous depression, and senile depression. Drug therapy is employed where indicated; for example, sedatives, hypnotics, and tranquilizers in excitement or insomnia, antidepressants in depression or listlessness, Antabuse in alcoholism, and glandular products in endocrine disorders. These somatic therapies will be discussed later. Inspirational group therapy is a helpful procedure in certain problems, for instance, for dependent, characterologically immature, alcoholic, drug addictive, and mentally ill patients.

Supportive measures during reconstructive treatment must be employed cautiously because the patient may invest the therapist with directive, authoritarian qualities that interfere with a good working relationship. Moreover, alleviation of symptoms and suffering may remove a most important motivation for continued treatment in some patients.

There are, nevertheless, certain circumstances under which support is necessary. The challenging of one's defenses exposes basic conflicts and may revive the early anxieties that inspired them. A period of some instability and turmoil is to be expected with reconstructive procedures, and the therapist may, where the reactions are severe, temporarily have to assume the role of a helping authority.

The specific kinds of supportive measures implemented here vary according to the

patient's needs. Where severe environmental disturbance exists, the therapist may suggest available resources that hold forth promise of mediation. The therapist may also aid the patient in resolving resistances toward utilizing the prescribed resources effectively. Active reassurance may be dispensed where the patient harbors gross misconceptions or where there is a threat of a dangerous shattering of the ego. There may be a cautious extension of advice when the patient is thoughtlessly embarking on a potentially destructive course of action. Encouragement certainly may be voiced when the patient does a significant job in thinking through a problem or in effectuating insight into action.

The degree of emotional support employed will depend upon the strength of the patient's ego. A withholding of support by the therapist, when the patient actually needs it, may be harmful. On the other hand, excessive support may interfere with assertiveness and activity. The person's reactions to support will depend on its symbolic meaning to the person. The most common response is an abatement of symptoms and a cessation of anxiety. Occasionally, however, anxiety breaks out due to fears of being overwhelmed and mutilated in a protective relationship. These reactions will have to be handled promptly, should they emerge.

REEDUCATIVE APPROACHES

See also Chapter 10 "Reeducative Therapy", Chapter 51 "Techniques in Behavior (Conditioning) Therapy, and Chapter 56 Adjunctive Aids in Psychotherapy

Reeducative measures are employed both as a complete goal-limited form of treatment and as interventions that are strategically incorporated into a reconstructive therapeutic program.

Current interest in cognitive therapy (Beck AT, 1971, 1976) accents the value of certain reeducational techniques during psychotherapy. The individual's cognitive set often determines what one feels and how one interprets reality. Utilizing this paradigm, patients are enjoined to examine how their *interpretation* of an event determines their feelings and whether the interpretation is based on facts or insubstantialities. Sometimes

patients are asked to keep a diary and jot down the thoughts that immediately precede certain feelings. In this way they learn first to identify provocative thinking patterns that inspire upsetting feelings and then to challenge the validity of their ideas.

The value of examining the connection of events with succeeding disturbing emotions is shown by the pilot study of A. T. Beck and Kovacs (1977), in which depressed patients who were treated with cognitive therapy did better than those who were given antidepressant drugs. Some forms of cognitive therapy focus on the various ego states of individuals during their daily operations. There is exploration of the interfaces of these states, elaboration of the dissimilar roles assumed during these states, explication of the multiform self-representations, and differentiations between self and object, and identification of the values and needs emerging with each ego state. In this way individuals become aware of habitual shifts in their orientations, some of the forces producing the shifts, and perhaps tactics through which control may be achieved before their emotions take over. During therapy, an integration of dissociated self- and object representations is attempted, with the aim of bringing the patient's self-concepts to a more mature level. Sicker patients, such as those who are borderline cases and those who have narcissistic character disorders, are apt to show splitting and confusion of self-object identities. Here the patients may utilize the therapist as an aspect of themselves during transference. This will call for therapeutic interventions, such as interpretations, that are more attuned to reconstructive than reeducative premises.

In some forms of reeducative therapy efforts are made to rehabilitate the individual as rapidly as possible by discovering and modifying factors that provoked the emotional illness and by surveying the available assets and liabilities in order to mobilize positive forces of the personality. In the medium of a warm relationship with the therapist, the patients are brought to an awareness of certain interpersonal conflicts that have contaminated their adjustment. Maladaptive attitudes are explored to point out to the patients the difficulties that these create for them. Individuals get viewpoints of how their reactions became conditioned and why they persist. Finally, they are helped to adjust with new, healthful, more adaptive patterns. In behavior and conditioning approaches, there is

a minimization of insight and a concentration on learning and reconditioning.

In reeducative therapy less weight is placed on exploring the origins of patterns, while more emphasis is put on reorganization of habits, regardless of their sources in constitution or in specific inimical experiences. During the process of retraining, early difficulties that originally produced disturbing character traits may spontaneously be remembered by the patient. As part of their schooling, the patients must be taught to face early childhood experiences and, if necessary, to change attitudes toward them.

The patients are encouraged to rectify remediable environmental difficulties, to adjust to irremediable handicaps while finding adequate compensations and sublimations, to enhance personality resources through education and activity, to abandon unrealistic goals, and to coordinate ambitions with capacities. The therapist concentrates on all of the healthy personality elements, actual and potential, that can neutralize, control, or rectify pathologic adjustment.

In dealing with abnormal traits and patterns, the therapist may strive to bring patients to where they can reason unemotionally, facing facts bravely, adjusting to painful memories and impulses without panic, meeting stresses of life with courage, and forsaking fantasy in thinking. Each trait that the patients exhibit may be taken up in detail, discussing its origin, purpose, value, and the ways it interferes with their happiness and adjustment. More adaptive substitive patterns may then be explored, and the patients may be urged to take positive courses of action.

A discussion of the patient's life history may reveal to the therapist that the patient has an awareness of the inordinate attachment to a domineering parent or parental surrogate who continues to infantilize him or her. Evidences of how dependency undermines the patient are brought to his or her attention, and the patient may be shown how some symptoms are produced by conflict over dependent need. If the patient evidences a desire to overcome dependency on the family, the wisdom of making decisions and of finding outlets for energy and interests may be indicated. It is to be expected, because neurotic reaction patterns are so deeply imbedded, that this advice will

not be heeded at first; but as the patient constantly experiences untoward emotions associated with the giving up of independence, the patient may agree with the therapist's observations and gradually experiment with new modes of adjustment.

Where patients are too compliant and recognize their compliance, it may be pointed out that they have probably always felt the need to be overrespectful to authority. Their security is perhaps bound up with this reaction. However, they have a right, as a human being, to their own opinions, and they need not accept the wishes or orders of other people unless they want to do so. They can review in their mind the pros and cons of any advice given them, and they may then accept or reject it as they see fit. If they do not wish to abide by the orders or judgments of other people, they can try to explain to them why their own plans seem best. Should they decide to conform with the wishes of others, they must be sure that this is what they really want, and that it is not what they feel forced to want. Above all, they must be logical rather than emotional in their choices of action. Specific ideas on how to function independently may be advanced. The help of other people with whom the patient lives may be enlisted in this training process.

An individual who is aware of a power drive may be shown how this is a dominating force in life, preoccupying thoughts and actions. Individuals may be partly aware of how they strive for power and strength in all of their interpersonal relationships. What they may not realize is how mercilessly their drive rules them and how it results in their forfeiting normal goals. The person may be advised how a power trend brings him or her into conflict with others and evokes retaliatory hostilities. It is necessary to get the patients to see the need of adopting a more mature attitude and of readjusting their standards in line with the reality situation. Other outlets than power may then be suggested to satisfy the patient's drive for self-assertiveness and self-esteem.

The same technique may be used in dealing with other compulsive neurotic patterns, such as detachment, aggression, and perfectionism. Their manifestations are repeatedly brought to the patient's attention, and the patient is shown why they stir up difficulties. The patient is challenged in his or her assumption that these are the only

means adjusting to life, and substitutive responses are suggested.

Patients may be acquainted with the ways in which their character drives operate insidiously. They may be shown that, unknown to themselves, they lash out at others, or vanquish them in actual deeds or in fantasy, or render themselves invulnerable and strong, or retreat from competition, or engage in any number of facades that become for them basic goals in life, making average pursuits meaningless.

Such unhealthy attitudes perhaps might be understandable were we to insist on what is probably not true—that they really are an inferior persons who have to eliminate adult and realistic methods of dealing with their problems. The patients must be shown the need to stop taking refuge in childhood defenses, and they must be apprised of the wisdom of facing their difficulties with decision and courage. However, because they have utilized their defenses for so many years, they must understand that these will not vanish immediately. Indeed, defenses will keep cropping up from time to time. Above all, there is no need for discouragement. When they become sufficiently strong, their defenses will no longer be required. Yet, they must not abandon their patterns out of a sole conviction that orders must be followed, or to please the therapist. Rather, as they realize the implications of their neurotic drives, they will want to substitute creative goals and patterns for those that have resulted in their present unhappiness.

The therapist should, in this way, actively encourage a conscious analysis by the patients of their customary trends as well as stimulate them to substitute new ways of thinking and acting. If the old patterns reappear, it may be necessary for the patients to try to bring them to as complete a halt as possible by deliberate effort. The patients should be encouraged to feel that they have the capacity to change, that others sicker than themselves have done so successfully.

Usually the patients will be dismayed to find that their character patterns are regarded as problems because they have accepted them as natural and normal. As they realize that these constantly bring them into difficulties with people and are responsible for much of their turmoil, they are supplied with a valid motivation to alter their scheme

of life. They are confronted with a choice for which they, themselves, will have to assume a full measure of responsibility.

Many persons faced with this choice are unwilling or unable to give up their destructive drives. The knowledge that frustration or pain will follow observance of their patterns is not enough to make them give up the gratifications that accrue from the propitiation of neurotic goals. Extreme examples of this are the alcoholic who appreciates the physical, social, and moral hardships that inevitably follow the bouts of drinking but seems unable to do anything about it, or the smoker who developing emphysema continues to live in an atmosphere of tobacco fumes, or the obese individual with hypertension who overstuffs with fattening foods. In cases where patients refuse to abandon their destructive habits or immature objectives, the knowledge that they are responsible for their own plight is healthier, from a therapeutic viewpoint, than the conviction that may have existed previously, to the effect that the sources of their misery lay outside of themselves.

Where one is convinced that one's adjustment is eminently unsatisfactory, where one realizes that one's gratifications do not compensate for the suffering that comes from indulgence of one's immature drives, where one is aware of how one's patterns interfere with mature goals, one may be motivated toward experimenting with new reactions toward people and toward oneself.

Once patterns that are inimical to adjustment are clearly defined and more adaptive substitutive reactions are suggested, a long period of experiment and training is necessary before unhealthy attitudes are replaced by those of a more mature nature.

Even where patients have the motivation to change, a struggle will be necessary to achieve reeducative effects. In spite of all good resolutions, the patients, at first, will find themselves responding automatically, in line with their customary habits. They will, however, become more and more conscious of their reactions, and, as they occur, they will better be able to subject them to analysis and control. Even though this may fail to stop them from following their usual patterns, they will become more and more aware of their

irrational motives, and they may develop greater determination to substitute more constructive behavior tendencies.

For instance, perfectionistic persons may become conscious of the fact that the impulse to do everything meticulously extends itself into every aspect of their lives and poisons relationships with people. They will see, as the therapist brings it to their attention, that the slightest failure to perform flawlessly suffices to create tension and panic. They may learn that the reason for their disturbance lies in the fact that when they are not perfect, their image of themselves is shattered and they feel unloved and unlovable. Life then becomes a constant series of frustrations, since it is obviously impossible to do things perfectly every minute of the day and still be human. The patients will, as they become aware of their inordinate expectations, find themselves toying with a more self-tolerant philosophy, which they will not wish to accept at first, probably because being mediocre is equivalent to being no good at all, and because they are unconvinced that perfectionism is not really the keynote of life. As they test the truth of the therapist's exhortations and as they realize the extent to which their perfectionistic strivings dominate them, they may attempt to restrain themselves before yielding to perfectionistic impulses. They will review in their mind the reasons why they must be perfect on every occasion. They may eventually even try to substitute for this impulse the attitude that they can do things casually without needing to be perfect.

To expedite these reeducational aims, behavior therapy may be helpful, a description of which follows in the next chapter.

51
Techniques in Behavior (Conditioning) Therapy

The Freudian economic concept of the personality as a closed energy system sponsored the idea that libido removed from one area must be relocated and that energy released by symptom removal must inevitably wreak its mischief elsewhere. The removal of symptoms, therefore, was considered irrational and the rewards dubious since energy soon displaced itself in other and perhaps more serious symptoms. No myth has survived as tenaciously as has this concept, which continues to be promulgated as dogma despite the fact that in practice symptoms are constantly being lifted with beneficial rather than destructive results.

In its early days behavior therapy was viewed by some clinicians as a viable and powerful means of bringing about symptom relief and removal. The assumption was that, even when effective, the net outcome would be primarily of an adjunctive or patching-up nature that had to be supplemented by more depth-directed, nonbehavioral approaches geared toward the total personality. Contemporary behavior therapy, however, is multidimensional and aims, in systematic fashion, at the modification of every relevant facet of the personality. This will include both maladaptive behavioral excesses (e.g., tics) and/or deficits (e.g., lack of assertion). It will embrace affective and cognitive modes of functioning; it will stress control from within (self-control) rather than control from without. It will take the form of a collaborative project with the patient rather than a *laissez faire,* "leave it to the patient to decide or not to decide," direction, on the one hand, or authoritarian direction, on the other.

Behavior therapy as it developed was rooted in concepts derived from conditioning and learning theory (Hilgard, 1956; Kimble, 1961), particularly from formulations of Pavlov, Skinner, and Hull, as well as from experimental and social psychology (Brady, 1985; Paul & Lentz, 1977; Pomereau & Brady, 1979). It was based on the hypothesis that since neurosis is a product of learning, "its elimination will be a matter of unlearning"

(Wolpe, 1958). It gradually embraced a wide and seemingly disparate array of procedures, all of which share certain common attributes: an unswerving allegiance to data and the methodology of the behavioral scientist, a rejection of metaphysical concepts and mentalistic processes, and predilection for what is now known as social learning theory (Wolpe & Lazarus, 1966; Bandura, 1969; Wolpe, 1971; Birk et al, 1973; O'Leary & Wilson, 1975). These techniques may be directly physiological or narrowly S-R (stimulus-response) in nature (e.g., aversive conditioning), highly imaginal (e.g., real-life—graded desensitization of an elevator phobia), stimulus specific (e.g., thought stoppage), stimulus situation complex (e.g., assertion training, behavioral rehearsal), of a contractual nature (e.g., contingency contracting), directly cognitive (e.g., cognitive behavior therapy, rational emotive therapy) conducted with the individual or in groups, or utilizing complex interpersonal interactions as in group behavior therapy (not to be confused with behavior therapy in groups), etc. etc. Affects, cognitions, and behavior will all come within the purview of the behavior therapist of the 80s and 90s (as contrasted with the behavior therapist of a decade ago) indicated by the outcome of carefully engineered behavior analysis of the total situation. As more therapists apply themselves to this area of treatment, they introduce their own original procedures and unique interpretations regarding operative learning mechanisms. The rapid growth of behavior therapy and the introduction into its orbit of a profusion of techniques had led to some confusion, although attempts are being made to establish a methodical way of looking at the different approaches (Brady, 1985) as follows: 1. The situations where problem behaviors occur, i.e., which situations exaggerate and which ameliorate the behaviors; 2. the special ways the problem behaviors manifest themselves and the intensity of their manifestations; 3. the effect of the behaviors on the patient and on others, as well as the consequences to the patient, to others, and to the environment; 4. the personal assets and resources available to support anticipated changes, and the areas in the environment on which we may draw for help; and 5. the possible impact on the patient and on others of anticipated improvement or cure. The past life and conditionings that have acted as a seedbed for problem behaviors, and the past and present reinforcements that have initiated and are now sustaining the behavior are also examined. A hierarchy of problem behaviors is

composed on paper with the object of establishing a priority regarding which problems to select for immediate focus and which for a possible later focus. Goals in therapy are discussed in terms of what the patient wants from therapy and what changes in behavior are necessary to achieve this. Some behavior therapists recommend a *Behavioral Self Rating Check List* (Cautela & Upper, 1975), which contains 73 kinds of behavior it is possible to change. The therapist must agree that the patient's goals are acceptable and not unreasonable. Next, a definition of the problem includes the situations in which problem behaviors occur, their frequency, the patient's thoughts and feelings that accompany them, the environmental consequences, and their effect on the behaviors. A clinical assessment, including history-taking, follows. Certain forms may be used, such as a *Reinforcement Survey Schedule* (Cautela & Kastenbaum, 1967) and the *Fear Survey Schedule* (Wolpe & Lang, 1964).

The patient may be asked to write down the reactions during an episode where problem behaviors occur (e.g., a phobic inspiring situation). The patient is also asked to quantify the reactions, to write down the number of times a day the symptoms occur, and to note the circumstances that surround their appearance. What is searched for are the stimuli that set off problem behaviors and their reinforcements. In several interviews sufficient information should have been gained. After presenting the therapist's hypothesis of the patient's difficulty and gaining acceptance of this, a treatment plan is devised and a contract with the patient drawn up. Therapy focuses on set goals. Should the individual fail to respond well in relation to the limited selected target, a wider range of targets, perhaps calling for different behavioral techniques, may be required.

The practice of behavior modification is most expediently executed where the therapist and patient both agree on the behaviors to be altered or required, on immediate and ultimate goals, and on the methods to be employed to achieve these objectives. Where the patient is unable to make adequate decisions, these determinations are sometimes made with a relative or other representative, who is kept informed about progress and changes in goals or methods. An assessment of the problem initially (the "behavioral analysis") includes the history of the behavioral difficulty, the circumstances under which

it now appears, its frequency, and the consequences following its occurrence. A careful record of the frequency of the distortion is generally kept during therapy by the patient or a member of the family. A search for overt or hidden reinforcements that maintain the noxious behavior is also pursued. The formulation of the treatment plan will depend on many factors, including the type of symptom, the forces that bring it about and maintain it, and the kind of environment in which the patient functions, including the influence of individuals with whom the patient is living.

The chief avenues to behavioral therapy are through desensitization modeling and cognitive approaches, and operant (instrumental) conditioning.

There are literally hundreds of techniques currently available to behavior therapists. Superficially, these might seem to share few common elements, ranging, as they do, from the naively simple to the complex, from the strictly physiological to the totally cognitive, etc. However, at least in principle if not always in fact, all possess certain common characteristics: acceptable only if adequately validated for the contemplated purpose; preceded by behavioral assessment, monitored throughout the ongoing intervention, and outcome evaluation carried out; stemming no matter how loosely from some form of clearly articulated learning theory framework.

SYSTEMATIC DESENSITIZATION

Techniques organized around classical conditioning are tailored for anxiety situations such as phobias, the product of unfortunate associations that continue to burden the individual without too much secondary gain or other subversive benefits. Therapy consists of a progressive desensitization to the anxiety situation, either by a slow exposure to gradually increasing increments of the anxiety stimulus, under as pleasurable or otherwise rewarding circumstances as possible, or by a mastery of fantasies of such stimuli in ever increasing intensity in the presence of an induced state of inner relaxation. Even where the anxiety situation is highly symbolized—for instance, phobic projection, which nonbehavioral therapists view as a product of deep inner conflict—it may be possible to overcome the symptom without the formality of insight. However, an

understanding of the sources of the problem may be helpful in avoiding a relapse by dealing correctively with some of the core problems that initiate the anxiety. This, too, would be taken into account by modern behavior therapists in their treatment strategy without recourse to concepts such as the unconscious or the achievement of insight. On the other hand, insight alone, without reconditioning, may leave the symptom unrelieved. An understanding and use of behavioral approaches can be helpful even to the practitioner who aims at personality reconstruction. These techniques may be especially valuable during phases of treatment where the patient offers severe resistances to the execution of insight into action.

While increasingly deemphasized in the armamentarium of the behavior therapist, perhaps the best known approach, and the easiest one to learn, is that of desensitization. In desensitization methods anxiety-provoking cues are presented in a positive or pleasurable climate. These cues must be graduated so that the responses that they evoke are always of lesser intensity than the positive feelings that coexist. In this way the aversive stimuli are gradually mastered in progressively stronger form. The method is most readily applicable to anxiety that is set loose by environmental cues. In the arrangement of stimulus hierarchies both environmental and response-produced cues are listed to encompass as many complex aversive social stimuli as possible. The most common positive anxiety-reversing stimulus, jointly presented with and calculated to neutralize and eventually extinguish the aversive stimuli, is muscular relaxation, often induced by hypnosis.

To his use of this technique Wolpe (1958) has given the name "reciprocal inhibition." Treatment is initiated by the construction of an "anxiety hierarchy." The patient is given the task to prepare a list of stimuli to which he or she reacts with unadaptive anxiety. The items are ranked in accordance with the intensity of anxiety that they induce. The least anxiety-provoking stimulus is placed at the bottom. The most disturbing stimulus is put at the top. The remainder are placed in accordance with their anxiety-arousing potential. The patient is then hypnotized and relaxed as deeply as is possible. In the trance it is suggested that the patient will imagine the weakest item in the anxiety hierarchy. If the

patient is capable of doing this without disturbing the relaxation state, the next item on the list is presented at the following session. With each successive session the succeeding intense anxiety stimulus is employed during relaxation until "at last the phobic stimulus can be presented at maximum intensity without impairing the calm relaxed state." At this point the patient will presumably have ceased to react with the previous anxiety, and to be able to face in life "even the strongest of the once phobic stimuli."

Wolpe denies that his therapy is useful only in simple phobias. He believes that even difficult "character neurosis" can be treated, since they consist of intricate systems of phobias that have been organized in complex units. "This," he says, "is not remarkable, if as will be contended, most neuroses are basically unadaptive conditioned anxiety reactions." Wolpe insists that in contrast to measures of success by all methods of therapy, ranging from traditional counseling to psychoanalysis, of a recorded 50 percent, his special method brings about an "apparently cured" and "much improved" rate of over 90 percent. It is important, however, to stress, as do sophisticated behavior therapists, that the presenting complaint is not necessarily either the one that requires desensitization or, if it is, that it may not be the one that should be given sole, or even primary, attention. For example, to desensitize an attorney to a fear of public speaking (the presenting complaint) may be of far less significance than desensitization to the fear of losing face should the attorney not win the case. Which desensitization strategy to employ, or whether to employ desensitization at all, or what other necessary behavioral techniques to employ in the restructuring of this particular individual's life can only be determined by a detailed and comprehensive behavioral analysis of the total life style of that individual and the relevant contingencies operating in the individual's life and the lives of meaningful others.

Attempts to standardize Wolpe's procedure have been made by Lazovik and Lang (1960). The pretraining procedure of five sessions includes the construction of an anxiety hierarchy (a series including the phobic object, graded from most to least frightening). Training in deep muscle relaxation after the method of Jacobson (1938) is followed by training in hypnosis, efforts being made to get the patient to learn to visualize hypnotic scenes vividly. Eleven sessions of systematic desensitization follow the pretraining period.

During these the patient is instructed to relax deeply, and items on the anxiety hierarchy are presented as scenes that are to be visualized clearly. The least frightening scene is presented first. When this is experienced for about 3 to 10 seconds without anxiety, the next item in the hierarchy is introduced. All scenes are presented at least twice. If any of the scenes make the patient anxious or apprehensive, the patient is instructed to raise the left hand a few inches. Should this happen, the scene is immediately discontinued and not repeated until the next session; rather, the last successfully completed item of the hierarchy is presented. From 2 to 4 scenes are attempted during each session of 45 minutes. The authors confirm Wolpe's method as remarkably effective for treating cases of phobia and insist that there is no substitution of other fears. This has also been my personal experience.

Edward Dengrove has prepared a leaflet for "fearful" patients that introduces them to the technique of systematic desensitization:

(Reprinted here with the permission of Dr. Dengrove)

The type of treatment that is being offered to you is known as systematic desensitization. It is based upon scientific studies of conditioned reflexes and is particularly helpful to persons who are fearful. It makes little difference what these fears are: whether of closed places, or being alone, walking alone, driving or flying; or whether one fears loss of self-control, criticism by others, and the like.

Kindly list *all* of the fears that disturb you. Make the list as complete as possible. We will go over the list together and reduce it to its basic units. Treatment will be directed to each individual fear.

The next step will be to teach you how to relax. There are several methods by which this may be accomplished. The particular method that suits your needs will be chosen. This is very important, for the more relaxed you are, the more rapid your progress to health. You cannot be relaxed and remain anxious or fearful at the same time.

When you are completely relaxed—not partially, but completely—I shall present to your visual imagination a series of situations. These will be based upon your presenting fears. They will be organized in series, graded from the most mild to the most intense. Each forms a hierarchy.

As you visualize each scene in the relaxed state, you may find yourself unmoved by what you see. Or you may experience an uneasiness or restlessness (anxiety). This is a critical point in treatment, and must be signalled to me. No matter how slight, I must be made aware of it.

I may ask, "Do you feel relaxed? Do you feel at ease?" If you do, then move your head up and down ever so slightly. If you do not, move it from side to side.

This is a critical point, for we can only proceed as fast as you are able to accept these visualized situations with ease. I shall not push or prod you. It is only by the ability to maintain your relaxed state that you are able to overcome these fears.

The desensitization takes place gradually by getting you to cope with small doses of anxiety at first, then gradually increasing the dosage a small amount at a time.

With children, desensitization is done in a less subtle manner. Consider a child who is afraid of dogs. The child is held by a trusted person who allows him to suck on a lollipop and point to a dog on a leash in the distance. A little later, the child, still held, is encouraged to view a dog through a pet-shop window. Still later, he is brought closer to a dog; and later, closer still. With the pleasure of the food and security of being held by a trusted person, the child gradually overcomes his fear. At first there are pictures of dogs, then toy dogs, small, friendly dogs, medium-sized dogs, and so forth. At last, he will be able to reach out and touch a dog.

This gives you a clue to a second part of treatment. You are to do the very things that you fear. One cannot overcome a fear by avoiding it, as you have done in the past, nor by trying to drown it out with continued medication. Medicine is helpful, but only a crutch, to be reduced and gradually thrown away.

The same principles of gradual desensitization must be employed. You are not to attempt any activity that produces overwhelming anxiety. However, you can and should try those tasks that are only mildly upsetting, at the same time attempting to quiet yourself. If the anxiety persists, stop what you are doing, for this will only set you back. Instead, return to doing those things that you can do without getting upset.

With this approach you will find yourself gradually doing more of these tasks that you avoided in the past. One can get used to almost any new situation that is approached gradually.

Interestingly, as the milder fears are overcome, the more strong ones lose their intensity and lessen, much as the contents of a gum machine diminish with the discharge of each piece of gum. The more one attempts with relaxation, the more rapid the improvement. But one must keep in mind that these attempts deal only with those productive of mild anxiety.

A warning: everyone must proceed at his or her own pace. Some slowly, others more rapidly. There is no reason to feel guilt or shame if one's progress is slow. The process of desensitization cannot be hurried by rushing into highly anxious situations. You will not be thrown into the water and made to swim or sink on your own. At times, under the pressure of need or anger, a few of you will make large strides but this is the exception to the rule.

Consider the woman who is afraid to leave her home. Her first move is to step

outside her front door and back again into the house. From there she gradually makes it to the street in front of her home, then around the house—by herself or with someone or while someone trusted is in the house. Each day this is extended until she is able to walk a house away, then two houses, then half-a-block; with someone, without someone, with someone at home, with no one there. Again, no new step is made until the previous step is mastered, and until it can be accomplished without any anxiety whatsoever. Each fear is attacked individually, daily or as frequently as this can be done.

Gradually you find yourself doing things without thinking about them. Sometimes it will be only after you have done something that you realize you have done it without forethought or anxiety. It may be that someone else will point out to you that you have done something you would not have attempted in the past.

A cooperative spouse is not only helpful and understanding but an essential part of this approach. He or she can be tremendously important to this undertaking. Marital problems tend to hold back progress and should be resolved.

It is by doing what we do in the office, and what you do for yourself away from the office, that will lead you to health. One or other of these techniques may be used alone, but when both are employed, progress is so much faster.

Systematic desensitization is sometimes expedited by the use of drugs, like Brevital, 1% solution, in small doses (Brady, 1966; Friedman & Silverstone, 1967). Slow intravenous injections to produce relaxation without drowsiness are particularly valuable for patients who are unable to relax or who are extraordinarily anxious. Pentothal (2% solution) is preferred by some therapists to Brevital.®

IMPLOSIVE THERAPY (FLOODING)

Implosive therapy is a modality utilized to help extinguish avoidance responses (e.g., phobias) as an alternative to relaxation-desensitization treatment (Kirchner & Hogan, 1966; Hogan & Kirchner, 1967; Stampfl, 1967). Exposure to a fear-provoking stimulus with no attempt to escape from it will tend to weaken the strength of the stimulus (Boulougouris & Marks, 1969). The patient here is instructed to approach the phobic situation and to tolerate it (by relaxing the muscles and by trying mentally to change the meaning of the danger imagined to invest the situation).

Eventually it is hoped that the fear will be extinguished. The therapist may model the proper approach behavior as an example of how controls can be established. Experience

convinces that in vivo desensitization is superior to desensitization through imagery, as, for example, in systematic desensitization. However, desensitization through imagery may be used as a preliminary therapy in order to reduce the level of an intense anxiety reaction that can prevent the patient from even attempting to expose oneself to a real situation. A trusting relationship with the therapist is of the greatest help to the patient whose terrors have kept the patient from confronting the phobic situation.

A massive form of in vivo desensitization, *implosive therapy or flooding,* exposes the patient to fear-provoking stimuli, escape from which is not permitted. Induced exaggerated forms of fearful imagery related to the phobia may precede actual immersion in the phobic situation, the therapist purposefully magnifying the sinister nature of the fantasy stimulus. After the patient learns to tolerate the imagery, the real stimulus in force is employed. Remaining in a fearsome position until the anxiety disappears may result in substantial improvement or cure. In some cases where a phobic situation exists outside the office, the therapist accompanies the patient to the site (bus, subway, elevator, funeral parlor, crowded street, etc.) and stays with the patient through the latter's anxiety attack until it is dispelled. In other cases, particularly where the patient for physical reasons cannot endure too strong anxiety, withdrawal from the scene is permitted as soon as the patient feels moderately uncomfortable. In obsessive-compulsive reactions the exposure is to the stimuli that produce the rituals and the patient is discouraged or blocked from engaging in them. For example, in hand-washing compulsions produced by touching dirt, the therapist first models rubbing the hands on the shoes or the floor and then enjoins the patient to do the same. The therapist sits with the patient, encouraging the patient not to go to the bathroom to scrub the hands. The results with this kind of therapy have been encouraging; however, "The therapist must not back away from the elicitation of anxiety, no matter how uncomfortable the patient becomes, and must not terminate the session before the extinction of anxiety is complete" (Seligman, 1979). Agreement must be reached with the patient in advance of using this technique that the patient will be willing to tolerate a certain amount of discomfort in overcoming the handicap, the advantages in time-saving being pointed out. It cannot be emphasized enough that the therapeutic alliance must be a firm one in order for the patient to trust the massive exposure to

flooding techniques. Time may have to be spent consolidating the relationship prior to suggesting the technique to the patient.

The exact way flooding works is not entirely known. There are so many variables in therapy that one cannot credit results exclusively to the methods employed, since the skill of the therapist, personality, case selection, etc. crucially influence results. Be this as it may, implosive therapy in the hands of a skilled operator may dramatically cure certain phobias.

Some patients reject implosive therapy out of panic, or they may not physically be able to tolerate the great anxiety release because of cardiac illness or a vulnerable ego structure that may shatter with resultant psychosis. Here systematic desensitization is best or *graded* exposure, where approach to the phobic object or situation in small steps is employed (Wilson, GT, 1980). In both flooding or graded exposure, the therapist or empathic assistant may accompany the phobic patient to the situation that requires mastery and this can have great reassurance value. It is important here that the therapist withdraws from the therapy gradually to avoid a dependency stalemate.

In extremely upset patients intravenous infusions of a short-acting barbiturate are sometimes helpful. The patient at the start of therapy may be given a slow intravenous injection of Pentothal® (thiopental sodium) in dilution of 2%, sufficient to produce relaxation without drowsiness. Pentothal® is available in 500 mg vials in combination packages with diluent of 20 mL vial of sterile water. Some therapists utilize a 1.25% concentration (Hussain, MZ, 1971), but the diluent here should be sterile sodium chloride to prevent hemolysis. Convenient sterile prefilled cartridge-needle units (Tubex, Wyeth Laboratories) are also available with 1½ grains of Pentothal.® A very slow injection of the drug is essential to avoid sleepiness. Once relaxation is obtained, the patient is shown pictures related to the phobic object or phobic situation and asked to picture himself or herself touching or holding the object or being involved in the situation. This continues throughout the session, the patient being asked to continue to imagine being immersed in the scene. Where artificial objects similar to the phobic object can be obtained (snakes,

worms, mice, roaches, etc.), the patient is enjoined to handle these. The session is brought to an end with the patient in a drug-relaxed state. As mastery occurs, sessions are conducted with lesser and lesser amounts of the drug and finally without it. Some therapists prefer a *1%* solution of Brevital® (methohexital sodium) to Pentothal.®

Home practice sessions may be valuable for some patients. These can cover a wide range of themes. A paradoxical technique that I have found valuable for some phobias is illustrated by the following directions given to patients:

> Running away from fearful situations or trying to crowd out of your mind a fearsome thought only reinforces your fear. If you practice producing the fearful situation deliberately in your mind as completely as possible, while studying your bodily reactions, you will begin extinguishing the fear. If when you are not practicing the fear comes upon you, do not push it aside; try to exaggerate it, experiencing the fear as fully as possible. Practice bringing on the fear at least three times daily. If you have a sympathetic friend whom you can talk to about your reactions while practicing, this can help.

OPERANT CONDITIONING

Techniques of operant (instrumental) conditioning, in which the subject is active in bringing about a situation toward achieving reward or avoiding punishment, supplement classical Pavlovian conditioning procedures (Krasner, L, 1971). Essentially, these techniques consist of reinforcements in the form of rewards or the withdrawal of an aversive (punishing) stimulus or event as soon as the subject executes a desired act. The subject is free to respond or not to respond instead of, as in classical conditioning, being passively subjected to events over which there was no control. The techniques are designed to strengthen existing constructive responses and to initiate new ones.

Operant approaches depend on the fact that human beings like other animals are influenced toward specific kinds of behavior by the reinforcers they receive for this behavior. Where a desired behavior is sought, the patient must first be able to accept the desirability of this behavior in terms of the rewards that will accrue from it. Many patients are confused regarding appropriate courses of action. The therapist's positive attention and approval following a remark that indicates a willingness to try a tactic, or the

execution of the desired behavior itself, or approximations of this behavior, may be reinforced through nodding, utterances of approval, or paying rapt attention to these desirable responses, or by granting material rewards. However, when the patient repeats a pathological pattern or verbally indicates nonproductive choices, the therapist may act disinterested and fail to respond to this behavior.

Operant conditioning works best in an environment that can be controlled. It is indicated in nonmotivated patients in institutions whose behavior must be modified to enable them to adjust more appropriately. The "token economy" of Ayllon and Azrin (1968), established in a state institution, illustrates an imaginative use of substitutive reinforcers. Since the desired reinforcers (ground passes, TV, cigarettes, canteen purchases, trips to town, and ordering items from a mail order catalogue) would not in all cases be immediately produced, tokens to exchange for these when available were found to be effective. Tokens were earned for better self-care and for work on and off the ward. The results in terms of morale and behavioral improvement, which in some cases led to recovery, were astonishing.

Bachrach (1962) provides an example of anorexia nervosa treated by operant conditioning techniques. Since food obviously did not have its expected reinforcing characteristics, a study was made of the stimuli that could act as reinforcers. Because the subjects enjoyed visits from people, music, reading, and television, they were at first deprived of these by being put in a barren room. Being visited by people, listening to records, seeing television, or reading books were made contingent upon eating and weight gain. In a little over a year of such operant conditioning, the patients' weight increased twofold.

Ayllon and Michael (1959) describe an experiment in operant-conditioning therapy done on the ward of a mental hospital by the nursing staff working under the supervision of a clinical psychologist. The patient sample consisted of 14 schizophrenics and 5 mentally defective patients. The kind of disturbing behavior (psychotic talk, acts, etc.) in each patient was recorded along with the nature and frequency of the naturally occurring

reinforcements (giving the patient attention, social approval, candy, ciagrettes). Then the nurses were instructed to observe the patients for about 1 to 3 minutes at regular intervals, to give them reinforcements only during desirable behavior, and to ignore undesirable behavior. Nonsocial behavior was to be reinforced temporarily if it replaced violent behavior. For instance, two patients who refused to eat unless spoon fed had a penchant for neat and meticulous appearance of their clothing. The nurses were instructed to spill food on their clothing during periods when they resisted feeding and to present social reinforcements when the patients fed themselves. The patients soon spontaneously began to reach for their spoons and eventually were feeding themselves. In a group of mentally defective patients who were collecting papers, rubbish, and magazines in their clothing next to their skin, the nurses were instructed not to pay attention (i.e., not to reinforce) this behavior, while flooding the ward with magazines to overcome the shortage. The hoarding tendency was overcome.

In the experimental control of behavior the specification of the response is usually simple to describe, but the identification of the stimulus that brings on the response may be obscure. Hence, one must work toward the desired response employing appropriate scheduled reinforcements in terms of what the subject considers to be significant rewards. At first, the most that can be expected are approximations of the final response. Reinforcement is restricted progressively to responses that are closer and closer to the end response. In this way behavior is shaped. Complex behavior patterns may be evolved by developing a series of coordinated responses, linking them together like a chain. Thus, employing food as the reinforcing stimulus, Ayllon and Michael (1959, 1964), as described above, brought chronic schizophrenics out of their disturbed behavior and psychotic isolation. Lindsley (1960) has also written about the operant conditioning of severely sick patients, and N. R. Ellis and his colleagues (1960) have had some interesting experience in retraining disturbed mental defectives.

Operant conditioning is suited for the removal of habits and patterns that serve a neurotic function from which people derive some immediate benefit (such as delinquent behavior, temper tantrums, etc.) at the expense of their total adjustment. It is also helpful

in developing new constructive patterns that are not in the individual's current repertoire. In the main, the treatment procedure consists of an identification of the untoward patterns and a careful delineation of the stimuli that bring them about. Next, the nature of the reinforcements to be employed are determined (attention, food, bribes, etc.) as well as the nature of any aversive stimuli that may help to interrupt the pattern to be corrected. In general, reinforcements are withheld (or aversive stimuli applied) when the behavior to be corrected is manifested, but reinforcements are given (or aversive stimuli removed) when substitutive and more adaptive behavior is displayed. In this way the individual is helped to develop more frustration tolerance and to control untoward behavior in favor of acts for which rewards are forthcoming.

Ferster (1964), in an article that details the tactics of operant conditioning, describes the treatment of autistic children. As is known, tantrums and destructive behavior in autistic children are usually reinforced by the persons with whom the children are in contact by their yielding to the children and satisfying their whims. Thus, the children may have learned that they can get candy if they scream loud enough or bang their head on the floor. Much of the child's behavior is operant, being contingent on reactions from the social environment. Ferster found that food was the most effective reinforcing agent. The sound of the candy dispenser prior to the release of candy acted as a secondary reinforcer. With some training, coins became the conditioned reinforcer, the coins operating devices within the room that could deliver the candy reward. Later, the coins were to be held for a period prior to their use before the reward was allotted. Then five coins were to be accumulated. Delays were increased by introducing a towel or lifejacket that later could be used in swimming or water play (another reinforcer) following the experimental session. While the repertory of the autistic child was limited, it was possible for the child to develop some frustration tolerance and controls.

Next, Ferster examined the circumstances in the early life of the child that originally had brought about, and still could bring about, behavioral disorders. The parental environment was also put under surveillance to see what factors weakened the child's performance, the resultant behavior, and the effect of this behavior on the people

surrounding the child. This was done to determine what reinforcements were operating and the possible ways of discouraging such reinforcements. It is likely that the atavistic and uncontrollable behavior of the autistic child starts with the reinforcement of small magnitudes of behavior such as whining. A shaping into violent responses occurs by differential reinforcement. By refusing to provide reinforcements of the child's behavior, we may expect the child gradually to abandon the behavior (extinction). Changing the environment gradually may be helpful in this respect, since the habitual reinforcing agencies on whom and which the child depends on are no longer present. By withholding positive reinforcements and rewarding conduct that slowly approximates adaptive behavior, it may be possible to effectuate behavioral change not only in psychotic children but also in psychotic adults without using aversive stimuli.

The techniques of operant conditioning are particularly suited for patients who are not accessible for traditional interviewing techniques, e.g., delinquents, psychopaths, drug addicts, psychotics, and mental defectives. The results may be rewarding where the reinforcements stem from objective environmental sources, such as reasonable and relatively nonneurotic individuals with whom the patient is in contact. The results are not so good where the agencies, such as parents, participate in the family neurosis and support the patient's acting-out as a way of satisfying their own needs. It is indeed difficult to prevent reinforcement of the patient's untoward behavior in many families since the inspiring motives are usually unrecognized and subject to conscious denial. Thus parents may become frustrated when their child begins to get better. Subtly the child may be maneuvered back to the old way of behavior with restoration of the defensive protesting of the parent.

Where the reinforcements are of an inner, perhaps unconscious nature, such as sexual excitation and a masochistic desire for punishment, operant conditioning may be of little use. For example, where shoplifting in a well-to-do matron occurs against all reason, it is difficult to find external reinforcements to put this antisocial behavior to halt in case stealing serves to gratify unsatisfied urgent unconscious orality with needs for compulsive acquisition.

In intelligent patients, however, a recognition of some of their unconscious motivations may enable them to execute the principles of operant conditioning for themselves. An executive in a large business firm, presumably happily married and adjusted, periodically would involve himself with prostitutes, whom he enjoined to strap him down to a bed and beat him unmercifully. Struggling to escape from this humiliation, he responded with a strong orgasm. After this experience his shame and guilt feelings, as well as his fears of being discovered, overwhelmed him to the point of depression and suicidal impulses. Although he pursued every device at his command, including exercise, prayer, and involvement in charitable activities to counteract his desire, his intervals of abstinence from flagellant desires would, without reason, be interrupted and he would go forth again toward another beating orgy.

In studying this case it was determined that what particularly delighted this man was sailing in Long Island Sound, where he had a boat. This, it was felt, could be employed as a reinforcement for the ability to control his masochism. It was first necessary, however, to add to the leverage of his will power some understanding of the meaning of his peculiar deviation. This, it was determined from dreams and free associations, related particularly to spankings from his mother during his childhood when he masturbated or was otherwise "bad." A fusion of orgiastic feelings with punishment apparently was the conditioning underlying his symptom. The origins of this affiliation were blunted but memories were activated through analytic techniques. This provided him with a new motivation to decondition himself. A plan was organized so that sailing was to be indulged only in the intervals of control. If a relapse occurred and he acted out his masochism, sailing was to be avoided for a month thereafter. If the impulse appeared and he could control it, he was rewarded by taking a short sea voyage (which he enjoyed as much as sailing) to Bermuda. During the winter, if he had been able to vanquish his symptom, he was to take a sailing vacation in southern waters. Within a year of this regime the patient's symptom was arrested, and whenever the desire returned minimally, he was able to overcome it by reviewing the history of the original development of the symptom. Coordinate with symptom improvement was a better personal and sexual relationship with his wife.

The problem in utilizing operant conditioning as an adjunctive technique consists in finding external reinforcements that are sufficiently interesting and important for patients to induce them to challenge patterns that have open and subversive values. However, if the therapist reviews areas of interest with a patient who is willing to cooperate, a sufficiently provocative reward or diversion that will help incite the patient to change may be uncovered.

The schedules of reinforcement may preferably be arranged at varying intervals and at unpredictable times. This is to produce an anticipatory set and to help prevent the extinguishing of a response that may come about if the patient expected reinforcement uniformly as a consequence of a new behavior. It may so happen that circumstances make it impossible to reward new behaviors each time. If the patient does not envision fulfillment without fail, the patient will not be too disappointed and angry when reinforcements do not appear. Rather, the patient will anticipate their arrival at some point.

Other conditioning techniques have been employed. For instance, Efron (1964) helped a patient stop uncinate seizures by inhaling from a vial odors of various aromatic chemicals (these had been proven effective in controlling the seizures) that were conditioned to a nonspecific visual stimulus, namely an inexpensive silvered bracelet. This was done by presenting simultaneously every 15 minutes, for a period of 8 days, the concentrated odor of essence of jasmine and the bracelet. The instructions were to stare intently for 15 to 30 seconds at the bracelet while sniffing a vial of jasmine. Except for 7 hours of sleep at night, the conditioning continued during the rest of the 17-hour period. At the end of 8 days of conditioning, the bracelet alone presented to the patient produced the effects of jasmine, which receded in a few seconds when the bracelet was removed from the patient's sight. The patient was exposed to reinforcements twice a day for the next week. A spontaneous seizure developing during the second week was stopped by the patient's merely staring at the bracelet for a few seconds. Thereafter the bracelet continued without fail to arrest seizures.

An excellent account of conditioning techniques toward painless childbirth is given by Bonstein (1958). Contained in the article are general suggestions for pain control.

Conditioning techniques have been utilized as diagnostic aids. Gantt (1964), employing the methods of Krasnogorsky and of Ivanov-Smolensky, has described a method for the study of motor conditional reflexes that can be applied to psychiatric diagnosis. Through the use of his technique he claims to be able to distinguish psychogenic from organic psychoses. This is because in psychogenic problems patients inhibit the expression of the elaborated conditional reflex, while in organic psychoses they fail absolutely in the function of forming new adaptive responses. L. Alexander (1964), employing a conditional psychogalvanic reflex technique, has developed a test for the differentiation of physical from psychogenic pain. Ban and Levy (1964) describe a diagnostic test based on conditioned-reflex therapy that measures evidence of change in patients exposed to any treatment regime. Conditioned-reflex techniques have also been employed to investigate the effectiveness of drugs in psychiatry (Alexander, L, 1964). How conditioning may enter into the genesis of attacks of asthma is discussed by Dekker, Pelser, and Groen (1964).

PUNISHMENT AND DEPRIVATION

Behavior therapists now recognize that punishment rarely works as a means of halting undesirable behavior. It is usually temporary in its effect and likely to exaggerate rather than solve problems. Getting individuals to stop hurtful activities because they get adequate rewards in exchange is much more effective. The patients may not be able to anticipate the rewards that accrue from constructive behavior until they have yielded their destructive activities, and it will be necessary for the therapist to provide interim reinforcements.

A child who consistently misbehaves, who refuses to eat, sleep, or give up childish habits like thumb-sucking and bedwetting will frustrate the parents and provoke angry responses. The parent will be tempted to punish the child for refusing to cooperate. This may do little other than to mobilize the child's guilt feelings and lead to self-punitive

activities (masochism) or to stimulate retaliating anger and defiance. Logic has little to do with these reactions. Or the parent may be tempted to remove certain privileges, such as taking away something that the child enjoys (e.g., allowance, desserts, or TV viewing). The consequences of such deprivation are usually the same as punishment. Yet punishment and deprivation may rarely be an expedient in temporarily stopping destructive behavior that the child refuses to halt. For instance, of their own accord, older children who are mercilessly beating a younger sibling may be forcefully required to retire to their rooms until they feel they can control themselves. But the expedient of punishment or deprivation must be used only in emergencies to put a stop to immediate destructive outbursts that do not yield to reason, verbal reprimand, or the ignoring of the behavior. In any event, the punishment or deprivation should be reasonable and never so drastic as to leave an enduring residue of anger and desire for revenge. It should always be used in conjunction with positive reinforcement for constructive behavior.

Far more effective are actions that tend to *extinguish* improper behavior. This may require little more than refusal to reinforce the behavior by paying too much attention to it or being ostensibly provoked by it. Thus, a parent may interrupt an undesirable activity by diverting a child's attention and substituting another activity for the disturbing one. Reinforcing the substitute activity by providing a proper reward for its indulgence will help extinguish the unwanted activity.

AVERSIVE CONTROL

There are times when all methods employed to halt disturbing behavior, particularly those that are life threatening or destructive, may fail, and the therapist may, with the consent and cooperation of the patient, have to resort to measures of blocking the behavior by associating it with unpleasant stimuli (Cautela, 1967; Rachman & Teasdale, 1969; Lovibond, 1970; Meletsky, 1980).

Aversive conditioning is sometimes employed to overcome certain undesirable behavioral components. Emetic drugs (apomorphine or emetine hydrochloride) were used for years in the treatment of alcholism by conditioning methods. Miller, Dvorak, and

Turner (1964) have described a technique of establishing aversion to alcohol through the employment of emetics in a group setting. A unique form of aversive stimulus-paralysis and suppression of respiration through intravenous injection of succinylcholine-chloride dihydrate has been reported by Sanderson et al. (1964). In addition to drugs, electric shock has been employed as an aversive stimulus for a variety of syndromes (McGuire & Vallance, 1964). Needless to say, unless one has an excellent working relationship with a patient, aversive conditioning poses some risk and may play into a patient's masochistic need. And, as noted in the preceding section, punitive conditioning is never employed in isolation by the modern behavior therapist; nowhere is this more evident than in the behavioral treatment of the alcoholic (Franks & Wilson, 1975). Hypnosis may be induced, if desired, and the aversive conditioning, if it is essential to use it, employed in the trance state.

In certain cases self-induced aversive conditioning may be helpful in controlling violently upsetting thoughts or impulses, such as occur in compulsive-obsessive reactions. The patient is supplied with a toy "shocking machine." This may be purchased in a store that sells tricks for the practical joker. It consists of a simulated book with a spicy title or a pack of cards, which, when opened, delivers a shock from a battery within. The shock (buzz) is harmless, yet annoying and even frightening. The patient, with the contraption in the hands, is requested to shut his or her eyes and then bring offensive thoughts to mind. As soon as they appear, the patient is to open the book or cards and keep it open until the thoughts completely disappear. After six to ten trials patients are usually surprised to find themselves unable to bring obsessive ideas to their minds, even when they try to force themselves to do so. The patient may be asked to practice this "exercise in thought control" two times daily, with as many trials as are necessary to eliminate the obsessions or impulses, even when the patient tries to bring them on.

Aversive conditioning may give patients confidence in their ability to occupy themselves with useful rather than self-destructive concerns. Carrying the device in their pocket may become a conditioned reassuring stimulus even though it is not used. Should the patients complain that the shock is too strong, they may reduce its intensity by

interposing a piece of facial tissue between their fingers and the box. An alternative pain stimulus may be provided by a rubber band around the wrist that is snapped whenever an aversive measure is required.

A typewritten form such as the following may be given to the patient to be practiced at home:

HUMAN AVOIDANCE OR AVERSIVE CONDITIONING (HOMEWORK)*

You can help yourself to get rid of undesirable, torturesome thoughts and habits after you and the doctor or his associates have agreed that these thoughts or habits are damaging to you. Repeated practice is necessary for most people at least one or more times per day in the beginning and then at gradually decreasing intervals until the thought or habit is gone. The doctor or his associates may help prescribe the intervals and amount of time most helpful to you as well as other helpful ideas.

I. Repetitive, self-damaging thoughts (thought-stopping)**

a. Close your eyes, hypnotize, or **relax yourself** and force the repetitive thought or the picture of the undesirable habit to be **visualized** in your mind for at least 2-3 seconds.

b. Almost immediately, shout **STOP** or if this is not possible, **think** STOP or if this is not possible, **think** STOP emphatically and promptly give yourself an unpleasant buzz with the buzzer at the same moment. Holding your breath can be used with the buzzer, or something unobtrusive for you, e.g., a clenched fist can be used at the same time in place of "STOP." (**It is important that during the pleasant and restful time after you have stopped the shock, visualize a successful, positive, helpful image or valuable substitute activity.)** As soon as these secondary things (breath holding, fist, etc.) work, use buzzer less and less frequently.

Repeat this entire procedure at the same sitting until you can no longer get the thought at that time or until at least 20 satisfactory repetitions have occurred. The entire procedure is to be repeated up to six times per day for 1 to 15 weeks. This will be

prescribed in accordance with the severity of your problem and the length of time you have had it. Make a note each day on the back of an appointment card or some other record such as a homework sheet of how frequently and for what number of repetitions you have been using the buzzer, or the word STOP, breath holding, fist, etc. A list of possible pleasant thoughts, activities, assets should be available.

II. Modification

In addition, you can carry the buzzer, or special pen if you prefer, with you and use it whenever you find yourself thinking repetitively or continuing your undesirable habit. If circumstances are such that it is impossible for you to use the buzzer during the larger part of the day, think the word STOP, etc. and imagine the uncomfortable buzz when you find yourself going back to the thought or habit. This will gradually become more successful after actual practice when practice is possible. Unless good success is being maintained with the STOP, breath holding, or other simultaneous gesture, and the pleasant thought or activity substitution, report to doctor.

Note: The buzzer should be held firmly with two fingers and the buzz should not be pleasant. If it seems too much to endure, however, even though it contains only a single pen-light type of battery, a single thickness of Kleenex placed under the fingers will modify the buzz sufficiently.

** Modified by Rothman after J. Wolpe.

Another form of aversive control is the withholding of positive reinforcements, such as the loss of certain privileges or the levying of fines, as a consequence of certain behaviors. Even though the effects of aversive control may be limited, it may have to be resorted to where self-injurious behavior cannot be stopped by any other method. For example, I have had referrals of patients with hair plucking that had failed to respond to years of insight therapy. They stopped their self-denuding habit after several sessions with a small shocking machine, which they carried with them thereafter. Obviously, desirable behavior that opposes the noxious habit should be rewarded. A variation of

aversive control is "overcorrection," whereby individuals are obliged not only to restore the original situation disrupted by their behavior, but also to engage in other corrective tasks that can prove tedious (Foxx & Azrin, 1972; Webster & Azrin, 1973).

IMAGERY TECHNIQUES

In desensitization through imagery it has been shown that the pairing of fear and relaxation responses reduces the intensity of phobic reactions. Following Wolpe's method of systematic desensitization ("reciprocal inhibition") a hierarchy of fearful situations is constructed. The overcoming of lower level fear images encourages a progressive ascension in the hierarchical scale until the top level fearful situation is mastered in fantasy. A state of muscle relaxation is first produced, along with the image of a relaxing scene. The subject is then asked to visualize the lowest level fearful image. When this is tolerated with comfort, the next higher image is introduced. Should fear arise at any point, the scene is shifted away from the hierarchy to the relaxing image, and the relaxing muscle exercises are repeated. The scene prior to the one that produced fear is then reintroduced and progression up the scale continued. As fear reduction in imagery continues, patients are encouraged to actually expose themselves to graduations of the phobic situation that brought them to therapy. It is assumed, of course, that in the initial "behavioral assessment" a study has been made of the various reinforcement contingencies and that these are considered as part of the total treatment plan. Some patients are unable to learn relaxation procedures, or cannot use imagery successfully, or hesitate to report sensations of anxiety, or are unwilling to practice for weeks without immediate relief (which is sometimes what it takes for a proper response to develop), and hence will not be able to utilize this technique.

The patient may also practice self-imagery for purposes of ego building. The patient can be given instructions that may be easily followed at home. A mimeographed or typed sheet, such as the one that follows, will enable the patient to select that which is best. A small shocking machine or snapping a rubber band on the wrists is used to deliver an unpleasant stimulus in indicated sections of the sheet. A number of useful fantasies for

self-imagery are detailed in the book by Kroger and Fezler (1976). See also Chapter 12 (Guided Imagery).

<div style="text-align: center;">

ASSERTIVE TRAINING

</div>

Among the most annoying deficits are not being able to stand up for one's rights, rejecting criticism even of a constructive nature, acceding to being coerced or manipulated by others, expressing one's desires and preferences only with guilt or embarrassment, and countenancing rejection as a sign of being worthless and debased. These deficits are usually associated with a devalued self-image and a hypertrophied and punitive conscience. Related as they are to such basic personality distortions, it is difficult to see how they can be altered without self-understanding.

A way of facilitating self-understanding, important to enduring change, is to bring patients to awareness of their anxieties, evasions, and other defenses through plunging them into situations where they must assert themselves. Whether thinking and acting in ways consonant with a positive self-concept can in themselves correct a devalued self-image is debatable, although some therapists assume "that if a patient behaves and thinks in a manner indicating a positive self concept, he has, in fact, acquired one" (Seligman, 1979). In my opinion, some cognitive alteration is essential.

A format that is often used for assertiveness training is a time-limited group of eight to ten patients led by a man/woman therapist team. A questionnaire rating reactions to certain situations may be found helpful (Gambrill & Richey, 1975). Patients are taught to differentiate acting assertive (expressing one's rights) from acting aggressive (putting others down). Discussions involve self-assessment of assertiveness by the group members. Modest goals are then set for each at first. The actual training procedures include such techniques as behavior rehearsal, role-playing, imagery and cognitive behavior therapy (relabeling certain acts). etc. (Smith, MJ, 1975) Homework is assigned with the object of increasing assertive responses and lowering non-assertive ones. A diary is kept of experiences. Modeling by the therapist is often employed. Patients set up problem situations in which there is practice in asking for a favor, saying "no" to an

unreasonable request, making a date with a person of the opposite sex, etc. The ability to accept rejection without anger, shame, or feelings of being inferior is developed by role-playing and discussion of feelings.

<div align="center">

IMPROVING HUMAN SELF-IMAGES RAPIDLY

(some newer and some experimental methods)

</div>

INTRODUCTION: You and the doctor or his associates have agreed that a less self-critical self-image of yourself is desirable; or a self-concept in which you feel less inferior and more self-confident, or less childlike, more active at finding a new job—remedying a situation—doing more housework—getting more exercise—or more comfortable physical and social activity—or some other changes in your innermost self-concept are necessary or desirable.

Method I: **Ego Building**. Under self-hypnosis or relaxation leave yourself with the self-image of pleasant feelings and times in your life you, and possibly others, thought you were at least somewhat successful. Tell yourself, "I promise to act in accordance with this image."

Method II: A gradual stepladder of improved self-images can be used under self-hypnosis or relaxation, and you can move up this imaginary ladder of improved self-images until you feel a tinge of anxiety. Step down to the last comfortable self-image you could get. As soon as possible, act in daily life according to this improved image—as if it is now you.

Method III: Visualize your "lazy" or passive self-image as perhaps you have looked after avoiding some important work—a picture that we have agreed should be changed. After imagining this picture for 2-3 seconds, give yourself a buzz, usually until the image stops. Repeat as prescribed, usually for about 20 pictures at a sitting, with at least daily repetition. Substitute an image of a time when you were slightly more pleased with yourself each time you relax from the buzz.

Method IV: This can be used if you have been taught self-hypnosis with body imagery changes, (a) Hypnotize yourself to picture how some of your character (expressed as face and body) looks to you. Usually the doctor or his associates will have agreed with you on a given signal or word for this unconscious image to appear clearly. If you find difficulty in separating "bad mother or bad father" (or other image previously discussed with the therapist) from **your** image, i.e., they stick, then try using the buzzer to break up the fusion and leave you with an **independent self-image**, or with "good" mother and father's love. (b) Then you may attempt to modify by fusing your image with someone who has, as you and your therapist have agreed, some desirable traits you'd gradually like to work toward in a **realistic** fashion. (c) If the old image is stubborn in leaving, or fusing with the image you and your therapist have agreed upon, use the buzzer as described in Method III and #1 under AVERSIVE CONDITIONING to modify the old image by buzzing it and thereby speeding up the desired fused image. Report changes to your therapist, and keep your goals practical and within easy steps forward.

NOTE: It is most important that you keep careful records of frequency of use, and just what happens with the images, and discuss this with the therapist. These methods are not the same as daydreaming. Homework time is limited to approved and improved images as prescribed and should be tried out in reality.

<center>Reprinted by permission of the author, Dr. Irwin Rothman.</center>

Coincident with such assertive performances, analytically trained therapists may explore individually or in a group format each individual's underlying conflicts that have been responsible for and that are sustaining devalued self-image. This combination of behavioral and dynamic therapy is offered for the purpose of giving the patient the best opportunity for correcting problems in assertiveness on a permanent level. Dynamic therapy alone over a long-term period may get at the core of the responsible personality distortions, but the treatment may bog down when, after insight is gained, the patients resist putting their insights into action. Starting off with assertive training, on the other hand, almost immediately puts the patients in a position where they are confronted by their anxiety and the defenses that prevent them from resolving their problem. They have

to deal with these as realities, not as theories.

It is interesting that in the face of this confrontation and in breaking through the resistance by practicing assertive exercises, many patients acquire insight into the dynamics of their problem. A dynamically oriented therapist will be able to expedite insight by examining and interpreting the patient's dreams, behavioral acting-out, and transference reactions. Past sources of trouble and early conflicts may surface; by working on these the therapist may connect them with the patient's current personality problems and more pointedly with the self-image pathology that expresses itself in symptoms. Even where the therapist is not dynamically oriented, some patients will put the pieces together by themselves.

Generally, in assertiveness training the patient is first taught to distinguish between assertiveness and aggressiveness. Too often they are considered identical. Assertiveness implies the need to stand up for one's rights and to refuse to relinquish one's rights. Aggression means a violation of another person's rights.

The ideal setting for assertive training is a group, although where a group is not available individual sessions can be productive. Patients keep a diary in which they record situations where they wanted or needed to act assertively, or to deny a request they felt was unreasonable, along with a notation of their feelings, their actual behavior, and their reactions to their behavior. A hierarchy of situations is constructed on paper, ranging from low level situations that are slightly difficult to handle to high level situations that the patient has found it impossible to manage. In role-playing one starts with low level situations, gradually working up to high level ones as mastery progresses. Some therapists advise the patient's utilizing a scale *(Subjective Units of Distress Scale*—SUDS) developed by Wolpe and Lazarus (1966) for record-keeping and role-playing. Other therapists employ biofeedback (EMG) to coordinate the items on the SUDS scale with subjective feelings of tension.

After role-playing promotes some confidence, the patients are encouraged to attempt low level assertive tasks in life itself, such as requesting things from people that

are not too difficult for them to give. Should failure occur, the patients are told they are not yet ready for the assignment rather than that they failed at it. Discussions of the tasks and reactions are carried on in the group, who cheer successes but do not castigate the patient for failures. Videotape feedback can be helpful in providing the patients with data on visible defenses. Progressively more demanding requests are encouraged until the patients gain confidence in asserting themselves without hesitation. A variety of other programs to enhance assertiveness may be set up, such as those of Eisler et al. (1973b; 1974), Hersen et al. (1973a, b), Whiteley & Flowers, 1977), Flowers & Booraem (1980).

The following outline, modified after J. Wolpe and prepared by I. Rothman and M.L. Carroll, provides examples of practice exercises in assertiveness:

SELF-DESENSITIZATION OR ANXIETY REDUCTION TECHNIQUES IN MAN*

A. Frequently you will be given a choice of self-relaxation or self-hypnotic techniques described in a booklet or in instructions given to you by the doctor. Practice the method you choose. Other types of training for self-help may also be shown you.

B. Make a written stepladder of situations which disturb you or are problems to you. Arrange these in order from the **most disturbing** to the **least**, or from least to most if you prefer. Please provide a clear copy of your stepladder for the doctor.

C. During your 70% successful relaxation periods, visualize dramatically (get a vivid mental picture of) yourself successfully handling the situations (going up your stepladder) from the least to slightly disturbing until you feel slightly tense, then stop. Relax until you are again at ease. This procedure should be done daily, usually for not more than 10 minutes at bedtime, or some other convenient time. This visualization should be about things you actually want and intend to do and not just daydreaming. Make it a practice to try the things you have successfully pictured yourself doing whenever possible. After a few days, longer or more frequent practice periods or several separate stepladders may be prescribed.

D. Try to record where you are on the list daily. The faithfulness with which you practice daily visualization is an indication of how much your healthy self

is willing to cooperate in the treatment against your self-destructive side. If your mind wanders from successful picturing, repeat the last successful picture. Remember that the mind can only concentrate on one thing at a time, although it may skip quickly. Bring back the thought you wish to work with for at least 2-3 seconds at a time. Your visualization will improve with practice. Stop when you feel anxiety at the same step on the stepladder more than three times, go back to a comfortable relaxation, and later add extra smaller steps between the worrisome ones.

E. The situations listed below are merely suggestions of areas which **may** be problems to you and how to handle them with this method. If any of the examples do apply to you, include them in your own stepladder (s), along with any other problem areas not listed here. Each area can be divided into **as many as 20 or more gradual steps** to visualize **and to conquer in actuality. If you** do not experience any anxiety while first visualizing situations which you find much too difficult to accomplish in real daily life, consult the doctor or his associates concerning this.

EXAMPLES:

(The first example is broken down to give you an idea of how to place situations on your own list.)

I. ASSERTION EXAMPLES:

Asserting yourself with other people without guilt, listing different types of people in order of decreasing difficulty from the boss (possible #1) to the office boy (possible #9) to the janitor (possible #15). This is a most important category for people with depression, strong self-damaging tendencies, and anxieties in dealing with other people.

Picture yourself:

(a) expressing affection openly for (1) pets, (2) children, (3) immediate family, (4) more distant relatives, (5) friends, (6) acquaintances— possibly in that order of difficulty for you.

(b) being assertive with your family, clerks, waitresses, policemen, and authority figures in the degree and order of difficulty fitting you.

(c) Discussing topics which are of interest to you with your family, other

relatives, and close friends.

(d) Making an effort and succeeding in discussing their interests.

(e) Stating your wishes without guilt to family, relatives, and close friends.

(f) Expressing disagreement without guilt to family, friends, other relatives.

(g) Following the same steps with casual friends and acquaintances.

(h) Requesting firmly that clerks, janitors, or any subordinates do their jobs promptly and properly.

(i) Expressing disagreement or your feeling of annoyance with those who do not fulfill their duties correctly.

(j) Talking about your job with fellow workers or firmly requesting that they do their share of any mutual job.

(k) Giving a report and expressing disagreement if necessary with your immediate superior in a tactful way.

(l) Giving a report and expressing disagreement if necessary to the highest superior with whom you must deal in a tactful way.

Other problem areas which can be broken down may include:

II. FEAR OF CRITICISM, REJECTION, DISAPPROVAL, OR HEALTHY DISAGREEMENT:

(a) Successfully facing sarcasm from family, friends, or associates

(b) Successfully facing direct disapproval or criticism from family, friends, or associates

(c) Successfully arguing and being unafraid of arguments

(d) Successfully facing feelings of being excluded by others

(e) Successfully facing being ignored or reprimanded

(f) Successfully dealing with persons you feel dislike you, etc

III. MEDICAL SYMPTOMS: Symptoms you have been told have no medical importance: getting busy with activities and ignoring symptoms such as rapid heartbeat, buzzing in ears, constant or intermittent pain from rheumatism, or similar symptoms if you know that they are not medically important. Arrange a stepladder of increasing time for enduring them and carrying on despite them.

IV. STAGE FRIGHT: successfully speaking to a group. Perhaps start with an empty room and gradually increase the number of people present to 100.

V. SOCIAL FRIGHT: enjoying entertaining and parties of increasing size from one friendly couple to any number of relative strangers.

VI. CROWDS: At ease in crowds of increasing size (elevators, trains, cramped quarters, open spaces, etc.).

VII. JOB SEEKING: Being at ease in applying for a job, starting with one you do not really want. Actually having several interviews before taking a job.

VIII. OPPOSITE SEX: Being at ease with members of the opposite sex, starting with someone unimportant to you and increasing periods of time and difficulty.

IX. DECISION MAKING: Being at ease in making your own decisions, without regrets and afterthought. Start with small decisions and increase importance.

* Reprinted by permission of the authors, Dr. I. Rothman and M. L. Carroll.

MODELING

Modeling can serve as a valuable means of social learning and personality development (Perry & Furukawa, 1980). The process involves both observational and performance aspects, theories of which have been adequately explicated in the literature (Bandura, 1977). By acting as a model, the therapist strives to provide cues for the patient that will help develop new behavioral skills, halt aberrant attitudes, and aid in problem-solving (Bandura, 1969). Both symbolic modeling (use of videotapes, films, audiotapes,

written scripts) and live modeling (the therapist performing a certain exemplary behavior like facing a phobic situation) may be employed. Multiple models have an advantage over single models since the opportunities for identification are greater. For example, a child fearful of dogs, observing other children petting a puppy may be induced to experiment with approach behaviors.

To reduce anxiety that may be aroused in the patient, relaxation exercises can be used in advance of the modeling activity. Thus, if patients have a great fear of having their blood pressure taken, the therapist may initially utilize systematic desensitization with the patients to calm them down, demonstrating the use of the blood pressure apparatus on himself or herself. Priming the patient by explaining what the patient will see in the modeling activity is also useful. Once the patient executes the modeled behavior, active rehearsal of the behavior along with reinforcements (comments of approval, material rewards) will tend to establish it more firmly.

Graded participant modeling consists of the setting up of a hierarchy of activities related to a feared object or situation. For example in a phobia of airplanes, flying is at the top of the list, and calling the airline for information about a special flight at the bottom. In between are driving to the airport, going to the counter to talk to the attendant, sitting in the waiting room, walking to the gates, watching planes landing and taking off. The therapist may model the behavior for all of these gradients, then repeat the least anxiety provoking and ask the patient to execute this. As anxiety is completely resolved, the patient is enjoined to try progressively difficult tasks until actual flying occurs.

New behaviors must of course be transferred by the patients to the settings in which they live, work and function, and here the patients may not get the same reactions and reinforcements they receive in the training settings. Preparing the patients for the trials of performance generalization and reviewing with them their experiences in the transfer of learning to different settings are an integral part of the training process.

Recommended readings that give examples of the actual modeling process itself are: Bandura et al. (1969) in relation to overcoming phobias; Melamed and Siegel (1975) in

anxiety reduction for children facing hospitalization and surgery; Csapo (1972) for correcting disturbed classroom behavior in withdrawn or disturbed children; Perry and Cerreto (1977) for training of living skills in mentally retarded persons; Hingtgen et al. (1967) for working with autistic children; Gutride et al. (1974) for helping psychotic patients reinstate adaptive behaviors; Sarason and Ganzer (1973) for rehabilitating juvenile delinquents; and Reeder and Kunce (1976) for preparing heroin addicts for adjustment following treatment. Modeling may also be used in professional training programs for counselors and therapists, e.g., to develop greater capacities for empathy (Perry, 1975).

COGNITIVE BEHAVIOR THERAPY

Recognizing that complex human behavior cannot be explained solely by conditioning paradigms, behaviorists since 1970 have turned to higher level processes, exploring what they have called "cognitive behavior therapy." As we might expect, different authorities have experimented with and developed innovative ways of implementing this new dimension. For example, some have focused on illogical thought patterns that in the past have forced the patient to draw false inferences from certain events, to overgeneralize from solitary incidents, and to fail to correct distortions even though life experience has pointed to the falsity of their assumptions (Beck, AT, 1976). Others have advocated more active training procedures, working with patients toward employing positive, constructive self-statements along with practicing relaxation techniques (Meichenbaum, 1977). Still others continue to use Ellis' (1962) technique of actively presenting rational solutions to replace the patient's maladaptive ones ("rational emotional imagery").

Instead of attempting to win patients over toward adopting a new philosophy toward life, or different attitudes toward themselves and others, as in persuasion *(q.v.)* the patients are given daily relearning exercises to change their thinking habits toward rational goals that they are trying to achieve. First, the patients are trained for several sessions in rational self-analysis to get at the basis of their problem. Next they are

enjoined to practice rational emotive imagery for a minimum of 3 10-minute periods each day during which the patients see themselves acting in constructive ways in relation to the upsetting or challenging situations in their lives (Maultsby, 1970).

Social learning precepts are prominently employed in training procedures with the object of rational restructuring of thought processes; of altering mental sets in line with optimistic rather than pessimistic expectations; of liberating oneself from the tyranny of conventional beliefs; of abandoning the notion that one has always to be right, loved, perfect, important, and happy; and of relinquishing the idea that one's past indelibly stamps out one's destiny.

Patients are aided in acquiring coping skills by (1) putting themselves into challenging or upsetting situations in fantasy and verbalizing their feelings, and (2) role-playing constructive solutions. There is accumulating experimental evidence that these techniques help to reduce anxiety and to change attitudes that create pathologic feelings and behavior. Skill in problem-solving is encouraged by showing the patient that attitudes, positive or negative, will definitely influence the outcomes; that it is essential to define and formulate the problem at hand for which a solution is needed; that alternative approaches should be designed in the event a chosen solution proves to be inadvisable; that a definite decision of a course of action must be made; and that verification of the validity of this choice in terms of achievement of set goals must finalize the process (Goldfried & Davison, 1976).

An example of how cognitive therapy is executed is provided by the treatment of depressive disorders. The cognitive theory of depression assumes that a cognitive triad exists (Beck & Young, 1985). Depressed patients have a starkly negative view of themselves, conceiving of themselves as worthless, unlovable, and deficient. They see the environment as overwhelming and believe they cannot cope with the pressures around them. They regard the future as hopeless. Events are distorted and twisted through illogical thinking to confirm these apprehensions with unjustifiable arbitrary inferences, overgeneralization, selective obstruction, and magnification. Early negative schemas,

evolved during early childhood and operative outside of awareness, act as predisposing factors and are activated by later life events. These cognitive distortions always contribute to depression with its physiological effects.

Cognitive therapy, which may be done on an individual or couples format, draws upon a number of techniques to change depressive thinking. The most difficult patients for either kind of format are severe endogenous depressions, bipolar depressions, organic brain syndromes, psychotic depression, schizoaffective disorders, and borderline personalities. Neurotic and mild endogenous depressions do best. But even in the severer depressions, cognitive therapy can be useful in combination with pharmacotherapy, milieu therapy, and supportive therapy. Apart from the usual empathic qualities essential in a therapist, considerable skill is needed along with the ability to communicate confidence and hopefulness. Goals, the specific problems to be focused on, and the agenda for each session are set collaboratively. Since patients may not understand a therapist's formulations yet avow that they do out of a need to please, the therapist should encourage feedback to make sure the meaning of the communications has been grasped. At the end of each session the therapist summarizes what has been done and asks the patient to write down the main points of the discussion. Homework assignments are important including readings, self-relaxation, and diversionary activities.

Cognitive techniques involve a search for automatic thoughts and maladaptive assumptions through questioning, imagery, and role playing. Once an automatic thought is elicited in the form of interpretations of an event, an analysis of the thought is jointly embarked on to test its validity. Here the patient's use of words may come up for study. Rectification of the habit of self-accusation necessitates reattribution of blame. Alternative solutions are encouraged, maladaptive assumptions are challenged. Faulty beliefs are analyzed. Behavioral techniques are utilized especially when a patient is highly passive and withdrawn. These include activities to improve mastery and enhance pleasure, training in self-reliance and assertiveness, role playing, and diversion techniques.

Some cognitive therapists utilize psychological inventories as part of the assessment

procedure. Among these are the Beck Depression Inventory (BDI) that scores the degree of depression, the Young Loneliness Inventory Score (Young, 1982) that reveals the degree of distress due to lack of intimate ties, and other tests. Interviewing is conducting mainly by a therapist focussing on the most distressing problem that concerns the patient and probing the "automatic thoughts" through questioning in order to understand the patient's perspective. A good area to explore at first is the inactivity and withdrawal that highlight and characterize depressive symptomology. Instead of criticizing, blaming, condemning, and reassuring the patient, the therapist continues to enjoin the patient to examine the immediate assumptions ("collaborative empiricist"). The therapist may ask the patient to select a small problem to work on together. Any suggested activity the patient brings up that can possibly bring the patient out of preoccupation with hopelessness is selected for "graded tasks" in the form of questions to break down resistance to following through with its execution. The patient may be asked to write out an activity schedule for the week. Some therapists routinely have their patients fill out the Beck Depressive Interview before each session so that progress can be monitored. Negative thoughts are chosen for questioning and probing of ways of coping with these and finding constructive alternatives. The therapist is alerted for dominant schema that control the patient's attitudes and relationships. Periodically, summaries are given to the patient of the themes that may be operating in the automatic thoughts. If the patient is planning a major decision, postponement may be recommended until a more realistic perspective is obtained.

Obviously, as one works with a patient character patterns will display themselves as reflected in the relationship to the therapist and to the therapeutic process itself. Distortions in the way the patient appraises things are clarified with the hope that through questioning and a "guided discovery" approach there will be a more realistic appraisal ("reattribution"). Continuing homework assignments may include keeping a daily record of dysfunctional thoughts by listing situations that lead to unpleasant thoughts and the stream of automatic daydreams or recollections that produce unpleasant emotions. A diary or *Weekly Activity Schedule* may also be kept to list and grade the degree of instances of mastery and pleasure. In therapy, maladaptive assumptions are continuously explored

especially "in the context of a concrete event" with the object of replacing automatic thoughts with rational thoughts. A technique *Point Counterpoint* is sometimes utilized to help such a replacement. Here in role playing, the therapist plays the devil's advocate by expressing the patient's own negative thinking while the patient defends a more rational stance. Hopefully, underlying destructive assumptions will be undermined with practice in and out of therapy. Other strategies may be devised to test the validity of one's assumptions that lead to depressive thinking and feeling. Patients are enjoined to test other hypotheses on which their assumptions, early schemas, and automatic thoughts are based. In vivo experiments within the patient's life situation are set up to test habitual beliefs and, during therapy, successes and failures are reviewed. Self-help homework assignments aid the patient in facing problems more realistically, and correcting thinking patterns that can lead to resolution of depression and to adaptive behavior.

CONTINGENCY CONTRACTING

Some behavior therapists try to direct the patient toward productive change through reinforcements in *contingency contracting.* It is agreed that the execution of desired behaviors (socialization, assertiveness, dietary abstinence, etc.) will result in certain positive rewards. The contract is drawn up between the patient and the therapist, or in couples therapy between the two partners. The selection of appropriate reinforcements may be aided by use of a *Reinforcement Survey Schedule* (Cautela & Kastenbaum, 1967). The contract is time-limited and specifies the behavior patients are to perform (e.g., smoking control, weight loss, assertive behaviors, etc.) and the rewards they are to receive for such behavior. The patients collect data in writing on the daily frequency of such behaviors and their reactions to their execution. The rewards must be reasonable, but must be sufficiently intense and meaningful for the patients to compensate them for whatever deprivations they undergo in performance of assigned tasks. The patients, for example, must feel that they are attaining a previously denied or absent prize and that they have earned it through their own efforts. If money is the reward, paid by a third party, this should not be accumulated but should be spent as soon as possible since saving may dilute the effort put into performance. Thus, a child who is rewarded with money for

certain socializing behaviors should not be requested to save the money for college. Rewards to adults may consist of vacations, trips, and various kinds of entertainment. Sometimes when patients reward themselves with money, they deposit money with the therapist, who then distributes it in accordance with a patient's compliance with the contract. In contracts between couples (contingency or exchange contracts), the desired behaviors on the part of one member are rewarded with specified behaviors on the part of the other member.

Do sought-for behaviors continue after the contract ends? The claim made by behavior therapists is that in well-conducted therapies the patient begins to enjoy the behaviors for their own sake and for what they do to self-image and self-respect.

A GENERAL OUTLINE OF BEHAVIOR THERAPY PRACTICE

There are many designs for the practice of behavioral modification. One that I have found useful follows:

1. Ask patients which behaviors they wish to strengthen and which they wish to diminish or extinguish.

2. Find out the situations under which undesirable traits or symptoms lessen or increase. Do not be concerned with explaining why the problem developed except insofar as the positive and aversive reinforcements that maintain it can be detected.

3. Select jointly with the patient (on the basis of the patient's priorities) which behaviors or reactions are to be altered first, leaning toward those that, in your opinion, are most modifiable.

4. Explore the degree of motivation of the patient for therapy, the consequences of present demeanor and the rewards anticipated from newly developed behavior. Challenge and work on the patient's motivation until it is certain that the patient unequivocally wishes to change for himself or herself and not to please others.

5. Examine in depth the behavioral constellation to be altered or strengthened, going into past history to determine the reinforcements that have

maintained the problem. Can patients clearly define what it is that they desire to change? Do they accept your formulation of the problem? If not, you, the therapist, assume an educational role to teach the patient the full implications and complete description of the behaviors that are appropriate for the desired change. Do patients clearly understand what is expected of them?

6. Identify the rewards (reinforcers) if any that are to be employed making sure that they have value for the patient. These reinforcers are made contingent on the desired behavior. A contract—verbal or, better, written — is drawn stating what is expected of the patient and the rewards for maintenance of the contract. The contract time should be made short, say a few days, with the idea of renewing the contract at the end of the contract time.

Sometimes contingency contracting is utilized, the patient and therapist deciding mutually not only on the kind of reinforcements that the patient is to receive on controlling problem behaviors or substituting constructive alternatives, but also the penalties to be imposed, if any, for perpetuation of disturbed behaviors. We, the therapists, may also impose penalties on ourselves should we not live up to our contract (appearing late for appointments, missing appointments, etc.), for example, reducing or cancelling fees. Token reinforcement systems may be set up, the patients receiving tokens for constructive behavior that they can exchange for luxuries, privileges, etc. (Ayllon & Azrin, 1968; O'Leary & Drabman, 1971). Token economies have been found to work well in some institutions and classrooms (Paul & Lentz, 1977).

7. Work out a planned schedule with patients to begin to approach their new behaviors under the least traumatic circumstances possible. If interpersonal relations are involved in the plan, the least challenging individuals are selected so that the patient may be minimally uncomfortable. In the shaping of a difficult behavior, the start should strive for minimal gains and immediate reinforcements, with the object of approximating the desired change, more and more reinforcements being given step by step as changes progress.

8. Ask the patient to keep a diary that lists each day the frequencies of new behaviors practiced. Praise is preferred for each success, but no criticism is given for failure. If no progress occurs, explore with the patient the

reasons for failure. Encourage the patient to try again and make suggestions as to new assignments that the patient is prepared to execute. Explore attitudes, beliefs, systems and other cognitions that may be acting as resistances to progress.

Behavior modeling by the therapist and role playing are introduced when necessary. If anxiety prevents the patient from following through on behavioral assignments, systematic desensitization may be tried and/or a mild tranquilizer suggested such as Xanax for a brief period of time only, recognizing its addictive potential. At each session the patient is given homework to expand on skills.

9. Where it is obvious that the patient is confused in acting in a constructive way, try behavior rehearsal (Casey, GA, 1973).

Here the therapist rehearses the patient in what to say and how to say it, covering a broad zone of interpersonal behavior, with both real and fantasied authorities and peer figures. The gestures to make, the words to say, the facial expressions to exhibit are all acted out. The rehearsal will bring out feelings in the patient that will need discussion. Sometimes it is helpful to make a recording (audio and video if available) to play responses back for the patient after each rehearsal. The therapist advantageously can play dual roles: first, that of the individual with whom the patient cannot seem to deal with in real life, and then, by changing chairs with the patient (role reversal), that of the patient with appropriate comments and gestures to indicate preferred reactions (modeling) while the patient is asked to put himself or herself in the position of the adversary. The patient may need constant or periodic coaching while this role playing goes on.

10. Individual sessions may later be complimented with family and group sessions where these are deemed helpful.

In family therapy sessions the attendant members are apprised of the circumstances that create and maintain behavioral difficulties. Appropriate ways of reacting with each other are suggested. Group sessions are usually conducted with the object of allowing each member about 10 minutes of time to describe what each has accomplished since the last session and the reactions. The members then make suggestions to each other as to

how difficulties may be overcome or progress increased.

> 11. Should a relapse occur, the best way to manage it is not to reward it with too much attention. Ignoring the relapse must be followed by adequate reinforcement when improvement resumes. Punishment should assiduously be avoided.

> 12. In the event resistance is obdurate and no progress occurs, explore frankly and openly the relationship with the patient. You as the therapist may very well look into your own feelings about the patient (countertransference) to see if you can perceive deleterious effects on the relationship.

There is, in my opinion, no reason why behavioral therapy cannot be practiced in a dynamic framework, although this may horrify some behavioral purists. Often dreams will reveal the nature of the resistance more readily than any other communication. Once the resistance is detected and explored, clarification or interpretation may turn the tide toward success in the behavioral effort.

A great deal of ingenuity is required to set up the design that will govern behavior therapy in a particular case. The treatment undergoes continued modifications in line with the observed behavioral change. Wide differences exist in the susceptibility of subjects to conditioning. However, the greater the quantum of anxiety, the more easily are conditioned responses established and the more difficult are these to extinguish. Generalized anxiety does not respond too well to behavior therapy unless it is possible to differentiate the conditioned stimuli that sponsor anxiety. It may be possible to break down anxiety or disturbed behavior into a number of phobic hierarchies and to deal with each hierarchy as a separate unit.

52
Techniques in Group, Family, and Marital Therapies

Group psychotherapy is a valuable and, in some cases, indispensable treatment method. Its historical development and uses in supportive, reeducative, and reconstructive approaches have been amply delineated and some of the important bibliography listed in the respective chapters. Group therapy may be employed both as an adjunctive aid to individual psychotherapy and as a treatment modality in its own right. There are some therapists who claim that not only are the results they obtain with groups equivalent to those of individual treatment, but in many cases even superior to it. Consequently, they dispense with individual therapy, except as an adjunct to a group approach. Other therapists, not so skilled in its use, tend to depreciate the effect and "depth" of group treatment. Among experienced therapists there is a feeling that combined or conjoint group and individual therapy is the treatment of choice. Problems show up in a group setting that never become apparent in a dyadic therapeutic relationship.

Evolving in a group are a number of processes that are intimately bound up with the outcome. Among the most important are the developing group cohesiveness and mutual assistance. What one finds evolving in the group are manifestations of empathy, support, challenge, confrontation, and interpretation; availability of identification models; opportunities for introducing projective identifications; investigative explorations; and a joint sharing of problems.

Needless to say, the specific way that the group is employed; its composition; the degree of activity or passivity of the therapist; the extent of the therapist's directiveness, maneuvers, and kinds of participation; the pursuits sanctioned within and outside the group; and the nature of interpretations will vary with the skill, experience, theoretical bias, and personality of the therapist. For example, some therapists assume an almost completely detached attitude on the assumption that this will dredge up the resentments

of the group members, in the wake of which basic inner conflicts will be exposed. Other therapists cast anonymity to the winds and virtually become participating patients in the group, acting-out as enthusiastically as any other member. Both methods in the opinion of their sponsors are promoted as the "best" and even "only way" to do group therapy. Actually, there is no "best" group method; this will vary with the predilections of the therapist. After blundering through a number of sessions, each therapist will settle down to a procedure that works best for him or her.

Group therapy may be utilized (1) independently, during which both intrapsychic and interpersonal operations are considered; (2) in combination with individual therapy conducted by the same therapist ("combined therapy")—individual sessions deal with the patient's resistances, transferential responses to the therapist, and primary separation anxiety, while group sessions focus chiefly on interpersonal phenomena; (3) in conjunction with individual therapy conducted by another therapist ("conjoint therapy"); and (4) as leaderless groups particularly after formal group therapy has ended (Kline, 1975).

Meetings in independent, combined, conjoint therapy may take place one or two times weekly and, in institutional settings, even daily. They may be supplemented with regularly scheduled meetings that are not attended by the therapist ("coordinated meetings")—the members may congregate before a regular session ("pre-meetings"), after a regular session ("post-meetings"), or at other times at specially designated places ("alternate meetings"). Coordinated meetings enable patients to discuss their feelings about the therapist more freely. They are generally less formal and more spontaneous than regular meetings. Acting-out is more than a casual possibility here, which may or may not prove to be beneficial to the patient. ("Closed groups" maintain a constant membership although new members may be added for special reasons. "Open groups" operate continuously with new members being added as regular members complete therapy and leave the group.)

Treatment in group therapy may be "therapist-centered," in which therapists take a

directive and more authoritarian role, moderating member-to-member communication, presenting interpretations, and limiting the patients' intragroup and extragroup activities ("triangular communication"). It may be "group-centered," in which the group operates as the primary authority, therapists functioning in a kind of consultative role. Here peer (sibling) and authority (parental) relationships are considered equally important; rotating leadership is encouraged; there is no interference with the relationships between patients ("circular communication"), which are constantly being broken, restored, and reorganized, the therapists controlling their anxiety about neurotic alliances; or "authority-denying" ("horizontal communication") may occur in which the therapists are on an equal plane with the patients, a structured relationship between therapists and patients being considered limiting to growth. In the latter case emotional interactions are considered most important; direct experience in the group is encouraged, therapists presenting their own problems to the group ("The group can grow if I grow with them.").

The group therapist, regardless of orientation, must be a good leader, requiring skills above and beyond those of a therapist.

How a therapist conducts a group will be determined

1. By the goals that the therapist sets—supportive, reeducative, or reconstructive.

2. By the constituent members—alcoholics, drug addicts, psychotics, stutterers, delinquents, psychoneurotics, character disorders, patients with heterogeneous problems.

3. By the therapist's training—group dynamics, rehabilitation, behavior therapy, cognitive therapy, existential therapy, psychodrama, psychoanalytically oriented psychotherapy, psychoanalysis.

4. By the therapist's personal ambitions and needs—characterologic and countertransferential.

INFLUENCES OF THE GROUP ON THE INDIVIDUAL

When people gather together in a group, phenomena are mobilized that may have an

influence on each individual. One of the effects is an immediate impression of strangeness and embarrassment. This soon gives way to a realization that others present are not too different from oneself in problems, weaknesses, and ways of relating. This encourages one to express oneself openly. The person soon discovers that the group fosters free expression of feelings or attitudes on any subject. There are no social taboos on content usually avoided in everyday interactions. The ability to open up varied forbidden topics, and the recognition that fellow members harbor the same fears and doubts, can be reassuring. Apart from the emotional catharsis experienced, the individual finds that problems can be shared with others without rejection or ridicule. Self-esteem and self-confidence are thereby enhanced. The individual begins to realize that he or she is not a reprehensible person deserving of blame or repudiation. The usual drives through which one achieves status and prestige may receive no sanction in the group. Indeed, they may be dealt with harshly or analyzed in terms of their neurotic components.

Humans are group creatures constantly looking to others for acceptance and validation of their own ideas. One of the most powerful molding influences in any group is the impact of group standards and values. These can have a markedly transforming influence on the personal persuasions by which individuals customarily govern themselves. A gradual incorporation of group convictions and judgments in a cohesive and developed group tends to neutralize self-oriented neurotic needs. The presence of the therapist acts as a safeguard against prevailing group values that are inappropriate. There is some validity in the belief that patients in a group may reinforce each other's rational reactions. This is because they collectively make up the norm from which they individually deviate. This is particularly true in a therapeutic group presided over by a therapist with healthy values; it is not so true in a group left to its own destiny, which so often will be diverted and taken over by a charismatic and power-driven member with qualities of leadership.

Group patterns evolve related to the roles members assume and the ways they perceive themselves; how and when they take over leadership; the specific motives assigned to them by other members; and the existing defensive maneuvers, such as

competitiveness, struggles for control, dominance, submissiveness, ingratiation, masochistic devices, aggressiveness, and violence. The fluctuating group interaction is influenced by levels of tension that affect participation, the sharing of ideas, and decision making. Arguments, the taking over of a session by a monopolizer, coming late, absenteeism, and the formation of subgroup clusters manifesting special likings and dislikings raise tensions that stimulate corrective action; however, if tension is too high, it will paralyze action. Extremes of harmony and congeniality will also tend to subdue activity.

A successful solution to an interpersonal problem enables the individual better to extend his success to relationships with people outside the group. It is to be expected that reactions to different members will selectively indulge a full range of prejudices. Displays of awe, infatuation, disgust, anger, hate, and sexual interest may be manifested toward members identified as archaic or vulgar or idealized models. Whereas these feelings are controlled and verbalizations related to them suppressed or repressed in the usual group setting; they are encouraged and even rewarded in the therapeutic group by approval from the therapist. The reactions of the person with whom one is immediately entangled presents opportunities to examine the reasonableness or unreasonableness of one's responses. The individual gradually learns to accept criticism and aggression without falling apart. This is a most crucial lesson; indeed soon recognized is the fact that aggression and criticism can be either proper or unjustified and that one can differentiate the two and manage responses accordingly.

The effect of interpretations from other group members may be striking. The individual begins to distinguish prejudiced opinions from factual ones, and may then generalize tolerance to the world at large. The fear of becoming violent and in turn being subject to physical attack and humiliation lessen. The group judgment is a moving force that cannot be resisted. Where a number of members share an opinion about an individual or behavior, the effect may be more intense than an interpretation by the therapist. As one patient put it: "If a person in a group calls you a horse, you have a right to be indignant. If a second person in the group calls you a horse, you have a right to be insulted. If a third

person in a group calls you a horse, you better look into yourself to see if you are acting like a horse." The group strengthens the individual's ability to express feelings toward the therapist, whether rational or irrational; one may be unable to do this during individual therapy.

One of the most important consequences of being in a group geared toward reconstructive goals is learning how emotional processes operate by observing how other members talk about and solve their problems. Dynamic thinking soon becomes a dominant mode in the group. Immediate symptoms are related to basic adaptational patterns. As these are traced to destructive past conditionings, resistance and transference may be mobilized and explored. In this way the patient begins to think more dynamically about himself or herself, the genetic origins of patterns, their manifestations in his or her present life, and the defensive maneuvers they inspire. Awareness of inner psychological operations is also sharpened through emotional involvements with other group members, through one's own spontaneous discoveries, and through interpretations from fellow members and the therapist. Instead of withdrawing, as in a usual life situation, the patient is encouraged to hold his or her ground and to express and analyze feelings and defenses. It is here that a psychotherapist trained in reconstructive therapy can make the greatest impact on the patient.

ADVANTAGES OF GROUP VERSUS INDIVIDUAL THERAPY

Group therapy has certain advantages over individual treatment. It is capable of registering deep impressions by virtue of the fact that the patient is exposed to the judgments of not one person, but a host of people. In individual therapy the patient soon learns how to cope with and to neutralize the influence of the therapist. It is much more difficult to do this in a group setting. Change is scored on different levels of the intrapsychic organization. This includes one's system of values, which is altered through percussion of disparate ideologies in the group. It is much easier for the individual to recast one's standards in a setting that is a reflection in miniature of the world than in the isolated confines of the dyadic therapeutic relationship.

Diversified intrapsychic defenses come out toward members of the group with whom the patient plays varying roles. Multiple transferences, both sequential and simultaneous, are readily established. The opportunity to relate in different ways to fellow members enables the individual to work through insights in the direction of change. Thus, if the patient finds it difficult to express him or herself aggressively or assertively, practice with the least threatening member may be in order. Thereafter there may be progressive challenge to others who are more threatening. In individual treatment the therapist may continue to be too powerful a figure to override. Moreover, even though the patient masters fear and guilt, he or she may find it difficult to transfer what has been learned during individual therapy to the environment outside the therapeutic setting.

Within the group the patient feels more protected, both by the therapist and by members with whom alliances have been formed, and he or she may be able to practice new attitudes more propitiously. For example, if Mary Smith has a problem in accepting any aggression and hostility that are directed toward her, the group will offer her the opportunity of exposure to these emotions in graduated doses. She will become more and more tolerant of the resentment extended toward her. She will learn to accept criticism— to reflect on it and to see whether it is justified or not—instead of reacting automatically with indignant or violent responses. Rigid character defenses often yield in group therapy as patients observe their ego-syntonic traits operating in others.

On the other hand, one advantage of individual therapy is that the focus is on the patient's personal problems, which often become diluted in a group setting. With so many other members of the group expressing themselves, it is not always possible for the patient to clarify significant feelings at the time he or she is experiencing them. Individual therapy enables the patient to look into the private world of fantasy and conflict and to explore intrapsychic mechanisms in greater depth. It permits a concentrated working through of past difficulties developed with parental authorities.

Outlining some of the benefits a patient may derive from group therapy, we may include (1) the opportunity to see that one is not alone in one's suffering and that

problems felt to be unique are shared by others; (2) the opportunity to break down one's detachment and tendencies to isolate oneself; (3) the opportunity to correct misconceptions in ideas about human behavior by listening to others and by exposing oneself to the group judgment; (4) the opportunity to observe dynamic processes in other people and to study one's own defenses in clear perspective in relation to a variety of critical situations that develop in the group; (5) the opportunity to modify personal destructive values and deviancies by conforming with the group norm; (6) the opportunity to relieve oneself of tension by expressing feelings and ideas to others openly; (7) the opportunity to gain insight into intrapsychic mechanisms and interpersonal processes, (particularly as multiple and split transferences develop), the group acting as a unit that replicates the family setting and sponsors reenactment of parental and sibling relationships; (8) the opportunity to observe one's reactions to competition and rivalry that are mobilized in the group; (9) the opportunity to learn and to accept constructive criticism; (10) the opportunity to express hostility and to absorb the reactions of others to one's hostility; (11) the opportunity to consume hostility from others and to gauge the reasonableness of one's reactions; (12) the opportunity to translate understanding into direct action and to receive help in resolving resistances to action; (13) the opportunity to gain support and reassurance from the other members when one's adaptive resources are at a breaking point; (14) the opportunity to help others which can be a rewarding experience in itself; (15) the opportunity to work through problems as they precipitate in relationship with others; (16) the opportunity to share difficulties with fellow members; (17) the opportunity to break down social fears and barriers; (18) the opportunity to learn to respect the rights and feelings of others, as well as to stand up to others when necessary; (19) the opportunity to develop new interests and make new friends; (20) the opportunity to perceive one's self-image by seeing a reflection of oneself in other people; (21) the opportunity to develop an affinity with others, with the group supplying identification-models; (22) the opportunity to relate unambivalently and to give as well as to receive; (23) the opportunity to enter into productive social relationships, the group acting as a bridge to the world.

ORGANIZING A GROUP

In organizing a group the therapist will be limited by the patients available. Nevertheless, one should choose patients who are sufficiently advanced in their understanding of themselves to be able to perceive their patterns as they will appear in the group setting. While the clinical diagnosis is not too important, experience shows that the following conditions and patients do poorly in a group; except perhaps when implemented by an experienced group therapist in a homogeneous group within an inpatient setup through supportive or reeducative group methods.

1. Psychopathic personalities and those with poor impulse control

2. Acute depressions and suicidal risks

3. Stutterers

4. True alcoholics

5. Hallucinating patients and those out of contact with reality

6. Patients with marked paranoidal tendencies

7. Hypomanics

8. Patients with a low intelligence

The age difference should preferably not exceed 20 years. Homogeneity in educational background and intelligence is desirable but not imperative. A well-balanced group often contains an "oral-dependent," a "schizoid-withdrawn," a "rigid-compulsive," and perhaps a "provocative" patient, such as one who is in a chronic anxiety state. This variety permits the members to observe a wide assortment of defense mechanisms and to experience tensions they might otherwise evade.

The number of group members may range optimally from 6 to 10. If a therapist feels uncomfortable with a large group, then the size of the group should be reduced. Marital status is relatively unimportant. A balance of males and females in the group allows for an opportunity to project and to experience feelings in relation to both sexes, although acting-out is more likely in a mixed group.

A heterogeneous group in terms of age, sex, and syndrome is most effective for reconstructive goals. A homogeneous group, composed of patients with the same problem, is best for alcoholism, substance abuse, obesity, smoking, sexual problems, insomnia, phobias, depression, delinquency, stuttering, criminality, marital problems, divorce, and geriatric problems, although an occasional person with such problems may do well with and stimulate activity in a hetergeneous group. The goals are both supportive and reeducative. Severely handicapped persons, such as paraplegics, women who have had mastectomies, patients undergoing renal dialyses, and laryngectomized patients, feel unrelated to the norm and do better in homogeneous groups. Adolescents seem to be more responsive in same-sex, same-age groups.

In introducing the matter of group therapy to a prospective member the therapist may explain that a group is being organized for purposes of treatment. Talking over problems or ideas in a group tends to expedite getting well. The patient may then be invited to join with the statement that perhaps a group may facilitate his or her progress. This, if the patient is in individual treatment, may be presented as a "promotion."

One of the problems that plagues neurotic individuals is the loss of a sense of group belongingness. To an extent, it is because they devalue themselves and feel rejected by others; partly it is because they anticipate that their own hostility will be reciprocated. As a consequence of this isolation, they lose identity with people and thus are robbed of a vital source of security. When a suggestion is made that they enter a group, they may imagine that their worst fears will come to pass. They will then pose a number of questions that usually reflect their resistance, and#the therapist will be obliged to answer them.

The following are common questions and suggested replies:

Q. How can other mixed-up people like myself help me?

A. People in a group actually do help each other. They become extremely sensitive and perceptive about problems, and they often may be of considerable service to other members. In the group the person has an opportunity to

observe how he or she interacts and to witness the nature of reactions to one. The therapist is present during the sessions to see that it goes along well. It's normal to feel some anxiety the first few sessions which provide "grist for the mill."

Q. I would be ashamed to bring up my problems to a group of people I don't know.

A. This is understandable. It is not necessary for you to divulge anything you do not wish to talk about. [*Actually this reassurance does not retard the patient from divulging the most intimate problems readily as soon as he or she begins to articulate.*] Without your permission I shall not bring up anything about you or your problems. This is up to you. Most people fear not being able to talk in a group. In reality, being with a group with whom you can be yourself is consoling, not frightening.

Q. What am I supposed to do in the group?

A. There is no need for you to do anything special. You may talk or you may remain silent as you wish. Generally one is not as embarrassed as one would imagine.

Q. Won't these people reveal things about each other outside the group?

A. One of the rules is that no mutual confidences are to be revealed to outsiders. Should this happen (and it rarely does), the person is dropped from the group.

Q. Supposing I meet someone in the group I know?

A. When it happens, it may actually prove to be an advantage. Any problems between two people who know each other can often be worked out.

Q. Won't the problems of the other people rub off on me?

A. Without any reservation I can say, "no." On the contrary, you may gain a great deal from observing how other people face and resolve their troubles. It can be a great educational experience for you.

Q. Do I continue seeing you individually?

A. Generally yes, but we will decide how frequently. Sometimes I may want you to try the group alone, but if that comes up, we can talk about it.

Q. Can I raise any issues I want in the group, even about you?

A. Unless you do, you will not get as much benefit out of the group as you might. It is important to talk about your feelings and ideas in relation to yourself, to outside people, to the group members, and to me. That is, if you wish to do so.

Q. Supposing my feelings are unreasonable?

A. This is why the group is of such value. In life there is very little opportunity to examine the reasonableness or unreasonableness of one's attitudes and responses. The group offers you an opportunity to test your assumptions. In the protected setting of the group a person can express one's ideas and emotions.

The length of a group therapy session is approximately *H* to 2 hours. The frequency of meetings is one to two sessions weekly, with alternate sessions once weekly if desired. The best seating arrangement is in a circle.

There are many advantages in employing cotherapists in a group, provided that problems between them do not prevent their working together. The literature on the subject of cotherapy and the difficulties that can occur between cotherapists that can sabotage their usefulness and destroy the group process are pointed out by J. B. Strauss (1975). Her own study deals with the results of a questionnaire that explores the ways therapists conceptualize their problems and how they try to cope with them. A most interesting finding was the difference of role perceptions of male and female therapists. Many problems can be overcome if the cotherapists meet periodically together with a supervisor whom both respect.

THE OPENING SESSIONS

At the first session the members are introduced by their first names, and the purpose of group discussions is clarified. This will vary with different therapists and different groups. Advanced patients will already have worked through some of their individual resistances in their sessions alone with the therapist. Newer patients may need

more explanations in the group setting. The more passive-dependent the patient, the more leadership will be demanded of the therapist. The technique employed during the opening session will be determined by the therapist's orientation and level of anxiety. Many therapists who use the group as an adjunct may assume a very passive role so as to elicit spontaneous reactions from different members for use in later individuals sessions.

Some therapists begin by simply stating that the group offers members an opportunity to talk about their feelings and eventually to understand their individual patterns. It is not necessary for the members to feel compelled to reveal something that they want to keep to themselves. However, communicating freely will help them to get a better grip on their problems. For instance, each member must have had certain definite feelings about entering the group; he or she may have been embarrassed, upset, or fearful. The therapist may then attempt to elicit these emotions, and, as one member expresses freely, others will join in, leading to a general airing of difficulties shared by all.

Before the close of the first session, some therapists find it advisable to stress the confidential nature of the meetings and to caution that each member is expected not to reveal to others the identity of the members and the subject matter discussed in the group. While no member will have to divulge secrets before he or she is ready, each will be encouraged to relate any incidents involving accidental or planned contacts with other members of the group outside of the sessions. Therapists who strongly believe that acting-out is deleterious will, in all probability, discourage any contact outside of the group. Sexual involvements may be forestalled by fostering verbalization of the patients' feelings and impulses toward each other. Usually the anxiety level drops markedly at the end of the first session, but rises temporarily at the outset of the second session.

During the early stages of treatment some therapists who are anxious to prevent acting-out at any cost will, at first, assume a despotic role that contrasts sharply with their role in individual sessions. Parenthetically, this may lead to more acting-out. They may try to keep patients from exposing painful revelations before the group is ready to support them. On the other hand, free verbal interaction may be encouraged in the group in order

to bring out each member's customary facades and defenses.

Later in the course of therapy authority is shared by various members, who are, from time to time, "elevated" and "dethroned" by the group according to its needs. Often individual members in their temporary authority posts may initiate ways of eliciting meaningful material. This may take the form of giving each person an opportunity to express him or herself at each session, or there may be a much more informal arrangement with the members spontaneously expressing what is on their minds at the moment. Actually, by the time emotions are beginning to flow freely within the group, there is no further need for procedural structuring; indeed, this should not be rigidly controlled at any time. The content of discussions will vary greatly, covering current incidents of importance in the lives of each member, dreams, attitudes toward others in the group or toward the therapist, and general areas, such as family relations, sex, dependency, and competition.

In previous chapters, principles of supportive and reeducative group therapy have been described. In this chapter, principles of group psychotherapy oriented around reconstructive goals are considered. In addition, behavior, experiential, transactional analytic, psychodramatic and role playing, family, and marital (couple) interventions are considered.

LATER SESSIONS

Ezriel (1973) believed that principles of classical individual psychoanalysis could be advantageously adapted to group therapy. Essentially mechanisms of the unconscious are uncovered and their meaning explicated through interpretation. The core of the neurotic process are unconscious need structures that constantly strive for satisfaction through transference reactions and that are dynamically related to resistances. "Here-and-now interpretations" of transference maneuvers with group members does not preclude examination of extratransference projections toward persons outside of the group. However, the therapists must be constantly on the alert for covert transference manifestations that relate directly to them but are being diluted by references to others.

Interpretation of transference with the therapist ("the required relationship") brings the patient closer to behavior patterns that the patient has been repudiating ("the avoided relationship") and permits reality testing that can demonstrate that anticipated calamities will not come to pass. Often such experiences enable the patient to make a connection between contemporary life and unresolved infantile conflicts. Unconscious common group tensions lead to the development of a group structure within which each member seeks to express transference needs. The therapist can advantageously analyze the structure of the group as it displays itself in a particular session and designate the roles played by the different members, thus delineating the defense mechanisms displayed by the individual members. Interpretation can thus be both individual-centered and group-centered; ideally the focus is on the two during each session. All activity in the group, as in classical individual analysis, other than interpretation must be assiduously avoided to prevent gratification of transference needs, which, while momentarily tension relieving, keeps basic conflicts alive.

Other authorities, especially in the United States, insist that the classical model is too limiting and introduce many modifications and active maneuvers such as the structural interventions of Minuchin (1974b). A dynamic viewpoint, nevertheless, is desirable even if nonanalytic methods are employed. It is essential, however, always to attune therapy to the presenting complaints. Where this is not done, one can expect poor results.

As the group becomes integrated and develops an "ego" of its own, members feel free to air intimate vexations. The patient gains more insight into personal difficulties recognizing that many troubles previously believed unique have a common base. The therapist should, therefore, direct energies toward stimulating thinking around universally shared problems, getting responses from other group members even though the subject under consideration is out of the ordinary. The patients may be asked to talk about personal impressions of the role the therapist is playing in the group. Thereafter the group is asked to discuss the verity of each patient's assumptions.

As Grotjahn (1973) has pointed out transference is a most important element of the

group experience. He describes three trends in transference: (1) transference to the therapist and central figure (e.g., paternal figure), (2) transference to peers (e.g., sibling), and (3) transference to the group itself (e.g., pregenital mother symbol). These different transference relationships are always present simultaneously, patients treating the group as if it were their own family. In working through transference and defenses dreams are advantageously utilized; but they are utilized in a somewhat different manner than in individual therapy, the group members and the therapist associating directly to the dream especially focusing on the thoughts and feelings it evokes in themselves, without waiting for the associations of the dreamer. In this way the dream becomes a part of group experience. Sometimes the therapist's reactions to a group member may be perceived correctly by a third member and interpreted.

Many therapists practicing individual psychoanalysis contend that group therapy waters down transference reactions, minimizes regressive reactions, and neutralizes emergence of a genuine transference neurosis. Character changes in depth are, therefore, circumvented. Durkin and Glatzer (1973) have elaborated on how a constant focus on process rather than content and how selective exploration of origins of defensive behavior during group therapy can effectively bring forth pre-oedipal as well as oedipal conflicts. Systematic analysis of intragroup transferences may act as a vehicle for successful transference interpretations and can lead to reconstructive personality changes of a deep and enduring nature.

Of vital importance is the opportunity for the development of multiple transferences during which varying members of the group function as vehicles for the projection of feelings, attitudes, and relationships with important persons in the individual's past existence. Of significance, too, is the fact that the group situation allows for "split transferences"—for example, projection of a "good" mother image on one member (or the therapist or the group as a whole) and of a "bad" image on another.

The basic rule in a group setting is for members individually to express themselves as freely and without restraint as possible. This encourages the disclosure of forbidden or

fearsome ideas and impulses without threat of rejection or punishment. The patterns of some individual members usually irritate and upset others in the group, mobilizing tension and stimulating appropriate and inappropriate responses. The monopolizing of most of the session's time and competitiveness for the therapist's attention bring about rapid responses from the other members. Many patients will react to a trait in a member that they despise in themselves, even though they may not be immediately aware of possessing that trait.

Some therapists work even at the start on group resistance. For example, they may believe that mobilization and release of hostility is essential toward the development of positive and cooperative attitudes. The activity they engage in, therefore, is designed to stir up hostility and to facilitate hostile verbalizations. Other therapists try to facilitate the activity of the members as "adjunct therapists." The interactional processes virtually do put the various group members in the role of cotherapists. Under the guidance of the therapist this role can be enhanced. The specific effect of member "cotherapists" may be analytic or it may be more supportive, encouraging, accepting, and empathic, thus providing an important dimension to supplement the work of the therapist. One way to enhance cotherapeutic participation is, even at the start, to analyze motivations of one or more members to stimulate curiosity and communication. The members are invited to put themselves into the place of a member chosen for focus, e.g., to imagine dreaming the same dream as the member and to interpret the meaning.

A patient finds it easier to examine the inner feelings that have been repudiated when sensing that the group and the therapist are supportive. If expressed feelings seem to elicit a sympathetic response from other members, the ensuing discussion often leads to a lifting of tension and a sharpening awareness of the patient's neurotic patterns. In the kaleidoscopic illuminations of the group each person's vision is broadened by taking advantage of the opportunity to observe and study his or her own and other members' reactions within the group—e.g., manifestations of hostility, fear, suspicion, or sexual feeling—and to relate them to the basic character structure. In this context the difficulties and antagonisms among members may, through analysis of the operative projections, lead

to a constructive solution.

Among the therapist's activities are clarifying, structuring, focusing, timing, interpreting individual and group resistances, encouraging group interaction, and clarifying group interrelations. The therapist's ability to accept hostility and criticism from one member paves the way for other members to engage in verbalizing and a working through of their own hostile emotions.

Reactions of the patient occur in complex clusters as a release of feeling within the group is accelerated. Lack of restraint in one group member often results in a similar lack of restraint in the others. A climate that tends to remove repression enables the patient to work toward a better understanding of inner conflicts.

The matter of alternate sessions calls for special attention. Although it is regarded by some as a sanctioned vehicle for acting-out, experience shows that it can provide opportunities for free interaction, testing, and exploring. It enables some patients to speak more freely about their feelings about the therapist and thereby to consolidate their separation from parental authority. It is essential, however, that activities at alternate sessions or elsewhere involving group members with each other be reported at the regular group sessions. Acting-out members should be seen also in individual therapy.

TECHNICAL OPERATIONS OF THE GROUP THERAPIST

The role of the group leader is to catalyze participation of the various members, to maintain an adequate level of tension, to promote decision making and problem solving, to encourage identifications, to foster an interest in the goals to be achieved, and to resolve competitiveness, resentments, and other defenses that block activity. Groups have a tendency to develop many resistances; for instance, the members form cliques, they come late, they socialize too much, they get frozen into interlocking roles. The therapist has a responsibility to deal with these overt obstructions, as well as with those that are more concealed and come through in acts like passivity, detachment, and ingratiation. The group interactions will permit the therapist to witness how individuals function with

others, their enmities, and their alliances.

How the leader communicates to the group will vary with the orientation and personal idiosyncrasies of the leader. Some leaders are mercilessly authoritarian, and they take over firm control, directing the various activities with despotic regulation. Others are so passive that they scarcely make their presence known. There are therapists who conceive of their role as a benevolent authority who grace their subjects with kindly guidance. There are those who insist the the function of the leader is to liberate the affects of patients that cause their paralysis as people. This, they believe, is accomplished best not by interpretation, but by establishing meaningful, deep relationships. Accordingly, a therapist must avoid setting up as a paradigm of health or virtue, one who is falsely objective, which may be merely a cover for the therapist's omnipotence. Some therapists contend that there is no reason why the therapist cannot reveal weaknesses and grow with patients, relating to their strengths. Experience convinces, however, that most therapists will do best in group therapy if they function with some discipline and if they sensitize themselves for counter-transference manifestations, which are more easy to elicit and more difficult to control in a group than in an individual setting since they too may unconsciously experience the group as their personal family. This does not mean that one must keep oneself in a straitjacket and not react to provocations. Expression of anger toward the group when this is justified, without threatening recriminations, may be exactly what the group needs.

There is always a temptation in group therapy to allow the group to indulge in social chatter, in endless mutual analysis, and in the recounting of dreams and personal experiences at length. This interferes with proper interaction in the group. The therapist must constantly remind the members that they are not there to act as professional psychoanalysts, attempting to figure out dynamics and to expound on theory. The best use of their time is in exploring their own immediate reactions. The principle activity of the therapist will be to resolve resistances to talking about feelings regarding one another and to try to break up fixed role behavior patterns.

The specific communicative media will also vary with the training of the therapist and the goals in treatment. A recounting of dreams, and particularly recurrent dreams and nightmares, may be activated by most analytically oriented therapists, as may the reporting of fantasies and daydreams. Interpersonal interaction may be facilitated by encouraging the free association of each patient about the others in what Alexander Wolf (1950) has called "going around." Patients are enjoined to recite whatever comes to their minds about their fellow members, whether logical or not. Free association about the therapist is also invited. Interpretation is an instrumentality considered essential for the proper working-through of pathogenic conflicts.

Other therapist activities include

1. Focusing the conversational theme around pertinent subjects when topics become irrelevant.

2. Creating tension by asking questions and pointing out interactions when there is a slackening of activity in the group.

3. Posing pointed questions to facilitate participation.

4. Dealing with individual and group resistances.

5. Supporting upset members.

6. Encouraging withdrawn members to talk.

7. Interfering with hostile pairings who upset the group with their quarreling.

8. Reminding the group that communication about and understanding of mutual relationships is more important than interpreting dynamics.

9. Managing silence, which tends to mobilize tension in the group.

Role playing and psychodrama may be introduced periodically. They have advantages and liabilities, as may touching (Spotnitz, 1972).

An important aspect of the therapist's function in the group is that of gauging and

regulating group tension and anxiety. It is well known that some degree of anxiety is one of the moving forces in therapy facilitating growth and change. But anxiety can also be disorganizing—if too much of it is aroused, the group cannot function; there is low cohesiveness, and dropouts occur. It is up to the therapist to step in and deal with excessive tension and maintain not a minimal level of tension, but an optimal one. If too little tension exists, a "dead" session may be resuscitated by requesting that the members "go around" associating freely about each other. A group that has settled into pallid social interchanges may also be revived by introducing a new active, disturbed member.

Perhaps the main task of the therapist is to detect resistances of the group as a whole as well as of the individual members. The dealing with resistance will depend on its manifestations and functions. The question is sometimes asked, "Should one share one's feelings with one's patients and act as a 'real' person rather than as a detached observer?" This depends on how it is done and the kind of relationship that the therapist has with the patients. To bring out one's *serious neurotic problems* may destroy the confidence of some group members in the therapist's capacity for objectivity, as well as the ability to help them, and the impair effectiveness of the therapeutic process. On the other hand, to share *feelings and reactions* will reveal the therapist as more human and less omniscient and give the patients confidence to talk more openly about their own anxieties.

As has been mentioned, a huge variety of resistances precipitate out in group therapy. Their dissolution has resulted in many innovative techniques. In a humanistic contribution Livingston (1975) describes two major forms of resistance that block progress in group therapy: contempt and masochism (sadomasochism). These defenses may, through the assumption of a special role on the part of the leader, be broken through in what the author calls the "vulnerable moment." During such intervals a patient allows himself or herself to be open and honest, and through a constructive sharing of an experience with the group and therapist, the patient may score substantial reconstructive gains. Describing how awareness of such readiness for change came about in his own group therapy as a patient, Livingston suggests techniques, some derived from Gestalt therapy, that may facilitate the working-through process.

A particularly insidious and masked form of resistance is acting-out. The initial reaction to a therapeutic group experience is generally a profoundly inspiring one. A good deal of the reaction is marshalled by hope, the patient projecting wishes to be accepted, understood, and loved without qualification. While defenses continue to operate, these are softened by the emotional catharsis that is experienced in verbalizing to strangers and by an idealization that projects onto them. Sooner or later he or she plummets back to the original defensive baseline as the patient discovers flaws in the idealized images of the group, as criticisms, challenges, and attacks justifiably and unjustifiably are leveled at him or her; and as multiple transference reactions come forth that, unfoundedly, make the group a facsimile of the patient's original family, with some members even sicker than those of the patient's own family. Frustration, disappointment, and even despair are apt to dominate responses, and acting-out may then occur verbally and behaviorally.

In groups conducted by unsophisticated therapists the acting-out dimension may be openly encouraged, the patients being helped or goaded into unrestrained speech and behavior without relating personal responses to underlying motivations. The temporary relief of tension and the pseudo-assertive expostulations are confused with cure. Follow-up almost invariably demonstrates how futile are the results. Many of the members become welded into reciprocal sadomasochistic alliances, and therapy becomes interminable. Others find excuses to leave the group.

The ability of the therapist to establish and to maintain proper communication is the principal means of averting this therapeutic impasse. A. Wolf (1975) illustrates how a therapist may utilize his or her own personality characteristics, for example, solicitude, capacity for healthy engagement, self-discipline, and sheer human decency, to resolve resistances and to enhance interaction. He refers to methods employed by Asya Kadis, which tend to encourage working through rather than acting-out and help foster character restructuring.

The control of acting-out requires a differentiation of acting-out behavior from impulsive and compulsive acts (Spotnitz, 1973). It is generally agreed that there is a

greater tendency toward acting-out in group therapy than in individual treatment. A primary function of acting-out, according to Spotnitz, is to avoid experiencing unpleasant emotions, often of preverbal origin, that cannot be tolerated. Action becomes tension alleviating. It often conveys information in a dramatic form to the effect that the individual is unable to verbalize freely. More constructively, it may serve as a means of attempting to master traumatic events, and it may actually help prevent the outbreak of psychosomatic illness or psychosis by discharging tension. However, the validity of acting-out is always justifiably challenged unless it results in reality testing or enables a patient to master a tendency toward resistive emotional action. Under these circumstances the patient's actions may be considered constructive and in some instances even maturational. If, on the other hand, investigation reveals that emotional action serves as a resistance to communication, it must be therapeutically handled as a form of resistance. Particularly damaging are actions that are destructive to the continuity of the group or to any of its members. Inadequate communication of understanding on the part of the therapist and failure to meet the patient's emotional needs may be responsible for acting-out, which may then take the form of the patient dropping out of the group. Awareness of this contingency may help the therapist deal with such behavior at its inception.

Another type of resistance is encountered on the part of members who refuse to participate in the treatment process. Innovative therapeutic approaches here may cut through the defensive system through the use of videotape recording and playback. R. L. Beck et al. (1975) describe such a program in which dance movement therapy is employed to demonstrate how incongruence between verbal and behavioral communication as a form of resistance may be resolved. Success may sometimes be scored through this approach (whereas traditional therapeutic modes are ineffective) and can lead to a more constructive use of verbal psychotherapy.

Special patients and syndromes may also require innovative methods. The unique personality needs and defenses of adolescents (for example, their lability of affect, their struggle for identity) require an atypical format in the conduct of group psychotherapy. There are differences in respect to activity, depth and content of discussion, and roles

taken within the group. Adolescents bring into the group (which influences its Gestalt) the rapidly shifting values of the contemporary social scene and their distinctive reactions to delights and horrors of our modern technological era. Their reactions differ from those of their parents, who were subjected to a different type of social conditioning. Moreover, the ease with which runaways may survive away from home in a commune and participation in the drug culture that surrounds them must be taken into account in any group psychotherapeutic plan. Kraft and Vick (1973) present an approach that acknowledges the pressing need in adolescents for expressions of their identity and creativeness by introducing into the group psychodramatic techniques and artistic activities, such as dance or movement, music, poetry, and various visual stimuli and by employing where indicated auxiliary therapists. Major conflicts of adolescents worked through in the group included individual excessive competitive behavior versus withdrawal tendencies, inadequate outlets for emotional expression versus emotional blocking, growing up toward individual responsibility versus dependency, and self-identification versus expected role assumption and various breakdowns in defensive operations. This type of group, according to the authors, provides a growth experience for the members, results being reflected in enhanced school performance, better peer relationships, and a general strengthening of ego functioning.

Riess (1973) describes in the conduct of a group of adolescents, or family of the adolescent, a structured "consensus technique" that he believes is ideally suited for diagnostic and therapeutic purposes. In this technique a problem situation in written or oral form is presented to each member who writes out what would be the appropriate outcome or way of action. The members then discuss the "solutions" and are given a limited time to come to a unanimous decision. In the course of the ensuing interactions, individual styles, reactions, and defenses become apparent and relationship problems emerge. The results may be utilized diagnostically. By mobilizing conflict and anxiety, defensive operations precipitate out rapidly, and where the therapist is trained dynamically to deal with defenses, therapy may become catalyzed.

One of the poignant problems of the group therapist is how to deal with "difficult"

borderline patients, that is, those who do not respond to the usual tactics or maneuvers during the group session, who are extraordinarily self-involved, sensitive, dissatisfied, and angry. Their impact on the group may be intense and not always constructive, since they attempt to destroy, to monopolize, and to provoke counteraggression from other members. Moreover, they engage in struggles with the group leader that can be disturbing to the latter, to say the least. Pines (1975) has described the dynamics of the "difficult" patient, employing some of the ideas of Foulkes, Kohut, and Kernberg. He makes some useful suggestions on how to manage their reactions and resistances.

Efforts to expedite group therapy and catalyze movement have resulted in therapists' evolving their own unique techniques. Thus, Vassiliou and Vassiliou (1974) employ a transactional method "synallactic collective image technique," which actualizes psychodynamic concepts within the framework of general systems theory. Utilizing artistic creations made by group members (free paintings, doodlings, or scribblings), the participants choose, through majority vote, one creation around which discussion is organized. In this way the members "talk" to each other through a common stimulus. Gradually, as different projections evolve, communalities are compared and a "collective image" of the group emerges that revolves around a central theme with individual variations. Throughout, the therapist operates actively in a key "catalytic regulatory" role, participating continuously in the group transaction.

Encounter and marathon techniques are capable, through the intense emotional atmosphere that they create, of cutting through defenses and rapidly reaching repressed feelings and impulses rarely accessible through the use of conventional techniques. However, such active procedures are unfortunately utilized by therapists as a means of dealing with their own countertransference. Thus, the sessions may be employed as an outlet for the therapist's hostility, boredom, need for social and physical contact, desire for dramatic "instant insights," and solution of professional and personal identity conflicts. The avoidance by encounter therapists of traditional concepts and practices, such as the analysis of countertransference, is a great liability and accounts for the bulk of negative therapeutic reactions and treatment failures. A. W. Rachman (1975) points out the

importance of countertransference analysis and suggests methods of examining countertransference.

Corsini (1973) describes a "behind-the-back" (BTB) technique that may serve a useful purpose for groups of people. The problem in ordinary group therapy is that people find it hard to be honest with one another to their faces. The BTB technique is a stylized and formalized procedure that requires a minimum amount of time on the part of the therapist and is one that a suitable group may utilize. Members of the group are prepared by informing them that the method is designed to help express oneself to others and to learn what others really think of one. They are then asked to volunteer their participation as both patients and therapists. Each member in the present and following sessions is given a half hour to tell his or her story without interruption. At the end of this time the involved patient is requested to sit with his back to the group while each member talks about the "absent" member. This requires 20 to 40 minutes. The absent member is asked to face the group again while the therapist briefly summarizes what has been said. The patient is given about 5 minutes to make a rebuttal, responses being studied by the therapist in terms of denials, agreements, evasions, and other defenses. Then the patient sits in the center of the group exposed to the interrogation of the group. The therapist may interrupt these questions and terminate the session by sending the patient out of the room should emotions become too violent. It is to be expected that the patient will be upset by his inquisition, but this very turmoil causes the patient to unfreeze, better to face up to problems, realizing how he or she impresses others. At the very next session the patient is asked to summarize the meaning of the past session. The BTB technique is planned to facilitate the release of emotions and to expedite change through altered behavior.

It is sometimes propitious, in the opinion of some therapists, once a dynamic understanding of a patient's emotional problems becomes clear, to expedite change through arranging an appropriate scenario that encourages the patient to act out conflicts in a controlled way. E. E. Mintz

(1974) presents a number of such episodes from her experience with marathon groups. The procedures employed, some of which draw from psychodramatic and Gestalt therapeutic techniques, are bounded only by the imagination and dramatic proclivities of the group leader and participant members. Patients who are vulnerable or resistant to "interpretations" in individual sessions are often, with this technique, better capable of cutting into core problems and facing their difficulties. Moreover, the process stimulates the other group members to open up many personal painful areas for discussion.

Bach (1974) utilizes and describes a technique of aggressive therapeutic group leadership through participating actively in fights that occur between members of marathon groups. He considers neutrality and passive objectivity, the preferred stance of psychoanalysis, a form of alienation and not caring, which violates the intimate participative spirit of the marathon experience. The therapist "attacks" by frank verbal explosions and expressions of frustration, irritation, and indignation justified by what is happening in the group. Such actions may be leveled at a passive cotherapist who refuses to participate actively in the group work, at a whole group of "ground-rule" violators (e.g., people who avoid confronting each other with their feelings), at subgroups (e.g., those who hide in a cozy, pairing maneuver), and at individual members who manifest patterns that interfere with the group experience (e.g., monopolizing, controlling, etc.). Bach provides amusing examples of his "attack therapy," which, though seemingly countertransferentially inspired at times, appear, according to his accounts, to result in a more intimate, experience-sharing communion among the members. He expresses his philosophy of therapy in this way: "We must all relearn how to fight to regain our genuineness. Only after this are we ready to share love."

C. Goldberg (1975), on the other hand, stresses an existential stance and believes that patients can be actively taught skills in interpersonal relationships that can mediate their own and others' loneliness and despair, and which can probe ubiquitous alienation and existential exhaustion. Toward this end, the group leader actively participates in the group through openness, self-disclosures, display of congruence of feeling, and modeling of behavior. There is a minimization of verbal and nonactive interaction. Interpersonal

skills are actively taught through such methods as a deciphering of nonverbal "body language," a listing and checking of one's irrational attitudes and an exposure of one's manipulations and defenses in order to influence situations outside the group and to revise strategies and core attitudes.

Many other group interventions have been described and are contained in the annual overview of group therapy by Wolberg & Schwartz (1973) and Wolberg & Aronson (1974-1983).

<center>SPECIAL PROBLEMS</center>

It can be seen from the previous discussion that some group therapists develop their unique techniques and ways of looking at group phenomena that, while valid for them, may not be sound, plausible, or found useful by every psychotherapist. Experimenting with these procedures and ideas, however, will reveal their value.

The mangement by the therapist of special problems among patients will be essential where they obstruct group interaction. The following are some of these.

The Silent Patient

Behind silence may lurk a variety of dynamisms. Sometimes detached, withdrawn persons may be drawn out by the therapist's asking them a pointed question in relation to what is currently going on in the group: "How do *you* feel about this?" Since the response will be hesitant and unsure, more aggressive patients may attempt to interrupt to take the floor over for themselves. The therapist may block this subterfuge and continue to encourage the reluctant patient to articulate. The patient may also be asked directly to report on any dreams. Sometimes it helps to allot a certain amount of time to each member, say, 5 minutes.

The Monopolizer

The person who attempts to monopolize the session may be manifesting a power

struggle with the therapist or a masochistic maneuver to bring on the wrath of the therapist and other group members. The aggressive, narcissistic patient who insists on dominating the session will usually be interrupted by one or more members who resent this takeover. Where this does not occur, the therapist may halt the patient by asking another member what he or she is thinking about or by directing a question at the group as to whether they want the monopolizing patient to carry on all the discussion. The same tactics may apply to an interacting pair who interminably carry on a discussion between themselves.

The Quarreling Dyad

A manifestation of unresolved sibling or parental rivalry is two patients who constantly engage in verbal dogfights. This eventually becomes boring for the rest of the group and may sponsor a withdrawal into fantasy. The best way to deal with this phenomenon is by working toward each participant's tracing of the transferential roots of the enmity in order to recognize how both are projecting unconscious aspects of themselves on each other. This should not be too difficult from their dreams and associations. An interruption by the therapist of uncontrollable outbreaks of bickering is, of course, in order.

Acting-out Patients

Because groups are action oriented, because multiple transferences are set loose, because individuals other than the therapist are available for the discharge of erotic or hostile impulses, because not enough opportunity is given each patient to verbalize, and because upsetting revelations on the part of the group members may set off identical problems in a patient, acting-out can be a disturbing phenomenon in groups. The therapist may caution the members to talk out rather than to act out. The group members may be required to report at a regular session the activities engaged in between members outside the group. The therapist may try to reduce the anxiety level of the group. It is possible that the therapist's own countertransference is encouraging the acting-out. One should be constantly on guard for this. It may be necessary to reorganize the group when too many

acting-out members are present. The therapist may insist on acting-out members being simultaneously in individual therapy.

The Private Session in the Group

Some patients will attempt to utilize the group time to get a private session with the therapist. They will look at and direct their conversation to the therapist, ignoring the presence of the group. This reaction is especially common in a patient who was an only child in the family of origin or who wants to be the preferred sibling. When this happens, the therapist may ask the patient to focus remarks on the group, may question the group as to how they feel about the patient's carrying on an intimate discussion with the therapist, may ask other members to associate to the patient's verbalizations, and finally, may suggest that the patient come in for a private session.

The Habitual Latecomer

Drifting into the session after it is under way will mobilize resentment among the members, particularly where it is repetitive. This resistance should be handled as a special problem, requesting the patient to try to understand what is behind this neglectful conduct. The latecomer ultimately may be threatened with removal from the group if he or she does not come on time. This may bring to the surface the resentment toward the group that is expressed in this symptom. The group members should be encouraged to deal with this problem, not just the therapist.

The Patient Who Insists that He or She Is Getting Worse not Better

There are patients who display a negative therapeutic reaction that they are only too eager to communicate to the group. Dependent patients who have been in the group for years, and who cling to it for emotional sustenance, usually join in to complain regarding the ineffectuality of therapy. This can influence the group morale and may be disturbing, especially to new members. The therapist may handle such a reaction by nondefensively citing examples from the progress made by various members of the group to disprove the

thesis that therapy does not help and, where applicable, may point out the aim of the complainant to drive certain members (especially new members) out of the group.

The Accessory Therapist

A variety of mechanisms operate in the patient who is trying to replace the therapist. It may be a protest on the part of a dependent patient to the therapist's passivity. It may be an attempt to undermine the authority of the therapist. It may be a way of seeking favor with the therapist. It may be a gesture to compete with and replace the therapist. Irrespective of its basis, the patient may soon gather about him a group of followers as well as adversaries. The best way to handle this maneuver is to ask the other members what they think is happening, until the therapeutic pretender quiets down. The therapist may also ask the competing patient why he or she feels obliged to "play psychoanalyst."

Mobilizing Activity

Where progress has bogged down and members seem to be in a stalemate, one may stir up activity by (1) asking the group why this is so, (2) introducing psychodrama or role playing, (3) asking a member to talk about the role assumed in the group, then going around the group requesting the other members to comment, (4) asking each member to talk about feelings concerning the two people on either side of him or her, (5) utilizing one or more techniques of encounter or Gestalt therapy, (6) extending the length of a session up to the extent of a marathon session, (7) introducing several new members into the group, (8) determining the nature of the resistance and interpreting it, (9) shifting some old members to a new group, (10) introducing a borderline patient into the group whose anxiety level is high, (11) taking and playing back video tapes of the group in action, (12) pointing out which stimuli in the group release repetitive patterns in each patient and interpreting their ramifications in outside relationships.

When a Therapist Becomes Bored with a Session

In this situation the therapist may ask, "Is anybody else besides me bored with this

conversation?"Then the group could explore the basis for such a reaction.

MISCELLANEOUS GROUP APPROACHES

Preintake and Postintake Groups

Preintake groups, which act as a forum for discussion and orientation, are a valuable aspect of clinic functioning where a delay is unavoidable before formal intake. Up to 20 people may attend, and sessions may be given at weekly, bimonthly, and even monthly intervals. Parents of children awaiting intake may be organized into a group of this type, which may meet for 3 to 6 monthly sessions. Postintake groups may take place before permanent assignment, and meetings may be spaced weekly or up to 1 month apart. Here some therapeutic changes are possible as disturbing problems are introduced and elaborated. These preliminary groups serve as useful means of selecting patients for ongoing group therapy. They are worthy orientation and psychoeducation devices and help prepare and motivate patients for therapy.

Special Age Groups

Group therapy with children is usually of an activity nature. The size of children's groups must be kept below that of adult groups (Geller, 1962). For instance, in the age group up to 6 years, two or three children constitute the total. Both boys and girls can be included. Single-sex groups are (1) from 6 to 8 years, which optimally consist of three to five members; (2) from 8 to 12 years, which may have four to six members; (3) from 12 to 14 years, which may contain six to eight youngsters; and (4) from 14 to 16 years, which have the same number. Mixed-sex groups at the oldest age level are sometimes possible.

Play therapy is the communicative medium up to 12 years of age, the focus being on feelings and conflicts. It is obvious that the ability to communicate is a prerequisite here. Beyond 12 years discussions rather than play constitute the best activity medium. Techniques include analysis of behavior in the group, confrontation, and dream and transference interpretation. Both activity (during which acting-out may be observed) and

discussion take place at various intervals. Interventions of the therapist should be such so as not to hamper spontaneity. Discussion is stimulated by the therapist, and silences are always interrupted. Ideally, individual therapy is carried on conjointly with group therapy, particularly at the beginning of treatment.

Group psychotherapy with older people has met with considerable success in maintaining interest and alertness, managing depression, promoting social integration, and enhancing the concept of self in both affective and organic disorders (Goldfarb & Wolk, 1966). Where the goal is reconstructive, oldsters may be mixed with younger people.

Behavior Therapy in Groups

Behavioral techniques (Lazarus 1968; Meacham & Wiesen, 1974; Wolpe, 1969; Liberman, 1970; Fensterheim, 1971) lend themselves admirably to group usage, and results, as well as controlled studies, indicate that behavioral change may be achieved by the employment of methods such as behavioral rehearsal, modeling, discrimination learning, and social reinforcement. The group process itself tends to accelerate behavioral strategies. Homogeneous groups seem to do best, the selection of members being restricted to those who may benefit from the retraining of specific target behaviors. Thus, the control of obesity, shyness, speaking anxiety, insomnia, and phobias (flying insects, mice, closed spaces, etc.) can best be achieved in a group where the participants are focused on the abolition of similar undesirable behaviors. In institutional settings, particularly with psychotic patients, group decision making strategies may be practiced, reinforcement being offered through token economies. Short-term hospitalization for severe obsessive-compulsives, and perhaps alcoholics and drug addicts, treated in special groups of populations with similar maladaptive behaviors can often be a rewarding enterprise (Rachman, S., et al, 1971).

Individually oriented behavioral interventions [see Chapter 51, Techniques in Behavior (Conditioning) Therapy] may be employed alone in a group setting, or in combination with psychodrama, role playing, Gestalt tactics, encounter maneuvers, or

formal group therapy procedures (inspirational, educational, or analytic) depending on the training and flexibility of the therapist.

A routine practiced commonly is to see the patient initially in individual therapy to take a history, to explore the problem area in depth as to origin, circumstances under which it is exaggerated, reinforcements it receives as well as secondary gains, and goals to be approached, employing the traditional behavioral analysis. If group therapy is decided on, it is best to introduce the patient into a newly formed group with persons suffering from the same difficulties and who have approximately the same level of intelligence and knowledge of psychological processes. The size of the group varies from 5 to 10 individuals. A cotherapist is valuable and sometimes indispensable as in the treatment of sexual problems. The initial few sessions may be relatively unstructured to help facilitate the group process. The time of sessions varies from 1½ to 3 or 4 hours. During the starting sessions members are encouraged to voice their problems and to define what they would like to achieve in the sessions, the therapist helping to clarify the goals.

A. P. Goldstein and Wolpe (1971) have outlined the following operations important in group behavioral treatment: feedback, modeling, behavior rehearsal, desensitization, motivational stimulation, and social reinforcement. *Feedback* is provided with confrontation of the reactions of the other members to the patient's own verbalizations and responses. This gives the patient an opportunity to alter these if it is desired. *Modeling* oneself after how others approach and master the desired behavior is an important learning modality. The therapists may engage in role playing or psychodrama to facilitate modeling. *Behavior rehearsal* similarly employs role playing involving the patient directly. Repetition of the process with different members helps solidify appropriate reactions, the patient engaging in role reversal when necessary. Here video playbacks may be important so that patients may see how they come across. Counterconditioning and extinction methods (systematic desensitization, role playing with the introduction of the anxiety-provoking stimulus, encouraging expression of forbidden emotions in the group like anger) eventually lead to *desensitization.* The therapist provides direction and guidelines for appropriate behavior, which with the pressure of the group, helps create *motivation*

and *social reinforcement.* Support is provided the patient when necessary. Specific assignments outside the group may be given the patient.

Relaxation methods may be employed in a group for the relief of tension and such symptoms as insomnia. Any of the hypnotic or meditational methods outlined in this volume (q.v.) may be utilized; their impact is catalyzed by implementation in a group atmosphere.

Behavioral tactics are ideally suited for habit disorders related to eating, such as obesity, smoking, gambling, alcoholic over-indulgence, and substance abuse. Members for each group must be chosen who suffer from the same problem and possess adequate motivation to cooperate with the interventions.

Where problems are centered around lack of assertiveness, assertiveness training can be highly effective. Fensterheim (1971) describes his method of dealing with this problem. Groups of 9 or 10 consisting of men and women in approximately the same number, roughly homogeneous as to age, marital status, achievement, education, and socioeconomic status (to enhance modeling) meet *2½* hours once weekly. Seats are arranged in a horseshoe configuration, the opening serving as a stage for role playing and behavior rehearsal. Sessions are begun by each member reporting on the assignment proposed the previous week. Successes are rewarded with approval by therapist and members. Failures are discussed. On the basis of the report, the assignment for the following week may be formulated. Special problems will evoke discussion by the group. Members are asked to keep their own records of assertive incidents that they indulged in during the past week. Special exercises are employed with role playing depending on problems of individual members, such as talking in a loud voice, behaving unpleasantly, telling an interesting story, expressing a warm feeling toward other group members, practicing progressive expressions of anger (reading a dialogue and portraying an angry role, improvising one's own dialogue, role playing angry scenes and incidents reported by other members, and role playing scenes from one's own life and experience). About 5 to 10 minutes of each session is spent doing these exercises over a 4-month period. Roughly

10 to 15 minutes may be used for systematic group desensitization from a common hierarchy prepared by the group. At the end of each session members formulate their own next assignment or if they are blocked, this is suggested.

Phobias respond remarkably well to group behavioral methods. Here the patient selection must also be homogeneous as in assertive training. Aronson (1974) describes a program that has been successful in 90 percent of his patients completing it. The program is designed for fear of flying (but the ideas can be adapted to other phobias, such as fear of cars, ships, elevators, tunnels, bridges, high places, etc.). Initial individual consultations are geared toward establishing a working relationship with the applicant, and essentially to do a behavioral analysis, although Aronson stresses a dynamic accent. A high degree of motivation is desirable. "How much do you want to get over this fear?" may be asked. At the first session the therapist structures the program (the first five sessions devoted to a discussion of fear of flying; one or two educational briefings with safety experts, pilots, and other air personnel to answer questions; seven to eight sessions on discussion and methods of overcoming the fears). The optional size of the goup is 8 to 12 persons. Meetings are for 1½ hours once weekly. Presession and postsession meetings of ½ hour each without the therapist may be recommended. Pertinent reading materials on air travel and development should be available.

The following rules are delineated, (a) Each member will within the time limitations, be permitted to talk freely about existing fears, (b) At the second session each member is to bring in a drawing depicting the most pleasurable aspect that he or she can imagine about a commercial air flight and a second drawing depicting the most unpleasant consequences. The individual is also invited to talk about any personal dreams about travel (In recounting such dreams no associations are encouraged nor interpretations made regarding defenses.) (c) The following exercises aimed at anxiety control are introduced.

> 1. While lying down or seated comfortably on a chair, visualize all the sensations and anxieties you experience while on a plane. Simply visualizing yourself on a plane may make you anxious at first. You may find yourself

wanting to avoid thinking about it.' If so, let your mind dwell on pleasant thoughts for a while. As soon as you feel somewhat more relaxed, reenter the fantasy of being anxious on a plane. Focus initially on the least frightening aspects of flight. Gradually allow yourself to visualize more frightening fears. Each time you practice this exercise you will be able to get closer to the dangerous situation and stay with it longer. Do this exercise twice a day for a week (based on Wolpe, 1969).

2. Picture yourself in the *most pleasant* situation you can imagine. Let your mind dwell on this situation as long as possible. Then imagine yourself on a plane. Some of the positive feelings you experienced in your fantasy will come back with you and help allay your anxiety when you next imagine yourself on a plane on the ground or actually flying (based on Perls, 1969).

3. Visualize the most unpleasant situation you can possibly think of—a situation even *more unpleasant* to you than being on a plane. You will find that when you leave this fantasy and imagine yourself flying or actually on a flight, you will experience less anxiety (based on Perls, 1969).

Should any of these exercises stir up anxiety, the members must indicate this to prevent it from getting too deep, (d) Should members start feeling strongly hostile to each other, the therapist encourages verbalization and explains that strong, positive feelings among all group members will be necessary for success, (e) Talking about personal matters other than those related to fears of flying is to be discouraged. (f) After the fourth or fifth session one or two educational sessions are held with local airline representatives to answer technical questions about flying and safety measures, (g) After the eighth session the entire group visits an airport and, if possible, meets in a stationary airliner for about 1 hour. Members talk about their fears every step of the way. Around the tenth and twelfth session the group leader suggests a target date for a short flight. If too much anxiety prevails, this date can be temporarily postponed until the anxiety recedes. The leader must set the time with the airline representatives and accompany the group. After the flight the group reconvenes to discuss the reactions. (h) Members are encouraged to arrange their own flights and to continue in group therapy for a few sessions thereafter.

Other phobias may be treated in a group setting following this format, introducing

whatever modifications are essential considering the nature of the target symptom. Videotaping and playback may be employed, should the therapist possess the apparatus, particularly for role-playing exercises.

Experiential (Encounter and Marathon) Therapy

The group therapy movement has mushroomed out to include a variety of forms. The traditional model, which focused on inspiration, education, and insight acquisition, has been supplemented by groups whose objective is experiential with a wide variety of techniques. Many names have been given to these new arrangements including Gestalt, human relations training, human awareness, leadership training, T-groups, sensitivity therapy, and encounter therapy. The time element (traditionally 90 minutes) has been stretched sometimes to several hours, 12 hours, 24 hours, or several days with time off for sleep (marathon groups). Encounter therapy may be an ongoing process like any other form of group therapy, or it may be brief, from one to a dozen sessions.

A constructive group experience with a small group of people who are educationally on a relatively equal level and who permit themselves to disclose their self-doubts and personal weaknesses can be most liberating to the participants. The fact that one can expose oneself to others and reveal fears and desires of which one is ashamed, without being rejected or ridiculed, can be reassuring and strengthening. The person feels accepted for oneself, with all of the flaws, rather than for the pose presented to the world. Whereas previously the individual may have regarded interpersonal relationships as threatening, they can now embrace a sustaining richness. As communication between the members broadens, they share more and more their hidden secrets and anxieties. They begin to trust and accept themselves as they learn to trust and accept the other participants. Interpersonal confrontations, while temporarily upsetting, may even ultimately bring the individual into contact with repudiated aspects of himself or herself.

By communicating without restraint the members are enabled to learn that other individuals have problems similar to and even more severe than their own. The realization enables them to relax their guards and to open up more with one another. The

"encounters" in the group will probably sooner or later release underlying patterns of conflict, such as hostility toward certain members, excessive tendencies to defy and obstruct, inferiority feelings, unrealistic expectations, grandiose boastings, and other maneuvers that have little to do with the immediate group situation but rather are manifestations of fundamental characterologic flaws. Under the guidance of a skilled group leader the encounter group becomes a means through which the members become aware of how they are creating many of their own troubles. By talking things out they are able to correct some of their misperceptions.

Some observers would call this process psychotherapy. We are dealing here with semantics. The effects of the encounter group can be psychotherapeutic, particularly in persons who are ready for change and who already have, perhaps in previous psychotherapeutic experiences, worked through their resistances to change. But psychotherapy, in most cases, is not the achieved objective. What is accomplished is an educational realignment that challenges certain attitudes and teaches the person how to function better in certain situations. If one happens in the course of this education to change a neurotic pattern of behavior, so much the better, but it must be emphasized that psychotherapeutic groups are run differently from encounter groups. They are organized on a long-term basis and focused on neurotic symptoms and intrapsychic processes.

Even though there is some evidence that encounter group experiences may have a therapeutic effect on neurotic personality structure, our observations at the Postgraduate Center for Mental Health indicate that personality changes, when they do occur, are temporary, rapidly disappearing once the participant leaves the encounter group and returns to one's habitual life setting. We have worked with the staffs of various institutional units, including psychiatric clinics, correctional institutions, schools, and a host of professional and nonprofessional organizations. Our delight at "depth" changes brought about by encounter techniques has been generally short-lived when we do follow-up studies after a reasonable time has elapsed. This fact does not depreciate what the encounter group can do for a participant, because in many instances it does alert the individuals to many neurotic shortcomings and motivates them to seek psychotherapy on

a more intensive level. Many of our "cured" encounter clients have later asked for thorough psychotherapeutic help, once they have an inkling of their problems.

The usual marathon group exposes group members to constant association of approximately 30 hours, generally in the course of which a 5-hour break is taken. During the first 15 hours of interaction there is a gradual sloughing off of defenses, and, in the last hours, a "feedback" is encouraged in which the therapist enjoins the patients to utilize the understanding of themselves to verbalize or execute certain constructive attitudes or patterns. Highly emotional outbursts are encountered with this intensity of exposure, and corrective emotional experiences seem to occur. The therapist participates actively with the group, expressing his or her own reactions to the members but avoiding interjecting personal needs and problems. A variety of techniques may be employed. For example, at Esalen a combination of theories and methods were used, including Perls' Gestalt therapy, Freud's unconscious motivational ideas. Rolfs structural integration and body balance, Lowen's bioenergetic theory, Moreno's psychodrama. Shutz's encounter tactics, and other sensitivity training methods (Quaytman, 1969). Some of these techniques have more recently been taken over by Erhard Seminars Training (EST).

Experiential therapies are sometimes resorted to by psychotherapists when their patients have reached a stalemate in individual or group therapy. In many cases the specific working on the resistance resolves such blockage of progress without the need for dramatic interventions. However, in spite of this, there are some patients who seem unable to move ahead. Productions dry up, boredom develops, motivation to continue therapy dwindles away. Under these circumstances some therapists have found that referring their patients for encounter therapy or a weekend marathon suddenly opens them up, producing a flood of fresh material to work on, and sponsoring more enthusiasm for continued treatment.

Not too many therapists are qualified to do experiential therapy. Apart from that which may be gained by participation as a patient in encounter groups or in several marathons, it requires a special personality structure of great extraversiveness,

spontaneous enthusiasm, and histrionic inventiveness. Sufficient flexibility must exist to permit a rapid switching of tactics and changing of formats to meet individual and group needs. The role of the leader will vary, of course, with the individual. Most therapists view themselves as participant observers who, while admitting and sharing some of their own problems, hold themselves up as models of expected behavior. Emotional stability of the therapist and control of countertransference are under these circumstances vital. The presence of a trained cotherapist is often of value in the service of objectivity. Both therapists who do marathon therapy and patients who receive it are usually enthusiastic. Follow-up studies have been more conservative as to the actual benefits. The immediate experience may be an intensely moving one, and participants usually believe that they have benefited and are reluctant to end their relationship. They feel that they have acquired a new understanding of themselves. Often they do. But we may anticipate that benefits will not persist unless the environment to which the member returns reinforces the new behaviors and attitudes that have been learned. This is usually not the case, however. One would anticipate that unless some intrapsychic change has occurred, the old defensive balances will usually be restored. It is for this reason that results will be best if the individual continues in individual or group therapy to work on the significance to him or her of the encounter or marathon experience.

It has been the practice, unfortunately, to offer encounters or marathons for unscreened applicants willing to pay the price of admission on the theory that even a bit of confrontation, challenge, and encounter can provide fruitful bounties. Undoubtedly, there are persons who may get a good deal out of an intensive interpersonal experience without formally entering into structured psychotherapy. This does not compensate for the unstable souls, balanced precariously on the razor edge of rationality, who can be damaged by exposure to such groups. There are some patients (usually borderline cases) who cannot tolerate the intense emotional relationships of the marathon experience (Stone, WN, & Tieger, 1971; Yalom & Lieberman, 1971). Such individuals may develop frank psychoses as a result of breakdown of their defenses. Unless the therapist is well trained and does diagnostic interviews on all applicants (which is not often the case), he or she is risking trouble, however infrequent this is reported.

Even where an initial diagnostic study qualifies a person for this type of therapy, difficulties can occur in those with fragile defenses. The task of the leader is to pick out of the group those members who in their speech and behavior are beginning to lose control. Removing such vulnerable persons from the group, temporarily by assigning to them isolated tasks and perhaps giving them supportive reassurance in a brief interview, may permit some of them to reenter the group when their reality sense is restored. The therapist will have to interrupt any challenges or attacks that are levied at such persons, refocusing attention elsewhere.

Generally, the individual entering an experiential or marathon group is instructed in the responsibility that he or she has in the group, the need for physical restraint and abstinence from drugs and alcohol, and the fact that while one's behavior in the group is related to one's life style, that there may be new and better ways of relating that one can learn. Sometimes a contract is drawn up as to what changes a person desires to achieve. Accordingly, the individual may gauge for oneself how far ahead to move. Emphasis is on the "here-and-now" rather than on the past.

As to encounter techniques, these vary with the inventiveness of the leader. In a small group the members may be asked to "go around" and give their impressions of all the other members, positive and negative. The leader may then say, "Reach out and put your hands on the shoulders of the person next to you. He or she will do likewise. Look into each other's eyes and say whatever comes into your mind." Or, "Hold the hands of the person next to you, and describe what you feel these hands are saying."

Utilizing art materials (crayons, chalk, pastels, etc.), the members may be asked to draw anything that represents how they feel and also how they would like to feel. The group later associates to or discusses these productions. The same may be done with clay or plasticene materials.

Two members may be asked to approach each other in front of the group and to communicate in nonverbal terms, i.e., by touching, gestures, facial expressions, etc. The group then discusses the nature of the communication.

Schutz (1967a) has described a number of "warm-up" and other techniques that may be used. One technique in helping a person give up rigid controls and distrust of others is to encourage him or her to stand with back to the therapist and to shut the eyes and fall straight back with trust that the therapist will surely prevent falling. Patients show many defenses to this maneuver, and the discussion of their fears and other feelings provides a stimulus for elaboration in the group. Later members may try this maneuver with each other when they develop confidence in permitting themselves to fall back.

Many touching maneuvers are employed for the same purpose. One is to invite patients to stretch out on a couch and to have them lifted by many hands and passed along, their bodies being stroked in the process. Associations to this are, as may be imagined, often interesting. In encounter groups, participants often play out their needs, impulses and conflicts not only through "verbal interchanges but also various nonverbal devices such as touching, massaging, holding, hugging, dancing, exercising, playing games, eyeball to eyeballing, acting out dreams and fantasies, etc." (Harper, 1975). Such groups which encourage an unrestrained expression of emotion may be helpful, at least temporarily, for inhibited, repressed individuals who require peer approval and modeling by a leader who also enjoins them to come forth with their feelings. But they may be harmful to vulnerable individuals who, having let the lid off their emotions, are left with residues of guilt and confusion after the group has disbanded. Dangers come from lack of provision for adequate postsession discussion, clarification, support, and interpretation; from inadequate selection procedures for members; and from inexperienced and untrained leaders who, though high in enthusiasm, are low in therapeutic understanding and sophistication.

Negative outcomes with experiential groups are to be expected in view of the superficial screening of the participants and the large number of untrained leaders who contact these groups with few or no limits on the selection of techniques. It would seem propititious to set up certification and licensure requirements for potential leaders of encounter groups to minimize hazards (Hartley, Roback, & Abramowitz, 1976).

It is to be expected that when people come together for an extended therapeutic experience that hopes are high and that there may be unreasonable expectations of benefit. Despite efforts to control postures and defenses and to substitute for them conventional modes of relating, the facades soon break down, particularly when the individual is criticized and challenged. The close contact, the extended time period of interaction, the developing fatigue, and actual and implied pressures for change all add to the uniqueness of the experience. Intimacies develop that the participant needs to control since subgroups and pairing are strongly discouraged. As the individual realizes the consequence of one's acts for the reactions of others, motivation for change may be increased. This is further augmented by reinforcements that one receives in the form of group approval for any changes that are exhibited. Where patients are not in ongoing groups or individual therapy, it is advisable to schedule a follow-up meeting 3 to 4 weeks later to discuss postmarathon impressions and experiences.

Because many participants have failed to achieve the hoped for relief from alienation, personal growth, and self-realization, the popularity of encounter groups has waned during the past decade.

The literature on encounter (experiential groups) has proliferated since the mid 1960s. The following are recommended: Back (1972), Burton (1969), M. Goodman (1972), Kuehn and Crinella (1969), E.E. Mintz (1967), Perls (1969), Rabin (1971), C.R. Rogers (1970), M. Rosenbaum (1969), Strean (1971-1972). The list continues to grow. Ample material has in the past been published on marathon therapy. A sampling follows: Bach (1966, 1967a-d), Casriel and Deitch (1968), Dies and Hess (1971), A. Ellis (1970), Gendzel (1970, 1972), J. Mann (1970), Rachman (1969, 1975), Sklar et al. (1970), Spotnitz (1968), Stoller (1967, 1968), Teicher et al. (1974), and Yalom and Lieberman (1971). In recent years interest in marathons has diminished.

Transactional Analytic Groups

Transactional analysis is a highly structured group of procedures, developed by Eric Berne in 1950, that is designed to help people achieve an expanded awareness of their

interpersonal operations. It is predicated on the idea that human beings carry within themselves a threefold set of directives that influence their behavior in positive and negative ways. The first group of prescripts are residues of parental conditionings, the individual functioning as if driven by the values and attitudes of the parents. When this happens the "parent" (P) within is said to take over. The second group of regulations are the survival remnants of the "child" (C) and consist of immature promptings and habitudes, parcels of the past. The third group, the "adult" (A), is the logical, grown-up self that mediates a reasonable disposition. These divisions roughly correspond to Freud's superego, id, and ego; indeed, there is much in transactional analysis that parodies traditional dynamic formulations. What is unique and original about the method is the crisp, humorous, provocative language tabs assigned to different patterns that people display in their relationship with each other. This enables some persons, confused by the complex concepts and vernacular of psychoanalysis, to acquire insight into their drives and defenses rapidly, to accept more readily responsibility for them, and to work toward a primacy of the "adult" within themselves. It is little wonder that the volumes *Games People Play* by Berne (1964) and *I'm OK—You're OK* by T. Harris (1967) have stirred the popular imagination, plummeting the books to the top of the best-seller list.

Not all therapists, however, are able to do transactional analysis. What is required is a combination of special traits that include an extremely keen sense of humor, a facility for dramatics, a quick ability to perceive patterns as they come through in the patient's speech and behavior, and a unique capacity to label their use with relevant salty titles.

Treatment in transactional analysis begins with several individual interviews. Patients are instructed in the dynamics of the transactional approach and may be given assigned readings (Berne, 1964; Harris, 1967). A treatment "contract" is drawn up describing the goal of therapy in a specific and clear-cut way, and the patient is introduced to the group. Four overlapping phases of therapy are generally described (Karpman, SB, 1972).

The first phase is structural analysis concerned with understanding and recognizing

"ego states," which objectively demonstrate themselves in body attitudes, tone of voice, vocabulary, and effect on others. Only one ego state manifests itself within the person at a time. Thus the individual's "parent" (P) may come through in vocabulary and behavior expressing what is right and wrong and what people should or should not do. The parent can be prejudiced, critical, pompous, and domineering, or nurturing, sympathetic, forgiving, reassuring, smothering, oversolicitous, infantilizing. The "adult" (A) is the "sensible, rational, logical, accurate, factual, objective, neutral, and straight-talking side of the personality." The "child" (C) can be "free," i.e., happy, intuitive, spontaneous, adventurous, and creative; or the child can be "adapted," i.e., showing reactions akin of those of parents like being sulky, frightened, guilty, sad, etc. The patient in the group during the first several weeks is encouraged to identify the ego states within oneself and as they come through in one's behavior toward the others in the group. The patient learns also of "skull transactions" (i.e., the internal dialogue that goes on between the ego states) as well as ways of "getting the trash out of your head" (i.e., the adult decision to start new internal dialogues—"A 'go away' or 'That's my Parent talking' often quickly helps a patient 'divorce the parent' "). Catchy slogans are used to identify and describe attitudes of P, A, and C. Decision making, views of the world, modes of cataloging external information, and even examining resistance to therapy are referred to the separate outlooks of parent, adult, and child.

The second phase of therapy is transactional analysis (TA), which deals with the clarifying and diagraming of conversations with others, as by drawing arrows from one of the ego states of the person to one of the ego states of the other person. One's child may talk to another's child ("fun talk"), or adult to adult ("straight talk"), or parent to child ("helpful talk"). Various combinations can thus exist. In a group a patient's transactions can be drawn on a blackboard. In this way the patient learns the typical "games" that he or she plays with people. Transference is handled as a "typical transaction" and the precedents traced to early family transactions.

The third phase is "game analysis." "Games" are involved transactions of a number of people that lead to a "payoff" unless interrupted. They have social and psychological

dimensions. Repetitive patterns and defenses are defined by provocative or humorous titles enabling the individual to accept them as part of the personality without too great anxiety. This is one of the virtues of transactional analysis. It is less apt than other dynamic therapies to set up resistance to the acknowledgment of destructive drives. The individual is more likely to accept the fact that he or she is driven by neurotic drives if these are presented humorously as universal foibles. The patient becomes less defensive and more willing to relinquish them.

One of the four basic positions is taken toward the world: (1) "I'm OK, you're OK," (2) "I'm OK, you're not OK," (3) "I'm not OK, you're OK," (4) "I'm not OK, you're not OK." Games are played for figurative "trading stamps" for the purpose of collecting important prizes. "For instance, a man needing only two more books of 'mad' stamps comes home from work, starts a fight with his wife, collects the two books of 'mad' stamps, and cashes them in at the bar for a justifiable drink." Discussion focuses on developing rapidly an awareness of both social and psychological levels of behavior—not in abstract terms but by recognizing how one utilizes people to perpetuate one's own aims ("payoffs"). Sooner or later, the individual is able to interrupt the games (avoid being "hooked," achieve a "quit point") before they eventuate into his habitual acting-out patterns. Thus a cynical attitude toward the games provides motivation to stop them.

The fourth phase is "script analysis." A script is the individual's life plan evolved in early childhood. A "script matrix" charts the relationship with the parents and the crucial injunctions that have circumscribed the individual's life. The "script story" delineates the patient's life pattern and outlines the predicted end of the script. In the course of exploring the script early memories may be revived. The object of working with scripts is to give up old unwanted ones and "get a new show on the road." " 'Permission' in therapy is given to break the 'witch mother' injunctions. This is followed by a necessary period of up to 6 weeks of protection for the new ego, and this is dependent on the therapist having more potency than the witch parents. Patients gain a final autonomy in therapy and choose their own style of life or even live script free.' " Countertransference is recognized. "The therapist should be alert to detect witch messages in his own script and should not pass

these on to his patients."

Transactional analysis for groups at one time attracted a sizable number of therapists, some of whom joined the International Transactional Analysis Association, which held seminars and study groups in many cities. Clinical membership was acquired after 2 years of supervised therapy and a written and oral examination. Publication on the subject has been ample, although interest somewhat has drifted away from transactional analysis during the past few years.

Psychodrama and Role Playing

Moreno (1934, 1946, 1966b) created a useful group therapy method, "psychodrama," which he first introduced in 1925 and that has evolved into a number of clinical methods, including sociodrama, the axiodrama, role playing, and the analytic psychodrama. Many of these have been incorporated into modern Gestalt, encounter, and marathon therapy.

In the hands of a skilled therapist psychodrama is a valuable adjunct in helping patients work through resistances toward translating their insights into action. The initial tactic in the group is the "warm-up" process to facilitate movement. This may take the form of the director (the therapist) insisting that the group remain silent ("cluster warm-up") for a.period. As tension mounts, it will finally be broken by some member expostulating about a problem, the verbalizations drawing a "cluster" of persons around the member. Other members may similarly come forth with feelings and stimulate "clusters" interested in what they are saying. Soon the whole group is brought together around a common theme. The "star" chosen is the person whose personality reflects the problem area most clearly. Another warm-up method is the "chain of association." Here the group spontaneously brings up fears and associations until an engrossing theme evolves. The star chosen is the person who is most concerned with the theme. A third warm-up is initiated by the director ("directed warm-up") who, knowing the problems of the constituent members, announces the theme. A "patient-directed warm-up" is one in which a patient announces to the group the subject with which he or she would like to

deal.

The star is groomed for the roles to play with representatives of important people in the patient's past and current life, selected from other group members ("auxiliaries") whose needs for insight preferably fit in with the parts they assume. The director facilitates the working together of the group on their problems, while focusing on one person (the "protagonist"). Among the techniques are (1) "role reversal," during which a protagonist and auxiliary reverse positions; (2) "the double," another member seconding for and supporting the protagonist; (3) "the soliloquy," characterized by a recitation by the protagonist of self-insights and projections; and (4) "the mirror," auxiliary egos portraying what the protagonist must feel.

By forcing themselves to verbalize and act parts, the members are helped to break through blocks in perceiving, feeling, and acting. Sometimes the therapist (the director) decides which life situations from the patient's history are to be reenacted in order to work at important conflictual foci. A technique often followed is that assumed by "auxiliary egos," who are trained workers or former patients "standing in" for the patient and spontaneously uttering ideas and thoughts that they believe the patient may not yet be able to verbalize, thus helping "to bring his personal and collective drama to life and to correct it" (Moreno, 1966a). As the patient reenacts situations, not only the self role, but also roles of other significant persons in his or her life, such as parents or siblings. The therapist, in the role as "director," may remain silent or inject questions and suggestions. Material elicited during psychodrama is immediately utilized in the presence of the "actor" patient and the group "audience." This technique usually has an emotionally cathartic value, and it may also help the patient understand problems revealed by one's personal actions and thoughts as well as those reflected by other members of the group. By venting feelings and fantasies in the role of actor, the patient often desensitize to inner terrors, achieves hidden wishes, prepares for future contingencies, and otherwise helps to resolve many deeper problems and conflicts. Psychodrama may, instead of being protagonist-centered, i.e., focused on private problems of the patient, be group-centered, concerning itself with problems facing all members of the group.

A valuable function of the auxiliary egos is to represent absentee persons important in the life of the protagonist. Auxiliary egos, thus, are best recruited from those persons present in the group who come from a sociocultural environment similar to that of the patient. The auxiliary egos portray the patient's own internal figures, forcing the patient to face them in reality. In this way the symbolic representatives of the inner life are experienced as real objects with whom the patient has an opportunity to cope. The director enters into the drama that is being portrayed with various instructions and interpretations. Choice or rejection of the auxiliary egos is vested in the protagonist or the director. Since auxiliary egos are representations, they may play any role, any age, either sex, even the part of a dead person whose memory is still alive in the protagonist. If necessary, and where the protagonist can tolerate it, bodily contact is made between the patient and the auxiliary ego to supply reassurances and to restore aspects of closeness that the protagonist has lacked. Thus, a person who never experienced real "fathering" may get this from the actions of an auxiliary ego.

Props are sometimes used, such as an "auxiliary chair" which may represent an absentee personage. Living or dead family members may be portrayed by several empty chairs around a table, each chair in fantasy being occupied by a different relative. In the dramatic interactions the protagonist may play the role of the relative with whom there is momentary concern by sitting in the special chair and speaking for that person. Sometimes a tall chair is employed to give a protagonist sitting in it a means of assuming a position of superiority. A fantasy prop sometimes used is the "magic shop," in which the shopkeeper dispenses to all the members of the group imaginary items cherished by each in exchange for values and attitudes that are to be identified and surrendered by each member.

Role reversal is a useful technique in psychodrama, two related individuals, for example, taking the role of one another expostulating how they imagine the other feels or portraying the behavior of the other. Where a protagonist is involved emotionally with an absent person, the latter may be portrayed by an auxiliary ego.

Rehearsal of future behavior is an aspect of psychodrama. The protagonist here will play out a situation that necessitates the execution of skills or the conquest of anxiety that is presently felt to be unmastered. Verbalizing inner doubts and fears, and applying oneself to the task of overcoming these, may be helpful in easing one through actions in real life.

The controlled acting-out of fearsome strivings and attitudes helps to expose them to clarification. Thus, obsessive gentleness may be revealed as a defense against the desire to lash out at real or imagined adversaries. A protagonist so burdened may be encouraged to swing away at imagined persons who obstruct. A woman whose spontaneity is crushed may be enabled to dance around the room, liberating herself from inhibitions that block expressive movement. A suicidal person may portray going through the notions of destroying himself in fantasy, thus helping the therapist to discuss openly an impulse that otherwise may be translated into tragic action.

Moreno (1966a) explains the value of psychodrama in these words:

> Because we cannot reach into the mind and see what the individual perceives and feels, psychodrama tries, with the cooperation of the patient, to transfer the mind 'outside' the individual and objectify it within a tangible, controllable universe. ... Its aim is to make total behavior directly visible, observable, and measurable.

In this way, patients are presented "with an opportunity for psychodynamic and sociocultural reintegration."

The psychodramatic technique has given rise to a number of *role-playing methods* that are being applied to education, industry, and other fields. Recognizing that the mere imparting of information does not guarantee its emotional acceptance or its execution into action, role playing is employed as a way of facilitating learning (Peters & Phelan, 1957a,b). As an example, a group of four participants and a group leader may be observed by four observers who sit apart from and in the rear of the participants. Initial interviews of 1 hour with each participant and observer are advantageous to determine motivations, expectations, and important psychopathological manifestations. Preliminary mapping of the procedure considers group combinations, problems to be considered, objectives and

desired modes of interaction. A short warm-up period is employed at the beginning of each session to establish rapport. Then the participants are assigned roles in a selected conflict situation. A discussion by the group of the issues involved, with delineation of possible alternative courses of action, is followed by the leader's interpretation of why various participants reacted the way that they did. Repetition of the conflict situation with the same participants gives them an opportunity to try out new adaptive methods and tests their capacities for change. It also fosters reinforcement of a new mental set. At the end of the session the group leader renders ego support in the form of praise for individual contributions and reassurance to lower any mobilized tension or anxiety. Approximately six 1-hour group sessions are followed by individual consultation with each member to determine ongoing reactions. Another series of six group sessions, or more, may be indicated. These procedures, while effectively altering attitudes and promoting skills, may not effectuate significant changes in the basic personality structure. More extensive role-playing tactics have been described by Corsini (1966) that are designed to deal with extensive inner conflicts.

Quality of Change in Group Psychotherapy

One must not be deceived regarding the quality and depth of changes observed among members of a group as a consequence of continued interaction. Changes are dramatic: the attacking and aggressive person becomes quiet and considerate; the dominant individual shows abilities to be submissive; the withdrawn person comes out of a shell and relates flexibly to the other members; the dependent, clinging soul is encouraged to express assertiveness. These effects will become apparent, sooner or later, as products of both group dynamics and the interpretive activities of the therapist and group members. But whether there will be a transfer of learning to the outside world sufficient to influence a better life adaptation is another matter. Often what we find in group therapy (as we witness it also in individual therapy) is that the individual fits the group reactions into a special slot. The role played in the group is disparate from the roles in other situations. The group expects one to behave in certain ways, and one obliges. It offers a shelter from the harsh realities of the external world. One can "be oneself" in the

group; but defenses may be checked at the therapist's door, and when leaving the therapist's office or the group at postsessions and alternate sessions, one may reclaim them. Only in this haven of safety can one trust oneself to act differently.

This confounding resistance is testimony to the fact that interpersonal change is not the equivalent of intrapsychic change. The former change may merely reflect the acquisition of a new set of social roles that the individual fastens onto and that enhance the repertoire of patterns. It is like acquiring a new wardrobe to be worn on special occasions. The individual underneath remains the same. From this one must not assume that group therapy is of no real consequence. Intrapsychic changes are possible if the person has the courage appreciably to test the changed assumptions and to apply new learning in the group to the other roles played in life. The therapist has a responsibility here in seeing that the patient does not lock into a comfortable stalemate in the group. The patient may be asked whey there are differences in his or her feelings and behavior inside as compared with those outside the group, and if there has been no change, why not. Sometimes the patient's resistance is a persistence of the desire to recreate the patient's original family in the group, with all the ambivalences that this entails from which the patient refuses to break loose. Supplementary individual sessions may be specifically applied to these questions.

FAMILY THERAPY

Families are composed of units of individuals engaged in continuing interrelationships that significantly influence mutual behaviors. Pathology in one member can have a determining effect on the entire family system, which, in turn, will modulate the degree and form of individual dysfunctions. Therapeutic interventions therefore must concern themselves with the organizational distortions of the family as a system. It follows from this that correction of psychopathology in any one or more members presupposes a restructuring of the family organization, which is, to say the least, a difficult undertaking. At the start of treatment, the therapist is usually confronted with the fact that the family, dysfunctional as it may be, has reached a level of stability (homeostasis) that

tends to resist modification. Attempts to alter faulty indigenous communication patterns, or efforts to move family boundaries outwardly toward remedial community resources are apt to be resisted. Family therapy is designed to deal with these rigidities (Gurman & Kniskern, 1981).

Contemporary techniques in family therapy are not uniform even though many of them are implemented under the rubric of presumably standard theories. They are essentially organized within the framework of three schools: structural family therapy, strategic family therapy, and intergenerational family therapy (Steinglass, 1984). Structural family therapy (Minuchin, 1974b; Minuchin & Fishman, 1981) focuses on the behavior of the family during the treatment session, and searches for patterns of alliance between two or more members as well as the firmness of their boundaries. Strategic family therapy emphasizes the symptomatic consequences of bad problem-solving. Homework is often assigned in the form of tasks for the different members, sometimes employing ambigious instructions. Patterns of communication may also be explored (Watzlawick, Weakland et al, 1974; Watzlawick et al, 1967), family problem-solving tactics investigated (Haley, 1976), and certain remedial or paradoxical tasks prescribed (Haley, 1976; Selvini-Palozzoli et al, 1978; Madanes, 1981). Intergenerational family therapy searches for patterns of "fusion" and "differentiation" that are passed along from one generation to another (Bowen, 1976). The theories and techniques of these three schools may seem worlds apart, but the effect on families of all of them can be significant when practiced by skilled and empathic family therapists.

Such practice can become quite involved, necessitating an understanding of individual and group therapy, systems theory, sociology, and group dynamics. During treatment the therapist must skillfully weave back and forth among the various members as resistance, transference, and defensive manifestations break loose. Countertransference is a fluid phenomenon in the process; identification with one or more the patients in the group commonly occurs. Since the actual difficulties are produced by the behavior of the individuals in the system, the resolution of such difficulties will necessitate changes in the behavior of the persons involved in the disorganizing

interactions. This is sometimes referred to as the "interactional" approach in family therapy. Problems are not regarded as the tip of the iceberg, so to speak, emerging from buried inner manifestations, but as the iceberg itself. A good number of the therapeutic interventions are directed at the activities that are being used as "solutions" to control or eliminate undesired behavior. These activities usually sustain and reinforce the difficulty. Since such solutions often serve merely to aggravate the problem, therapy is concentrated on eliminating these futile solutions. New problem-solving methods are encouraged, focused on behavioral alterations rather than intellectual insights. A behavioral change in any member of a system can produce a change in the entire system. Accordingly, treatment may concentrate on the member who is most responsible for bringing about difficulties in the system, although the family as a whole is taken into consideration.

Many models for family therapy exist—and are still developing as psychotherapists of different professions, with varying theoretical viewpoints, evolve modes of working in relation to the needs of families and the structure and function of the agencies through which treatment is being implemented (Sager & Kaplan, 1972). Understandably, therapists have special ways of looking at family pathology and they organize their ideas, as has been pointed out, around favorite systems, such as behavioral family therapy, structural family therapy, psychodynamically oriented family therapy, and systems family therapy. Yet a therapist's clinical operations with families are influenced more by individual style of working with patients and the therapist's own unresolved family problems than by the theories espoused. This results in many different forms of practice that vary in such areas as selection of the unit of intervention (i.e., identified patient and parents, or total immediate family including siblings, extended family, distant relatives, etc.); time allotted to sessions (1 hour to several days [marathon family therapy]); duration of therapy (one session to many months); activity during sessions (listening, supporting, challenging, confronting, guiding, advising, censoring, praising, reassuring, etc.); relative emphasis on insight and behavioral alteration; and employment of adjunctive procedures (videotaping, use of one-way mirrors, role-playing, etc.).

How to manage resistance in family therapy is another area of discrepancy. Families

struggle to maintain the homeostasis of a neurotic family system by preserving pathologic ways of relating. A great many of the current writings about family therapy specify contrasting ways of dealing with such resistance, and one is impressed with the lack of agreement for proper management of this disturbing phenomenon.

Sometimes family therapy is undertaken in clinics and family organizations, particularly those dealing with children for the purpose of reducing waiting lists. Under these circumstances therapy may be started even at the first interview as part of the intake and diagnostic process. Sometimes a group of workers visit the family in the home after an intake interview with the family and a diagnostic interview with the child (Hammer & Shapiro, 1965). Visiting the home has certain advantages since the members will demonstrate less defensiveness at home than at the clinic or office, displaying habitual reactions more easily.

Multiple therapists are often employed, circumventing to an extent the countertransference that develops in a one-to-one relationship. Individual therapy may be done concurrently by the different members of the team with selected members of the family (Hammer, 1967). Resistance is also more easily managed when more than one team member approaches a patient from a different perspective. The family facade is then more easily dissolved, and family members are more readily motivated to relate with their inner and latent feelings.

Sundry problems are experienced by therapists when dealing with another therapist who is treating a member within the family group. Disagreements will occur in observation, in emphasis of what is important, in diagnosis, and in the type of intervention best suited for specific situations. Competitiveness between therapists may interfere with their capacity to be objective. They may be offended by disagreements with or criticisms of their operations. There is finally the matter of expense and the finding of qualified professionals who can make their time coincide with that of the therapist. Opportunities are obviously better in a clinic than in a private setting, since fixed staff is available. There is an advantage in doing multiple therapy in a training center since a trainee may gain a

great deal working with a more experienced therapist. Constructive collaboration between therapists tends to reinforce the impact of interpretations. It helps the resolution of resistance.

Working with a family group may serve purely as a diagnostic procedure, to spot psychopathology, and to aid in the assignment of therapists to individual family members who most need help. The focus may be on the relationships between parents, parents and children, and parents and grandparents. If a tangible problem exists, this may constitute the area around which explorations are organized. Short-term goals usually deal with a family crisis (Bar-ten, 1971). Long-term goals are fluid and have to be adapted to the needs of the family. The objective, for example, may be to hold the members together in a fragmented family. It may be to help adolescents separate and find their own individuality. Sometimes asking each member of the family "What would you like to see changed in the family?" helps provide a focus. Each member may have a different idea about what should be changed. This will give the therapist valuable clues. At the end of the first session, a statement may be made to the family by the therapist as to what the problem seems to be.

It is vital in family therapy to understand and to respect the cultural background. The therapist must not deviate much from the accepted cultural system since this will offend some of the members and create resistance. Sometimes it is helpful to introduce an individual into the family group as a cotherapist who is part of the same subcultural setting, and who is capable of better translating the family code. This individual must, of course, have had some training at least as a paraprofessional.

Desirable goals of family therapy include resolution of conflicts, improved understanding and communication among family members, enhanced family solidarity, and greater tolerance for and appreciation of individuality (Zuk, 1974). All of these goals may not be achievable. In crisis resolution, for example, the total of one to six sessions, *which is the maximum number* acceptable to many lower-class families, may achieve little other than an overcoming of the immediate emergency. Somewhat more extensive are the objectives of short-term family therapy, which, though of longer duration, still may

produce little other than symptom reduction, largely because of the reluctance of the family members to involve themselves in extensive verbal interchange. Middle-class families are more willing to regard therapy as a learning experience and, accordingly, do not set strict time limits on treatment, usually accepting up to 25 to 30 sessions. They are often rewarded with more enduring changes. Sophisticated middle-class and upper middle-class families are generally better disposed to the more extensive goals of long-term therapy, e.g., alteration of values.

It is surprising how much can be done in from 3 to 15 family sessions, but follow-up individual or group therapy may be required. Parents soon begin to realize that problems that have exploded into crises have a long history, the roots of which extend into their own early upbringing. Guilt feelings, defensiveness, indignation, and attacking maneuvers may give way to more rational forms of reaction when even a partial picture of the dynamics unfolds itself.

Individual therapy may be done conjunctively with family therapy or at phases when work on a more intensive level is required. For instance, a husband whose authority is being challenged may require help in mastering his anxiety and in giving him some understanding of what is happening. Or a mother and father may need education regarding the processes that go on during adolescence, which can help them understand and deal with their own rebellious child. The family therapist, accordingly, will need the combined skills of the individual therapist, group therapist, sociologist, educator, and social worker.

A number of ethical issues are involved in doing family therapy (Morrison et al. 1982; Hines & Hare-Mustin, 1978; Sider & Clements, 1982). Among these is the question of whose interest is primary, the individual being seen by the therapist or the family? Maintaining the integrity of the family and its other members may mean sacrificing goals that the individual wants desperately to achieve. For example, where a married man seeks a divorce because of an involvement with another woman, should the therapist encourage this knowing that a family with small children and a handicapped wife, who by herself

cannot manage the household, will have to be devastated by the family break-up? Another issue is the matter of confidentiality. Are therapists privileged to reveal information that seems vital for other family members to know? Further questions involve such points as to whether traditional ideas of an ideal family model should be held sacrosanct, whether the same therapist who does family therapy should also see individual members when they need it, how and when to arrange for conferences between outside therapists doing individual therapy with a group member and the family therapist, and whether members should be encouraged to reveal all, some, or no secrets they have concealed.

Doing family therapy is not without its risks, since the neurotic disturbance of one or more members may be the penalty the family is paying for holding itself together. Complementary symbiotic patterns may, when examined and resolved, tend to leave the members without defenses and worse off than before. A child's rebellion may be the only way that the child can preserve his or her integrity against a neurotic or psychotic parent. To interfere with this show of automony may prevent the child from achieving any kind of self-actualization, resulting in crippling inhibitions. Disorganization of the family structure may be a consequence of insight into the neurotic basis for the existing relationships. Divorce, for example, may enable a woman with colitis to live her life without abdominal pain. But she may find herself, as a result, in empty waters, isolated and burdened with children she may not be able to rear by herself. Her need for her husband may then become painfully apparent. Mindful of these contingencies, it is important to work against the too rapid precipitation of drastic changes in the family structure. It is here that life experience as well as professional experience will stand the therapist in good stead. Intensive individual psychotherapy may have to be employed at points where drastic changes in the life situation are imminent.

Some family therapists insist that the initial consultation include all family members. This is possible where family therapy is specifically requested. Usually one member of the family applies or is sent for help; this will necessitate one or more preliminary interviews prior to involving the entire family. Dealing with the resistence of a family to the securing of help, or of a patient to involving the family will call for skillful explanation and

negotiation. All members of the immediate family and important members of the extended family as well as intimate friends are best included at least at the beginning. The therapist must be prepared to deal with explosive anger and accusations, channeling and defusing these to prevent the withdrawal of key members and breakup of treatment before it gets a start.

Great tact is needed in avoiding the show of favoritism since members usually attempt to woo the therapist to their side in the arguments that ensue. A delicate point is how to handle personal "secrets" revealed to the therapist during an individual session, the exposure of which may have an unforseen effect, good or bad, on the family. It is best that the therapist treat the secret as confidential information and that members themselves make the decision when, if ever, to reveal what they dread bringing to light. Another important point is the matter of establishing a verbal contract regarding the areas to be dealt with and the hoped for objectives in order to avoid later misunderstanding. Sessions are usually held once weekly for 1½ to 2 hours. It goes without saying that the goals of selective problem solving will require fewer sessions than those of extensive reconstructive changes in the family members. Video recording with playback is a strikingly useful tool, and among the techniques is "crossconfrontation," during which a family unit is exposed to tape recorded excerpts demonstrating interactions.

Insofar as actual techniques are concerned (supportive, reeducative, and reconstructive), the existing styles are many even within the same practice models—structural, behavioral, psychodynamic, family systems, strategic, or experiential. An example of one stage of a structure, of diagnostic technique is described by Satir (1964a & b). The total interview consists of seven tasks.

The first task ("Main Problem") involves interviewing each family member separately, starting with the father, then the mother and the children in order of their age. Each is asked to discuss briefly: "What do you think is the main problem in your family?" They are each requested not to discuss their answers with other family members until later. Then the same question is asked of the group as a whole, gathered together in the

interviewer's office. They are requested to arrive at some kind of consensus. This will expose the interactions and defenses of the members.

The second task ("Plan Something") is composed of a number of parts: (1) The family as a whole is requested to "plan something to do as a family." This enables the therapist to see how the family approaches joint decisions. (2) Next each parent is requested to plan something with all of the children and then the children to plan something that they can all do together. (3) The father and mother are asked to plan something that they can do as a couple. This reveals data of the operation of family subunits.

The third task ("The Meeting") includes the husband and wife only. The question asked them is, "How, out of all the people in the world, did you two get together?" The role each spouse plays in answering this is noted.

The fourth task ("The Proverb") consists of giving the husband and wife a copy of the proverb, "A rolling stone gathers no moss." Five minutes are devoted to getting the meaning from the couple and coming to a conclusion. They then are asked to call the children in and teach them the meaning of the proverb. This enables the therapist to perceive how the parents operate as peers and then as parents, how they teach things to their children, and how the children react.

The fifth task ("Main Fault and Main Asset") requires that the family sit around a table; then each person is given a blank card on which to write the main fault of the person to the left. The therapist, after stating that this will be done, writes two cards and adds them to the others. These contain the words "too good" and "too weak." The therapist then shuffles the cards and reads out the fault written on the top card. Each person is asked in turn to identify which family member has this fault. This exposes the negative value system of the family and prepares the family for the phase of treatment when the task is assigned to avoid open and direct criticism. Following this, each person is requested to identify his or her own main fault. This is succeeded by the assignment for each person to write on a card what he or she admires most about the person to the left. The therapist also fills out two cards: (1) "always speak clearly" and (2) "always lets you know where

you stand." Experience shows that this part of the task, which is most difficult, exposes the positive value system of the family.

The sixth task ("Who is in charge") consists of asking the family, "Who do you think is in charge of the family?" This yields clues regarding how members perceive the leadership structure and their feelings about it.

The seventh task ("Recognition of Resemblance and Difference") requests the husband and wife to identify which of the children is like him or her and which like the other spouse. Then each child is asked which parent he or she believes to resemble most and the similar and the similar and different characteristics possessed in relation to both parents. The parents are also asked how each is like and unlike the other spouse. This points to the family identification processes.

These structured interviews last from 1 to 1½ hours and are employed as research diagnostic, and therapeutic tools. The network of communication patterns forms the basis for therapeutic intervention.

Further active procedures include (1) preparation of a list by each member of what they would like to see changed (this may act as a focus for negotiating a joint decision), (2) asking the family to discuss a recent argument, (3) asking each member to discuss what he likes and dislikes about other members, (4) changing the seating order periodically, (5) using puppets with members talking through them.

Zuk (1971a), Minuchin (1965, 1974b), and Minuchin and Montalvo (1967), have outlined a number of other strategies along structural lines that therapists have found useful. A search is instituted for alliances and splits in the family, the existing power hierarchies, family modes of conflict management with restoring authority lines, rearranging alliances, and reconstituting normal boundaries. Seating rearrangements and homework tasks are instituted to promote these objectives. Passivity on the part of the therapist will bring few rewards. The idea of allowing a family to engage in a free-for-all squabble often accomplishes nothing more than to encourage greater antagonism

between the members. Providing some structure in the session, on the other hand, can be most helpful. This is done by asking specific questions, directing the different members to explore certain areas of feeling, and suggesting what behavior changes should be undertaken. Goals for the family are set by the therapist, at the same time that the family members are encouraged to utilize their own resources in moving toward behavior change. For diagnostic purposes, if the therapist deems that it is appropriate to do so (and that the family will not be lost after the first session), it may be advisable to observe an undirected family in action in order to get a biopsy of the existing pathology and the distorted lines of communication. Once this is done, the therapist will be in a better position to structure, guide, direct, educate, and set goals.

In psychodynamic models insight and self-understanding are the goals of a family therapy with emphasis on the unconscious promotion of patterns of behavior, and the relationship of such patterns to past conditionings. The systems model, such as that of Bowen (1960), stresses the need for differentiation from one's family in order to achieve true identity. The understanding and resolution of relationship triangles that exist within the family is essential. A search for transgenerational transmission of problems is executed in quest of helping the patient achieve self-differentiation. In the strategic model resistance is not bypassed but joined, nondangerous symptoms may paradoxically be encouraged, and unusual home assignments given to the members. In assigning tasks in family therapy, the therapist attempts to alter the existing family system by asking members to engage in unusual activities that are foreign to their customary roles. This entails some risk because the assignments may spark resentment and sabotage. To avoid this, some therapists join the neurotic system by paradoxically emphasizing that for the time being the members must keep things as they are. Then, when the confidence of the family is gained, slow alterations in role are suggested followed by more extensive changes.

In the behavioral model, some therapists find a self-rating check list such as the one by Cautela and Upper (1975) useful as an assessment tool. An effort is made to identify the stimuli that activate symptoms and problem behaviors. Can these be controlled? How

does the patient participate in bringing them on? Further information is occasionally obtained by the patient filling out certain standardization forms (Walsh, 1967, 1968). Observation of the patient in actual situations where problem behaviors occur (with family at home, in phobia mobilizing situations, etc.) may be helpful if this can be arranged. The use of visual imagery to identify cognitive elements associated with problem behaviors has been described by Meichenbaum (1971). The next step is quantification of the problem. The frequency and duration of problem behaviors are charted, recording how often and under what circumstances difficulties occur (Homme, 1965). A man with headaches, for example, is given homework to report the days and times when his headaches appear, the immediate circumstances preceding the onset of headaches, the consequences of his headaches to himself and others around him, and what if anything he does to relieve them. The third step is examining the reinforcing contingencies. Are there any gains the patient derives from symptoms or problem behaviors, like sympathy from those around him, freedom from responsibility, etc. If so, can these reinforcers be supplied by altered activities less destructive to the patient? Is the patient aware of such gains? A woman with periodic fainting spells was brought to the realization that these episodes focused attention on her by her family. Assured regarding their functional nature by the family physician who had been summoned to several such emergencies, the therapist suggested the family show studied neglect after a spell. On the other hand, the members were to lavish attention and praise on the patient when she engaged in constructive family activities. The fourth step is outlining the treatment plan. Once sufficient information is available, a hypothesis is presented to the patient, the treatment plan is formulated, agreement is reached on the focus and goals, and a contract is executed.

In actual family therapy practice several of these models may be combined depending on the kinds of problems that must be treated. The management of socially aggressive children especially constitutes a challenge to parents in our contemporary society. Belligerent and hostile children can stir up trouble for the entire family. A number of approaches have developed dealing with this specific problem; one of the best known being the methods developed by G. R. Patterson and his associates (Patterson & Gullion,

1968; Patterson, 1971; Patterson et al, 1975). A social learning approach teaches families to discover the ways in which they reinforce the disturbed child's behavior and how unwittingly they are taught to respond destructively to the child's provocations, thus adding fuel to the fire. Some techniques include immediate *isolation* of the child for 3 to 5 minutes (no more) when misbehaving, writing a contract with the child defining desirable and undesirable behaviors and prescribing good behavior that may be swapped for privileges.

Hostility that emerges in family therapy often derails the therapeutic process. How to deal with it is an important technical question. Usually the hostility is directed at a selected member who may be the identified patient or a parent who may be blamed for the events leading to the crisis. Unless hostile interchanges are interrupted, the status quo will tend to remain. One method is to divert the hostility by asking questions related to nonpersonal areas: the housing situation, arrangement of rooms, daily routines, employment, certain historical events, etc. Some therapists, who feel they have a good relationship with the family, sometimes try to focus the hostility on themselves to take it away from the scapegoated member. This may be done by asking: "I wonder if there is something I have done or not done that upsets you. I am suggesting that you are really angry at me." Opening up areas of transference can be highly productive at times, but the therapist must be able to control his or her own countertransference. The best way of dealing with hostility, of course, is to interpret it in terms of the personality needs, and defenses of the attacker. This is possible only after a therapeutic alliance has been established, the family pathology comprehended, and the dynamics of the individual family members understood.

The most difficult problem that the therapist will encounter in family therapy is the need and the determined effort (despite protests avowing a desire for change) to maintain the status quo. Yet there are healthy elements that exist in each family on which the therapist can draw. It is important to emphasize these in therapy rather than the prevailing psychopathology.

Reconstructive family therapy may require sessions for several months or several years, depending on the family pathology and goals. It is often articulated with individual or group reconstructive psychotherapy for family members who need special help. The focus here is on intrapsychic experience. The methodology will vary with the relationship designs and the communication systems. The focus is on transferential reverberations and resistances. During the group session it may become apparent that the "identified patient" is not the one who needs most intensive help. Since the patient may be responding to neurotic provocations from another family member, the latter may be the one who should be seen individually. The following case-history brings this out:

> The primary patient is a 22-year-old man whose chief symptom is undiluted anxiety that interferes with his functioning. His relationships are highly competitive with males, the patient assuming a submissive self-castigating role. With females the patient detaches, fantasies of sexual engagement inspiring anxiety. At home the family is involved in constant quarreling, the patient engaging principally with his father, complaining that his father is excessively passive, manipulated by his mother, who is extraordinarily demanding of and ambitious for him. The two younger sisters display rebellious and withdrawal tendencies that have not yet become too pathological. In individual sessions the father presents himself as a misunderstood martyr. During the first few family sessions, however, it becomes obvious that he dominates and incessantly criticizes the family, especially the mother. The patient and sisters constantly take pot shots at him for acting too strong and dictatorial. The father responds with the expression that any weakness is inadmissible; it is important to deny illness or fear. This, it soon follows, is a pattern that prevailed in the father's own family. The father's father forced himself to work almost constantly as a duty. He died from a cardiac attack at an early age after refusing to see doctors for what seems to have been anginal pains. The father expresses admiration for his own father's "guts." During this recital the patient slumps in his chair interrupting with deprecatory comments. On questioning, he admits feeling defeated and under attack. Recognizing the father's role in stirring up the family, the father was referred for interviews with a therapist. This resulted in a rapid abatement of the patient's symptoms and a more congenial atmosphere at home.

A multiple family group of several families from the same background and socioeconomic level permits mutual exploration of common problems, the ability to observe difficulties in a more objective light, and the availability of a peer group to whom a family can relate who can help educate and be educated (Laqueur, 1968, 1972). The family code is more likely to become translated by a peer family than by a therapist who may come from a different background.

In reviewing 58 outcome studies of family therapy as compared to alternative treatments (i.e., individual therapy, group therapy, hospitalization, and drug therapy) Kniskern and Gurman (1980) found that 41 (i.e., 70 percent) of the family therapy outcomes were found to be superior, 15 (i.e., 25 percent) were found to be equal, and only two (i.e., 4 percent) were found to be inferior. Many of the primary patients in the studies complained of clinical problems (such as depressions) for which individual psychopathology traditionally is believed implicated. However, the authors, probably with good reason, state that interactional difficulties, such as marital problems, are the most likely conditions to respond best to family and conjoint marital therapy. Compared to such approaches, individual therapy, concurrent marital therapy (where one therapist sees each partner separately), and collaborative marital therapy (where each spouse is seen by different therapists) produce less impressive results. What is interesting, nevertheless, is that individual psychopathological difficulties, other than interactional problems, do respond well to good family therapy methods. Family therapy is highly desirable because the problems do not start or stop with the patient. The least that can be accomplished is the achievement of better lines of family communication and a softening of scapegoating. Family therapy may be one of the most effective ways of reducing rehospitalization, in addition to safeguarding maintenance medication. Many problem families exist, the members sometimes being entangled in complex interpersonal difficulties that seem impossible to unravel. The untrained therapist is apt to encounter insuperable difficulties with these families. On the other hand, an effective family therapist may accomplish good results impossible to achieve by another method.

MARITAL (COUPLE) THERAPY

Marital therapy is important for a variety of reasons. First, it presents an in vivo scan of the relationship operations of the patient who seeks treatment vis-à-vis the marital partner. From a diagnostic viewpoint this is advantageous because it reduces speculation about the patient's interpersonal psychopathology. Second, it enables enlisting the cooperation of the spouse toward helping the patient execute a therapeutic program for management of severe symptoms by serving in the role of cotherapist. Third, it permits

observation of and dealing with emerging anxieties and defenses of the spouse that ordinarily might sabotage the progress being made by the patient. Fourth, it permits a more direct entering into and correction of the communication system of the patient as it displays itself in emotional interchanges. Marriage is a vehicle through which people constantly try to satisfy an assortment of needs and influences. It is often regarded by neurotic people as a way of overcoming defects in their own development and handicaps in their current life situation. The marital partner is therefore cajoled, seduced, or terrorized to perform and is held responsible for any deficiency in projected assignments. This imposes an enormous burden on the healthier of the two spouses since the demands made are usually impossible to fulfill.

On top of it all, the habitual hostilities, anxieties, defenses and coping devices that have plagued the individual since childhood become transferred over to the most conveniently available recipient—the spouse. The expression of such improprieties is complicated by reactive guilt feelings, remorse, and attempts at reparation, which in turn invite attack from the injured spouse, perpetuating the continuing chain of indignation, anger, and counterattack. Couples often get locked into this sadomasochistic circuit. It would seem that the battling partners need each other to act out mutual neurotic needs, which insidiously may keep the marriage together while serving as a platform for combat. A final neurotic gesture is the blaming of each other for personal shortcomings, mediocrities, failings, and even symptoms. Disillusionment is inevitable unless the spouses are willing to compromise. But where the needs of a marital partner are too insistent and the initial idealization and expectancies are too high, the explosive mixture gradually accumulates until detonated by some (perhaps minor) incident that will tend to blow the marriage apart. One severely neurotic member preying on a more healthy spouse is bad enough, but where both members are working on each other, the atomic stockpile builds up to frightening proportions.

Marriage calls for intricate adjustments. It involves not only dealing with one's personal difficulties but also the normal problems and the irrationalities of one's partner. Because marital adjustment is one of the most difficult and stressful human challenges, it

is little wonder that so many people get disturbed under its impact. Problems in marriage and difficulties with a spouse account for almost 50 percent of the reasons why people seek professional help (Martin & Lief, 1973; Sager et al, 1968).

The task of marital therapy is twofold. First, it endeavors to help the patient overcome disturbing symptomatic complaints. Second, it strives to keep a shaky marriage together where there is even a small chance of its success, strengthening the couple's psychological defenses in the process, or, if the marriage cannot be saved, helping the partners separate with a minimum of conflict and bad feeling, particularly where children are involved.

Marital relationships are commonly sabotaged by the emotional defects of one or both partners. Where a marriage has deteriorated and the couple is motivated to work toward its betterment, there is a good chance that with proper treatment the relationship will improve. This does not mean that all marriages can be saved. In some cases the "chemical" combination of the union is irreconcilably explosive. Husband and wife are too much at loggerheads in their ideas, values, and goals to achieve even a reasonable meeting of the minds; or there is a barrenness of love and unabating cruelty toward each other; or sexual incompatibilities exist of too great severity; or there is uncontrollable and continued violence toward the children. Many couples are already virtually separated but still living together interlocked in a marital death grip from which they cannot loosen themselves before coming to therapy. Here the marriage may not be worthy of saving. The goal, as has been mentioned, may be to help the couple master their guilt and achieve the strength to separate. Generally, however, where couples are not too contentious and are willing to face their feelings and examine their behavior, marital therapy can help a marriage survive.

Marital therapy techniques draw from multiple fields, including psychoanalysis, behavior therapy, family therapy, group therapy, marriage counseling, child therapy, and family casework. Although the objects are the mastery of neurotic suffering and alteration of the relationship between the couple, a hoped-for, and usually serendipitous objective is

intrapsychic change, which surprisingly may come about in those with a readiness for such change and relief from the distracting cross-fire between the two spouses. Conceptual schemes for the actual conduct of marital therapy are not unified, but the most successful approaches stress the importance of communication (Watzlawick et al, 1967; Minuchin, 1974) toward effecting changes in the transactional system. A system behavioral approach is particularly helpful, concentrating "on observable behavior and rules of current communication (Bolte, 1970; Hurvitz, 1970; Kotler, 1967; Mangus, 1957) without immediate recourse to a historical 'Why'" (Berman & Lief, 1975).

Greene (1972) has pointed out that the great variations in marital patterns require flexibility in therapeutic techniques. He proposes a "six-C" classification of therapeutic modalities:

I. Supportive Therapy

    A. Crisis counseling

II. Intensive Therapy

    A. Classic psychoanalytic psychotherapy

    B. Collaborative therapy

    C. Concurrent therapy

    D. Conjoint marital therapy

    E. Combined therapies

      1. Simple therapy

      2. Conjoint family therapy

      3. Combined-collaborative therapy

      4. Marital group psychotherapy

"Crisis counseling" stresses sociocultural forces in the "here-and-now" situation. The

"classic approach" is the usual dyadic one-to-one relationship with both partners seeing separate therapists who do not communicate. The focus here is on the individual's personal difficulties with the marriage as the backdrop. It is used where one partner has severe acting-out problems of which the other partner is unaware (e.g., continuous infidelity or homosexuality), where there is preference for this approach, where one partner refuses to share the therapist, and where spouses have widely divergent goals in terms of the marriage problem. The "collaborative approach" is similarly dyadic, but it sanctions communication between the two therapists by regularly scheduled meetings (Martin & Bird, 1963). The same therapist treats both partners individually in the "concurrent approach," which is aimed at bringing about insight into behavior patterns as they affect each member (Solomon & Greene, 1963). This approach results in the lowest divorce rates. Where strong sibling rivalry attitudes exist, or where there are severe character disorders, psychoses, or paranoid reactions, the concurrent approach cannot be used.

These dyadic methods may be educationally oriented, focused on the marital relationship and on strategies of straightening it out by utilizing a variety of counseling and behavioral techniques. Should it become apparent that the patient has a severe personality or emotional problem being projected into the marital situation, individual psychotherapy may be indicated. In a considerable number of cases the marital equilibrium will be restored, and the spouse will change with the stabilization and better adaptation of the patient. However, where the spouse is incapable of change and the patient is unable to adapt to this impasse, the marriage will continue as a traumatic source for both.

The "conjoint marital approach," which is the most common form (Satir, 1965; Fitzgerald, 1969), is used both for counseling and intensive therapy. Here the partners meet jointly with the therapist at the same session. This approach fosters communication between the partners and brings out more clearly the marital dynamics. With the "combined therapies" (1) the "simple" form combines individual, concurrent, and conjoint sessions in various arrangements; (2) "conjoint family therapy" includes one or more of

the children; (3) the "combined-collaborative" form permits regular meetings of the partners together with the two therapists at the same session; and (4) "marital group therapy" consists of group therapy with four couples and one or two therapists (Blinder & Kirschenbaum, 1967; Framo, 1973).

Thus, there are many ways of working with couples but one of the most popular short-term methods is based on a social learning model and involves no more than 12 to 16 one hour to 1£ hour sessions. (Hahlweg & Jacobson, 1984; Jacobson & Margolin, 1979; Lieberman et al. 1980; Stuart, 1980). Such behavioral marital therapy focuses on securing better communication, relationship, conflict reducing, and problem solving skills through an active, directive approach aided by consistent assigned homework exercises. Usually the therapist sets the agenda with input from the couple regarding progress or difficulties with the homework assignments.

We would make an assumption that if the couple appears for therapy or counseling they are interested in staying together. We would assume also that at one time they had a good relationship. Accordingly, it might be a strategic start in therapy to ask the couple how they originally happened to meet and how they got along at the beginning. From this the history of their difficulties would naturally follow. In recalling the circumstances of their early meeting and the congeniality that existed at one time, it may be possible to get the couple off the track of their bitterness and disillusionment with each other. Many couples forget that they have had a pleasing or happy background at one time, a foundation on which they can repair their present demoralization and wreck of a relationship. Talking about a happier past may give the two partners some hope that they can overcome their bitterness and develop better modes of communication and problem solving.

The actual techniques that are employed will vary with goals in treatment and whether we envisage therapy as solely a means of restoring harmony to the distressed couple or whether structural personality changes in one or both partners are possible. Where deep personality problems exist in one or both of the members, marital therapy,

which is a short-term approach, will probably need reinforcement with individual dynamic therapy, since negotiation of differences may prove to be of no avail. Some therapists start with the short-term goal and only later move toward a more intensive process when it becomes obvious that severe personality problems interfere with progress.

In certain cases one member comes for treatment with the presenting complaint of a symptom, such as migraine, depression, agoraphobia or other neurotic disorders even though the true source of stress that provokes the symptom lies in the marital relationship. Indeed, a denial mechanism may exist of such severity that the therapist will have to approach the marital problem obliquely. In most cases however marital stress becomes an important complaint, but the patient may believe that nothing can be done about it since, in the opinion of the patient, the partner refuses to cooperate.

It is rare that marital difficulties are totally one-sided. It is rare, too, that the mate will not come in to see the therapist if the latter handles the situation correctly. The presenting patient may be asked if he or she can convince the mate to come in to see the therapist. The following is from a recording of an interview:

> *Pt.* She's impossible. She won't listen. She says I'm nuts and it's all my doing—the mess we're in. I can't talk to her.

> *Th.* Do you think she would come into see me if you asked her?

> *Pt.* I already asked her to come here with me, and she refused. Frankly, I think it would be a waste of time.

> *Th.* You must have had some hope that coming here would help the situation.

> *Pt.* I suppose I'm looking for magic. I know she won't change.

> *Th.* Would you mind if I telephoned her to come to see me about your problem? I would tell her it will be of help to me in helping you if she could give me an idea of what you're like. *(smiles)* Sometimes this defuses things. She won't feel I'm getting her here to accuse her.

> *Pt.* By all means, maybe she'll come in if you convince her it's all my fault.

> *Th.* I'm sure it isn't, but I'll do my best to ease her into talking things out.

The entire object of getting the mate into the therapist's office is to start a relationship with her or him. By listening with an empathic ear, emphasizing how difficult things must be, the therapist usually can gain confidence. In the case cited the following telephone conversation took place:

Th. Is this Mrs. B?

Mrs. B. Yes.

Th. This is Dr. Wolberg. I hope you will forgive me for calling you. I know it's an imposition. But your husband came in to see me, as you know.

Mrs. B. Yes, I do.

Th. I know it's been extremely difficult for you. But it would help me to help your husband if you could come in and tell me a little bit about him, and about what's happening.

Mrs. B. If I came in, I wouldn't stop talking. *(laughs)*

Th. So much the better, you could give me an idea of him and what has been going on. It must have been very rough.

Mrs. B. I'll be glad to come in.

The interview with Mrs. B went along smoothly, and little difficulty was experienced in starting therapy with the couple.

Unless one of the marital partners is paranoidal or completely unwilling to alter the marriage relationship, it should not be too difficult to convince both members to work with the therapist. The design of therapy will vary with the presenting problems and the preferred style of the therapist. Some therapists begin joint sessions immediately after the initial interview. Others prefer seeing the mate alone to assess the problem before starting joint sessions. It is helpful to ask each partner about the relationship their parents have had with one another. Sometimes just talking about this, patients discover that they are acting out roles patterned after parental models.

Where a marital problem is acknowledged by both partners and they seem willing to do something about it, the couple may be seen together right from the start of therapy. But where denial mechanisms are strong, it may be advantageous for the same therapist to

begin individual therapy separately with both spouses, different appointments being given the two (*concurrent marital therapy).* They may not yet be ready for couple therapy, which can be instituted later. Where hostility between the partners is high, and appropriate communication is difficult, the therapist may be able to start a relationship individually with each partner, being wisely careful not to fall into the trap of being used by either against the other. It takes a good deal of ingenuity to do this. The therapist may anticipate competitiveness for attention, desires to be the preferred one, misinterpretations of what the therapist says to support an importunate demand on the part of one spouse, and resentment at the partner and therapist for presumed collaboration. Where the spouse of the patient seeking help refuses to see the therapist, one may try a referral to another professional or suggest that there be a personal selection of a therapist. In such a case the different therapists sometimes may have conferences to exchange information and discuss developments and plans (*collaborative marital therapy).* Where the spouse absolutely refuses any kind of therapy, treatment may be started with the presenting patient alone (*individual marital therapy),* trying to influence the reluctant partner indirectly.

Assuming that one is finally able to bring the partners together in therapy, the initial session may be initiated by asking each of the partners to discuss why they are coming for help as each sees it. The couple may then be queried as to how they originally met and how they happened to decide to get married or to live together. Whenever the two get into an argument or fire charges at each other, the therapist may interrupt the negative exchanges and get them back to talking about positive things that were or are happening. Some therapists find it helpful to spend at least one session alone with each of the spouses, reviewing the past histories, experiences, and problems of each particularly their relationship with each other, sexual and otherwise. At individual sessions, information may come up that will not readily be exposed in joint sessions. The matter of confidentiality should be stressed. Some therapists rely heavily on questionnaires to fill out such as the "Areas of Change Questionnaire," "Marital Status Inventory," the "Dyadic Adjustment Scale," the "Marital Precounseling Inventory," the "Marital Activities Inventory," and the "Sexual Interaction Inventory" (Wood & Jacobson, 1985), which will

help in developing a treatment plan.

We usually find that central to many of the problems of marital couples are difficulties in communication. Behavioral approaches to communication training contain a number of procedures geared toward acquisition of communication skills with provision for feedback instructions and behavioral rehearsal. Dynamically oriented therapists may use these as part of their treatment with marital problems.

During joint sessions the therapist will have observed patterns of communication issuing out of the interaction of the couple, and will be able to offer the couple information about their verbal and nonverbal exchanges (criticisms of one by the other, attacks, praise, protectiveness, etc.) in descriptive terms without interpreting the deeper meaning or motivations for such exchanges (which, of course, can be made in a dynamic approach). Immediate feedback to both partners of provocative and disturbed communication patterns may help break the chain reaction of attack, counterattack or retreat that is characteristic of the couple's verbal interactions. With adequate preparation, video feedback may also be used with some advantage. In employing feedback the therapist should not lose any opportunity to comment on *positive* communication patterns in the hope of reinforcing these. Thus when a partner praises his or her mate the therapist may say, "I liked the way you complimented (or praised) him (her)."

Generally couples are not fully aware of their abrasive thrusts at each other or their corrosive answers to comments. Following an unjustified verbal blast, the therapist may ask a partner to reconsider what the spouse has said and then to give an alternative response. Sometimes the therapist may model a response, playing the roles of both the husband and the wife to avoid a sense of discrimination or favoritism. Cotherapists, if this is the format, may each play the role of one of the spouses and model communication.

Behavior rehearsal is an important part of the relearning process, in that couples may practice in order to increase their skills of communication. Here the therapist provides instructions and modeling if necessary, giving continuing feedback. A valuable technique is *role reversal,* each spouse taking the role of the other in talking about a

special situation. In this way, marital partners may teach each other problem-solving skills.

One of the most common difficulties is the insistent use of aversive control strategies by one or both partners ("If you do that again, I'm going to leave you"). Verbal threats and coercion increase until the only way left to deal with mutual intimidation is by detachment techniques, which cause estrangement from one another, further enhancing conflict. By arriving at some sort of agreement regarding areas of change through discussion, an avenue is opened for problem-solving which can be kept alive and expanded by proper reinforcements. Before changes in behavior can be proposed, however, there must be a clear definition of the problem (Jacobson & Margolin, 1979).

The sessions in a short-term format are generally highly structured and understandably call for a good deal of empathy, flexibility, and playing of many roles. "The therapist serves as a director, sympathizer, teacher, evaluator, instigator, and a juggler balancing these roles while providing perspective and insight as necessary." (Wood & Jacobson, 1985).

It is important to inform a couple that they should expect no immediate improvement in their relationship but after a few sessions devoted to studying the problems, they should *if they cooperate with the procedures that will be prescribed,* notice that matters between them are taking on a more optimistic turn. In this way, one can forestall the disappointment that follows when magical expectations of immediate change do not come to pass. Generally, some precipitating factor will have brought the marital conflict to a head and the couple will be anxious to talk about it. The discussion, arguments, angry displays, and frustrations that become manifest will be like a biopsy of the basic pathological issues. A therapist who steps into a marital melee will have more than was bargained for, particularly when each of the participants attempts to recruit the therapist as an ally against the other partner. It is here that the therapist may become emotionally involved, being tempted to fulfill the roles of arbiter, judge and high priest, rendering verdicts, making decisions, establishing criteria, and setting values. Personal

standards and prejudices will unfailingly impose themselves and the therapist's own unresolved problems will vigorously come to the fore.

A great deal has been written about countertransference in psychotherapy, but in no other area than marital therapy is it apt to be so pronounced, particularly in cases where the therapist's own marriage is a mess. No wiser words have been said than for the marital therapist to look at his or her own marital values before the marriages of others can effectively be dealt with. Even though a therapist has some personal problems, an awareness of these and of how judgment may be warped by certain offensive behaviors or attitudes on the part of the therapist's patients should permit greater objectivity. The therapist therefore should carefully avoid being brought into assuming the role of a referee or judge who decides who is right or who is wrong; or ally with one or the other antagonists. This may be difficult for some therapists to do since it is natural to try to assess blame. A guiding principle in marital therapy is to try to search out and to enhance the strengths of a relationship not the weaknesses. Consequently, the therapist may emphasize positive factors that exist and to remind the couple that their relationship has not always been a bad one. A good deal of time may also have to be spent in talking about existing environmental problems that have initiated or that are sustaining the difficulties between the two.

It is important from the outset not to express any condemnatory attitude toward either partner for behavior or characteristics that they are exhibiting either in the interview or outside. There will be ample opportunity later to interpret what is happening, and this is aimed toward insightful rather than punitive objectives. A woman may resent the role that she believes her husband expects of her as a dutiful wife, and she may respond by being defiant and neglectful. Her husband may counterattack by detaching himself from her and the family and by impotence. The chasm of misunderstanding grows deeper and deeper until each has accumulated an enormous bag of justifiable grievances. A therapist who takes sides will probably lose both patients. Once the dynamics become clear, the therapist may point out the inevitability of misunderstanding on the basis of the background, upbringing, value systems, and

pressures that are being exerted by the partners on each other without laying down strict rules about male and female roles. If the therapist has the confidence of the couple, they will turn to him or her for some constructive guidance, which may be offered without being dictatorial about what should be done. It may be pointed out that difficulties exist in all relationships and that some compromise is always necessary, the ground rules to be negotiated through constructive communication.

Willy-nilly, the therapist will find a role assigned, by both members as an arbiter, guide, and potential ally to justify mutual opinions, disgruntlements, and claims. It takes a good deal of fancy footwork to avoid being maneuvered into a judgmental role. Countertransference is to be expected, and one's ability to detect one's own prejudices and predilections borne out of one's background and experience will help keep the therapeutic situation afloat. There are instances where one mate is manifestly unfair in behavior toward the other, or in liberties assumed, and the therapist may find it difficult to remain neutral. It will take ingenuity to get one mate to alter his or her behavior or to help the other member accept the situation with whatever compromises can be negotiated.

For example, one of my male patients who had married late in life, insisted on staying out late "with the boys" two nights weekly. His wife objected on the basis that she felt neglected and lonesome. At interview it was apparent that she suspected infidelity, which she tried to substantiate on the basis of decreasing frequency of intercourse. I was able to convince her, from my interview with her husband, that staying out late constituted a means by which some husbands maintain their independence which is being threatened by feelings of increasing devotion to their wives. This is what happened in this particular case. The husband, a detached person, had avoided close involvements with women until he met his wife. Thwarting his need for independence would, I hazarded, result in increasing detachment from her as a defense and perhaps a development of impotency. The patient's depression, related to hostility at being challenged and "browbeaten," lifted as his wife recognized the dynamics and accepted her husband's need for greater freedom. Joint sessions during which each partner unburdened themselves and

traced their attitudes to past experiences resulted in a firming up of the relationship.

Taking an area in which a desire for change has been expressed, each member may be asked to discuss briefly how he or she believes the issue may be resolved with the object of negotiating an agreement on a suitable solution. Communication and problem-solving skills are studied here. Some therapists provide each of the couples with a checklist and a rating scale to score daily happy and non-pleasing exchanges (Patterson, 1976; Weiss & Cerreto, 1980). These instruments have a therapeutic value in pointing out areas of possible improvement as well as providing the therapist with a means of comparing the appraisals of both members.

All of the foregoing measures are useful in devising a treatment plan that is discussed with the couple and to which the couple can add input. Agreement to abide by the terms of the plan is best obtained to enhance the collaborative effort. To repeat, the therapeutic process focuses on increasing positive and eliminating coercive and aversive exchanges. It is hoped that this will spontaneously be developed and carried through by both members. Any difficulty that emerges offers an opportunity for trouble-shooting to analyze the problem and to provide alternative solutions ("brain storming"). Communication skills are taught by suggestion and modeling and are practiced both during sessions and as part of homework. The ability to accept criticism and to have the courage to avoid responding in kind to a negative remark or act is encouraged.

Contracts may be negotiated to try to help firm up behavioral changes. Contingency contracting which operates on the basis of quid pro quo conciliations plays an important part in marital therapy, particularly in its behaviorally oriented forms. Here couples by negotiation come to a written agreement of what each member has to do in the relationship to produce changes with which both members are in harmony.

In contingency contracts each partner promises to alter some aspect of behavior the other partner finds disagreeable. Contingency contracting is for those in whom verbal resolutions alone are not sufficient to put a restraint on their impulsiveness. The presence of a legal-like document helps to promote compliance with prescribed behaviors. When

carried out, positive actions produce reciprocal pleasing responses that act as reinforcers for mutually constructive behaviors. The contract should be specific, spelling out exactly the kind of activities to be executed; otherwise arguments may break out as to meanings of vague expressions. The behavioral changes of each should also be sufficiently equivalent so that both partners feel they are getting an equal share of benefits.

One must keep in mind that the very behaviors that a spouse grumbles about may subversively be reinforced by certain actions of the offended spouse because such behaviors satisfy unconscious needs or defenses in the latter. Thus, a woman complaining about infrequency of sexual relationships may during the sexual experience act in a disinterested, bored, or sarcastic manner. In this way, she punishes the very behavior she desires to increase. When we investigate why these ambivalent attitudes exist, we may find that, in spite of a surface interest, sexuality is laden with a great deal of fear, guilt, and shame. Or her anger at or disgust with her husband forbids carnal intimacy. Or perhaps there is a prohibitive incestuous barrier to sexual activity. Such dispositions, which have their origin in earlier conditionings, might cause us to anticipate that the wife would be unable to halt her punishing activities even though in the contingency contract she promised to do so. This may actually be the case in instances where underlying needs and defenses are intensely and urgently pressing. On the other hand, even where such tendencies act as negative reinforcers, experience teaches that people can exercise a considerable degree of willful control over inner impulses, and through self-discipline and continuing practice gradually master adverse predispositions. It is, of course, helpful to provide in the contract positive reinforcements of some kind for the control of repugnant reactions. In the case cited, the husband may reward his mate for refraining from her customary reactions with praise and some material or behavioral bounty that is significant to his wife. Where no improvement in the sexual situation occurs, however, it may be necessary to utilize a more psychoanalytically oriented approach aimed at expanding the couple's understanding of their motivations and behavior.

The matter of confidentiality is especially important. The patient is told that information given in private sessions will not be revealed to the other member of the

couple. The members may be encouraged to talk freely and not hold anything back, but that is up to them. The therapist will not bring up topics that are taboo unless asked to. This encourages the disclosure of secrets so one can work with what comes out.

It is to be expected that where couples have been living in neurotic symbiosis that an alteration in the accustomed response of one member to the other's provocations will arouse anxieties in one or both members. Resistance will generally take the form of a desire to halt joint sessions. Interpretations of the resistance and the reasons behind it are necessary to keep the couple in therapy.

During sessions one may observe physical movements between husbands and wives that serve as forms of nonverbal communication to convey emotional meanings. These are in the form of approach and separation movements and, at different stages of treatment, seating rearrangements among couples, which may be explored with the object of analyzing the underlying dynamics. In the process one may observe one's own countertransference responses, which one should attempt to understand and to resolve.

While the therapist may make suggestions from time to time, it is vital that patients be made aware of the fact that they must work out their own solutions utilizing their own free will.

There are several impasses that may occur in marital therapy. One of the most difficult is the spouse who has a fixed position about divorce. This usually means that he or she does not want therapy except to try to convince the mate to accept the position. Often the lawyer of one mate may be responsible for this impasse. Another problem is when one member of the couple is in individual therapy with another therapist who differs in philosophy and goals from the marital therapist. Then a conference with the other therapist may be in order. Once contact has been established, coordinated therapy may be essential to break up an impasse. Where the marital breakdown has proceeded to a point of no return, both therapists may encourage utilizing divorce mediation procedures to minimize the trauma on the partners and children.

Important adjuncts to marital therapy are role playing and sexual therapy methods (Masters & Johnson, 1970; Kaplan, 1974). Alger (1967a) illustrates the use of the paradigmatic approach in marital therapy, the goal of which is to imitate a pattern one of the partners displays by acting out a part. Alger (1967b) also employs videotape recordings and playback in couple's sessions. His technique consists of a video recording of the first 15 minutes of a joint marital session, which is immediately played back over a television monitor. The participants may ask to stop the recording at any point to comment on the effect of their behavior on others. Viewing themselves as they talk and interact stimulates a great deal of feeling and expedites communication. Video viewing is now being employed with increasing frequency (Alger & Hogan, 1969; Berger, MM, 1969).

The presence of two therapists (cotherapists) lessens the possibility of exclusive alliances and of a dyadic impasse (Alger, 1967a; Markowitz, 1967). Each of the therapists may function as an alternate ego for one of the patients aerating ideas and sentiments the patient does not dare express. In this way the patient may gain the strength to face impulses and attitudes on the periphery of awareness. Substantiating the value of cotherapy are four truisms: (1) Two heads are better than one. (A second therapist may be able to illuminate areas missed by the first. Each may be able to correct bias and detect countertransference in the other.) (2) One therapist may support a patient under attack by mate when he or she needs a helping hand. (3) One therapist may engage in confrontation and challenging maneuvers while the other therapist interprets reactions of the patient or supports the latter if necessary. (4) Two therapists lessen the danger of the therapist being utilized as a judge or as a guru who knows and gives all the answers.

A mixed male-female team has advantages in providing opportunities for identification. The disadvantages of cotherapy are competitiveness and friction between the therapists and alliances of one therapist with one patient against the other therapist and the other patient. These may be modified by conferences together or in some cases with a trusted colleague acting in a supervisory capacity. There are advantages and disadvantages in conjoint marriage therapy with a husband-and-wife team (Bellville et al, 1969). The inevitable differences arising between the therapist couple are more volatile

and unrepressed than in an unrelated couple and can threaten the therapeutic process. In their resolution, however, they offer the patient couple an opportunity to observe how a well-related couple negotiate differences, make compromises, and adapt themselves to each other's individual way of looking at things. It stands to reason that the therapist couple both must be reasonably adjusted, have an understanding about the therapeutic process, and preferably have been in personal therapy or coupled therapy themselves.

The behavioral approaches described may not be able to help marital difficulties that are too firmly anchored in intrapsychic disturbances. The prescription of tasks and exercises that are intended to influence couples to be less abrasive toward each other, to communicate more constructively, and to foster a balanced relationship will therefore not succeed in those couples whose behavior is intractably motivated by urgent unconscious needs and impelling inner conflicts. For example, if a wife transferentially relates to a husband as if he represents a hateful brother with whom she was in competition during early childhood, she may resent being nice to him and continuously fail in her therapeutic assignments. A husband who is struggling with a dependency need, idealizing his wife as a mother figure who must love, nurture and take care of him, may be unable to give up acting irresponsibly, resisting the independent role his wife insists he must assume as a condition for more fruitful living together.

We should not minimize the utility of the various persuasive, behavioral, and cognitive techniques practiced to expedite marital congeniality. They can be valuable, but they will miss their mark if one utilizes them while ignoring the enormously important developmentally inspired motivational forces that are constantly maneuvering marital partners to act against their best interests. These more insistently dictate the terms of conduct than any injunctions, maxims, precepts, recipes, prohibitions, and interpretations.

Whether or not the therapist deals with factors of transference or projective identification and utilizes dreams will depend on the training of the therapist, the goals desired, and the level of understanding of both patients. Dramatic results are sometimes obtained where marital partners associate to each other's dreams. This helps them

become less defensive with each other. By the same token, transference phenomena brought out into the open as they relate to the therapist and to each other, aired without restraint, will bring forth emotions that with proper interpretation can prove helpful. Sager (1967) points out that it is important for anyone doing marital therapy "to be aware and work through reactions to, and general philosophy regarding, maleness and femaleness, maturity, marriage roles, career, money, relationship to children, and a host of other cathected concepts." Flexibility and tolerance for values other than their own are important assets for marital therapists.

The hope is that change occurring in the office and at home will be generalized to other relationships. Any relapses provide opportunities to anticipate future problems. The couple is requested to search for any cues that can trigger difficulties and to practice dealing with them before trouble precipitates.

In many cases progress is enhanced by couples working together in couple groups. As communication improves and relationship skills consolidate, intervals between sessions are increased. Couple groups may continue for a while without the presence of the therapist. Problems and relapses are anticipated and ways of managing them are discussed.

Follow-up sessions with the marital partners after therapy are wise to prevent a falling back into the old destructive patterns, the intervals between follow-up visits gradually being increased in the event improved adjustment continues.

53
Homework Assignments

One of the most neglected aspects of psychotherapy is assigning homework through which patients can facilitate means of controlling or eliminating self-defeating patterns. It is often assumed that the lessons absorbed in the therapist's office will automatically carry over into everyday life. This cherished hope does not always come to pass. The average patient generally dissociates the learnings in the therapist's office from behavior at home, at school, at work, and in the community. After psychologically purging oneself during a session, outside the office the patient often slips back into familiar patterns. It can be helpful, therefore, in consolidating therapeutic gains to insist that therapy does not stop with the exit from the treatment room. The patient must put into practice what is learned during the sessions in order for any change to register itself permanently. And when treatment has ended, the patient will certainly need to reinforce new modes of coping by continuing homework; otherwise, in returning to the customary environment, relapse may be inevitable.

The assigned tasks are usually related to what is immediately going on in therapy, whether they involve exploring the nature of one's problems, charting the frequency of symptoms and recording the circumstances under which they appear, recognizing the constructive and destructive elements in the immediate environment, observing behavioral patterns and reinforcing those that are adaptive, picking out situations that enhance or lower self-esteem, studying one's relationships with people, examining dreams and fantasies, or seeing what resistances block the putting of understanding into productive action. Practice sessions devoted to assertive and other constructive forms of behavior are especially helpful. Some of the assigned exercises strive to inculcate new values and philosophies that contribute to a more productive adjustment. A relaxing and ego-building audio recording as well as assigned readings are additional useful accessories.

Instructions may be given the patient along the following lines:

1. *Look squarely al your immediate life situation.* What elements are to your liking? Are these elements good for you and constructive, and do they need reinforcement? Or should they be minimized or eliminated because they get you into problems? What elements are destructive? What can you do to make them less destructive? Should they be eliminated completely? How can you go about doing this? Once you have decided on a plan of action, proceed with it a step at a time, doing something about it each day.

2. *What patterns of behavior would you like to change, patterns that should be changed?* How far back do they go? Do you see any connection between these patterns and things that happened to you as a child? Realize that you may not have been responsible for what happened to you as a child, but you are responsible for perpetuating these patterns now, for letting these patterns ruin your happiness at the present time. *You can do something about them.* When you observe yourself acting these patterns out, STOP. Ask yourself are you going to let them control you? Say to yourself, "I am able now to stop this nonsense," *and do it.* For example, every time you beat yourself and depreciate yourself, or act out a bad pattern and say you are helpless to control it, are you doing these things to prove that you are defenseless and that therefore somebody should come along and take care of you? Are you punishing yourself because you feel guilty about something? It is easy to say you are a crippled child and that some kind person must take care of you. But remember you pay an awful price for this dependency by getting depressed, feeling physically ill, and destroying your feelings of self-worth. Every time you control a bad pattern, reward yourself by doing something nice for yourself, something you enjoy and that is good for you.

3. *What patterns of behavior would you like to develop that are constructive?* Would you like to be more assertive for instance? If so, plan to do something that calls for assertiveness each day.

These assignments may be given verbally to the patient in the therapist's own words. If a relaxing and ego-building cassette tape has been made, remind the patient that results are contingent on utilizing the tape preferably at least twice daily. Keeping a diary and jotting down one's reactions and discoveries may prove to be a valuable adjunct.

In addition to the above, some patients may benefit from a printed or typewritten set of directions, such as suggested below. These may be adapted to specific problems. The list may be given to and discussed with the patient shortly before termination.

1. *Whenever you get upset or your symptoms return or get worse, ask yourself why this is so.* Try to establish a relationship between the symptoms and happenings in your environment. Did something occur that made you feel guilty or angered you or that you didn't like? Are you punishing yourself because you feel guilty? Is something going on in your relationship with a person who is close to you or with the people who are around you that is hard for you to take? Or is something bothering you that you find difficult to admit even to yourself? It is often helpful to keep a written record of the number of times daily that your symptoms return and approximately when they started and when they stopped. If you jot down the things that happened immediately before the symptoms started, and the circumstances, if any, that relieved them, you may be able to learn to control your symptoms or eliminate them.

2. *What are the circumstances that boost and the things that diminish the feelings about yourself?* When do you feel good about yourself and when do you feel bad? Are these feelings connected with your successes or your failures? What makes you feel inferior, and what makes you feel superior? Do you feel better when you are alone and away from people, or do you feel better when you are with people? What kind of people?

3. *Observe the form of your relationship with people.* What tensions do you get with people? What kind of people do you like and dislike? Are these tensions with all people or certain kinds of people? What do people do to upset you? In what ways do you get upset? What do you do to upset them or get yourself upset when you are with them? What do you do and what do they do that tends to make you angry? What problems do you have with your parents, mate, children, boss, associates at work, authorities, people in general? Do you tend to treat anyone in a way similar to the patterns that you established with your father, mother, siblings? How is your reaction to people above you, below you, equal to you? What are your expectations when you meet a very attractive person of the opposite sex? Do you try to make yourself too dependent on certain people?

4. *Observing daydreams or night dreams.* A useful outline for observing the meaning of one's day or night dreams includes three questions: What is

your feeling about yourself in the dream? What problem are you wrestling with in the dream? By what means do you reach, or fail to reach, a solution to the problem that presents itself in the dream?

Recurring dreams are particularly significant because they represent a continuing core problem in one's life. Again, whenever possible, you should attempt, if you can, to relate the content of your dreams to what is happening in your life at that time. One man found that he had recurring dreams of bloodshed but that those dreams only occurred after he had made an attempt to assert himself by asking for a raise in pay or by going out with a girl that he liked. He was much surprised to discover that his frightening dreams were actually evidence that he still had some old childish fears about standing up for himself.

5. *Observing resistances to putting understanding into action.* Expect inevitable resistance when you try to stop neurotic patterns. And there can be tension and fear when one faces a challenge that formerly has been evaded. When delaying and avoidance continue to occur, it is well to question the reasons for the delay and ask why one is afraid—and then to take heart and deliberately challenge the fear to see if it can be overcome.

The disciplined practice of these principles of self-observation can lead to progressive growth. Patterns have to be recognized and revised if one is to achieve more satisfying goals in life. But as everyone knows, the habits of years give ground grudgingly and slowly. Ideally, however, the process of personality understanding and growth is marked by several discrete features: There is the awareness that one's problems do not occur fortuitously but are intimately connected with the events (especially the human interactions) of one's life. For a given individual there is a certain quality of human event that generates anxiety, conflict, and stress. These phenomena, once detected, may lead next to a searching for the origin and history of these patterns. It is not impossible to see how these patterns operated as far back as a person can remember—perhaps even the very earliest memory contains something of the same thing. Seeing the conditions under which fears originate, and under which they are not retriggered, one may next determine whether one can be more the master of one's life rather than a victim of it. Could we be different from the way we have always known ourselves to be? And ever so slowly, we may challenge one habitual childish fear at a time, pushing ourselves to break out of the

prison of our neurotic self-defeating patterns. Success breeds success, and victory leads to victory. Defeats are reanalyzed in accord with their place in the psychic structure. Seeing ourselves defeated by the same old enemies, we are buoyed up in knowing that formulations about our personalities are correct, and we are then encouraged to fight on. Increasingly, we can express a claim to a new life; we find ourselves able to be more expressive. Self-recriminations diminish. Our capacities expand, and we gratify more of our needs. Feeling less frustrated in life, and therefore less angry, we can enter into relationships with people with more openness and a greater ability to share.

These are idealistic goals, but they represent a guide along the way toward greater self-observation and richer living. Fidelity to the practice of self-observation, together with the actual translation of understanding into action, can be a lifelong quest marked by high adventure and notable results.

The knowledge of oneself and how one reacts continues to constitute a health and mature behavior.

The above tasks given to the patient as an assignment in therapy can provide material to be discussed during the treatment hour. In addition to problem solving and symptom control, an attempt may be made to alter the individual's sense of values by developing a different way of conceptualizing himself or herself and of coping with the stresses and strains of everyday life.

Evolving a More Constructive Life Philosophy

One of the ways psychotherapy influences people is by helping them to develop new values and philosophies of living. However, the history of the majority of patients, prior to their seeking therapy, attests to futile gropings for some kind of philosophical answer to their dilemmas. The search may proceed from Christian to Oriental philosophies, from prurience to moralism, from self-centeredness to community mindedness. What at first seems firmly established soon becomes dubious as new ideas and concepts are proffered by different authorities. It is far better to evolve philosophies that are anchored in some

realistic conception of one's personal universe than to accept fleeting cosmic sentiments and suppositions no matter how sound their source may seem. Even a brief period of psychotherapy may till the soil for the growth of a healthier sense of values. We may be able during this span to inculcate in the person a philosophy predicted on science rather than on cultism.

The question that naturally follows in a therapy program is: Can we as therapists expedite matters by acting in an educational capacity, pointing out faulty values and indicating healthy ones that the patient may advantageously adopt? If so, what are the viewpoints to be stressed?

Actually, no matter how nondirective a therapist may imagine him or herself to be, the patient will soon pick up from explicit or implicit cues the tenor of the therapist's philosophies and values. The kinds of questions the therapist asks, the focus of interpretive activities, confrontations and acquiescences, silences and expressions of interest, all designate points of view contagious to the patient, which the patient tends to incorporate, consciously and unconsciously, ultimately espousing the very conceptual commodities that are prized by the therapist. Why not then openly present new precepts that can serve the patient better? Superficial as they sound, the few precepts that can be tendered may be instrumental in accelerating a better adjustment.

The precepts presented to the patient for practice at home may embody persuasive suggestions on how to isolate the past from the present, modes of managing anxiety, learning to endure a certain amount of tension and anxiety, tolerating a certain measure of anger and hostility, handling frustration and deprivation, correcting remediable elements in one's environment, adapting oneself to irremediable elements in one's life situation, using willpower to stop engaging in destructive activities, stopping unreasonable demands on oneself, challenging a devalued self-image, deriving the utmost enjoyment in life that is possible, and accepting one's social role. Not all patients need these directives, but they may be helpful especially in supportive and reeducative programs. But even in reconstructive therapy there are many patients who can benefit from them. The degree of

authoritativeness in giving suggestions will vary ranging from highest in supportive therapy and lowest in reconstructive therapy.

Isolating the Past from the Present

All persons are victimized by their past, which may operate as mischief mongers in the present. A good adjustment presupposes modulating one's activities to present-day considerations rather than resigning to promptings inspired by childish needs and misinterpretations. In therapy the patient may become aware of the early patterns that repeat themselves in adult life. This may provide one with an incentive for change. On the other hand, it may give the patient an excuse to rationalize defects on the basis that unalterable damage has been done by the parents, who are responsible for all of his or her trouble. The therapist may remind the patient that the patient, like anyone else, has a tendency to project outmoded feelings, fears, and attitudes into the present. Early hurtful experiences undoubtedly contribute to the patient's insecurity and to devalued self-esteem. They continue to contaminate one's adjustment *now,* and, therefore, must try to overcome them. Thus, the therapist would make a statement similar to the following:

> *Th.* Ruminating on your unfortunate childhood and bitter past experiences are indulgences you cannot afford. These can poison your present life if you let them do this. It is a credit to you as a person to rise above your early misfortunes. Attempt to restrain yourself when you fall back into thinking about past events and you no longer can control or when you find yourself behaving childishly. Remember, you may not have been responsible for what happened to you when you were a child, but you *are* responsible for perpetuating these patterns in the present. Say to yourself, "I'm going to release myself from the bonds of the past." And work at it.

Handling Tension and Anxiety

The patient may be reminded that tension and anxiety may appear but that something positive can be done about them.

> *Th.* Every time you experience tension, or any other symptoms for that matter, ask yourself why? Is it the immediate situation you are in? Is it something which happened before that is stirring you up? Is it something you believe will happen in the future? Once you have identified the source of your tension or trouble, you will be in a better position to handle it. The least that will occur is that you will not feel so helpless since you know a little about its origins. You will then be in a better position to do things to correct your trouble.

The idea that one need not be a helpless victim of symptoms tends to restore feelings of mastery. A patient who was given this suggestion went to a new class. While listening to the lecturer, she began to experience tension and anxiety. Asking herself why, she realized she was reacting to the presence of a classmate who came from her own neighborhood and knew her family. She then recognized that she felt guilty about her interest in one of the men in the class. This happened to be the real reason why she registered for the course. She realized that she feared the neighbor's revealing her interest in the man to her parents if she sat near him or was friendly to him. She then thought about her mother who was a repressive, punitive person who had warned her about sexual activities. With this understanding, she suddenly became angry at her classmate. When she asked herself why she was so furious, it dawned on her that she was actually embittered at her own mother. Her tension and hostility disappeared when she resolved to follow her impulses on the basis that she was now old enough to do what she wished.

Tolerating a Certain Amount of Tension and Anxiety

Some tension and anxiety are inherent parts of living. There is no escape from them. The patient must be brought around to the fact that one will have to tolerate and handle a certain amount of anxiety.

> *Th.* Even when you are finished with therapy, a certain amount of tension and anxiety are to be expected. All persons have to live with some anxiety and tension, and these may precipitate various symptoms from time to time. If you do get some anxiety now and then, ride it and try to figure out what is stirring it up. But, remember, you are no worse off than anyone else simply because you have some anxiety. If you are unable to resolve your tensions entirely through self-observation, try to involve yourself in any outside activities that will get your mind off your tensions.

Tolerating a Certain Amount of Hostility

If the patient can be made to understand that he or she will occasionally get resentful and that if the reason for this is explored, the patient may be able to avoid projecting anger or converting it into symptoms.

> *Th.* If you feel tense and upset, ask yourself if you are angry at anything. See if you can figure out what is causing your resentment. Permit yourself to feel angry if the occasion justifies it, but

express your anger in proportion to what the situation will tolerate. You do not have to do anything that will result in trouble for you; nevertheless, see if you can release some of your anger. If you can do nothing more, talk out loud about it when you are alone, or engage in muscular exercises to provide an outlet for aggression, like punching a pillow. In spite of these activities you may still feel angry to a certain degree. So long as you keep it in hand while recognizing that it exists, it need not hurt you. All people have to live with a certain amount of anger.

Tolerating a Certain Amount of Frustration and Deprivation

No person can ever obtain a full gratification of all of one's needs, and the patient must come to this realization.

> *Th.* It is important to remember that you still can derive a great deal of joy out of eighty per cent rather than one hundred percent. Expect to be frustrated to some extent and learn to live with it.

Correcting Remediable Elements in One's Environment

The patient may be reminded of the responsibility to remedy any alterable factors in one's life situation.

> *Th.* Once you have identified any area of trouble, try to figure out what can be done about it. Lay out a plan of action. You may not be able to implement this entirely, but do as much of it as you can immediately, and then routinely keep working at it. No matter how hopeless things seem, if you apply yourself, you can do much to rectify matters. Do not get discouraged. Just keep working away.

Adjusting to Irremediable Elements in One's Life Situation

No matter how much we may wish to correct certain conditions, practical considerations may prevent our doing much about them. For example, one may have to learn to live with a handicapped child or a sick husband or wife. One's financial situation may be irreparably marginal. There are certain things all people have to cope with, certain situations from which they cannot escape. If the patient lives in the hope of extrication from an unfortunate plight by magic, he or she will be in constant frustration.

> *Th.* There are certain things every person has to learn to accept. Try your best to alter them as much as you can. And then if some troubles continue, just tell yourself you must live with some of them, and resolve not to let them tear you down. It takes a good deal of courage and character to live with your troubles, but you may have a responsibility to carry them. If you

start feeling sorry for yourself, you are bound to be upset. So just plug away at it and build up insulation to help you carry on. Say to yourself: "I am not going to respond to trouble like a weather vane. I will remedy the trouble if I can. If I cannot, I will adjust to it. I will concentrate on the good things in my life and minimize the bad."

Using Will Power to Stop Engaging in Destructive Activities

One of the unfortunate consequences of a dynamic approach is that the patient believes the idea that he or she is under the influence of unconscious monsters that cannot be controlled. The patient will, therefore, justify the acting-out on the basis of "automatic repetition-compulsions." Actually, once the patient has a glimmer of what is happening, there is no reason why the cooperation of will power cannot be enlisted to help inhibit himself or herself.

> *Th.* If you know a situation will be bad for you, try to divert yourself from acting it out even if you have to use your will power. There is no reason why you can't work out substitute solutions that are less destructive to you even though they may not immediately be so gratifying. Remember, a certain amount of deprivation and frustration is normal, and it is a complement to you as a person to be able to give up gratifications that are ultimately hurtful to you. Remember, too, that some of the chief benefits you get out of your symptoms are masochistic, a kind of need to punish yourself. You can learn to overcome this too. When you observe yourself acting neurotically, stop in your tracks and figure out what you are doing.

A conventional housewife was involved sexually with two of her friend's husbands. She found herself unable to resist their advances, even though the sexual experiences were not particularly fulfilling. She felt ashamed and was guilt-ridden by her actions. There was obviously some deeper motive that prompted the patient to act out sexually, but the threat to her marriage and relationship with her husband required an immediate halting of her activity. I remarked to her: "Until you figure out some of your underlying feelings, it is best for you to stop your affairs right now. How would you feel about stopping right now? Let's give ourselves a couple of months to figure out this thing. Frankly, I don't see how we can make progress unless you do." The patient reluctantly acquiesced; but soon she was relieved that somebody was supporting her inner resolution to resist. The interval enabled us to explore her disappointment with her husband, her resentment toward him, and to find outlets for her desires for freedom and self-expression in more appropriate channels than sexual acting-out. If the patient has been

given a chart detailing the interactions of dependency, low feelings of independence, hostility, devalued self-esteem and detachment, their manifestations as well as reaction formations to neutralize them, he or she may be enjoined to study the chart and see how one's own drives and needs, with their consequences, fit into the overall design.

Stopping Unreasonable Demands on Oneself

Pushing beyond the limits of one's capacities or setting too high personal standards require sober self-assessment. Are they to satisfy one's own ambitions or those of parents? Are they to do things perfectionistically? If so, does the patient feel greater independence or stature as a person when he or she succeeds?

> *Th.* All people have their assets and liabilities. You may never be able to accomplish what some persons can do; and there are some things you can do that others will find impossible. Of course, if you try hard enough, you may probably do the impossible, but you'll be worn down so it won't mean much to you. You can still live up to your creative potentials without going to extremes. You can really wear yourself out if you push yourself too hard. So just try to relax and to enjoy what you have, making the most out of yourself without tearing yourself to pieces. Just do the best you can, avoiding using perfectionism as a standard for yourself.

Challenging a Devalued Self-image

Often an individual retires on the investment of conviction of self-devaluation. What need is there for one to make any effort if one is so constitutionally inferior that all of the best intentions and well-directed activities will lead to naught? It is expedient to show the patient that he or she is utilizing self-devaluation as a destructive implement to bolster helplessness and perhaps to sponsor dependency. In this way one makes capital out of a handicap. Pointing out realistic assets the patient possesses may not succeed in destroying the vitiated image of oneself; but it does help to reevaluate potentialities and to avoid the despair of considering oneself completely hopeless. One may point out to the patient instances of personal successes. In this respect, encouraging the patient to adopt the idea that he or she can succeed in an activity in which he or she is interested, and to expand a present asset, may prove to be a saving grace. A woman with a deep sense of inferiority and lack of self-confidence was exhorted to add to her knowledge of horticulture with

which she was fascinated. At gatherings she was emboldened to talk about her specialty when an appropriate occasion presented itself. She found herself the center of attention among a group of suburbanites who were eager to acquire expert information. This provided her with a means of social contact and with a way of doing things for others that built up a more estimable feeling about herself.

Logic obviously cannot convince a person with devalued self-esteem that he or she has merit. Unless a proper assessment is made of existing virtues, however, the person will be retarded in correcting the distorted self-image.

> *Th.* You do have a tendency to devalue yourself as a result of everything that has happened to you. From what I can observe, there is no real reason why you should. If you do, you may be using self-devaluation as a way of punishing yourself because of guilt, or of making people feel sorry for you, or of rendering yourself helpless and dependent. You know, all people are different; every person has a uniqueness, like every thumbprint is unique. The fact that you do not possess some qualities other people have does not make you inferior.

Deriving the Utmost Enjoyment from Life

Focusing on troubles and displeasures in one's existence can deprive a person of joys that are one's right as a human being. The need to develop a sense of humor and to get the grimness out of one's daily life may be stressed.

> *Th.* Try to minimize the bad or hurtful elements and concentrate on the good and constructive things about yourself and your situation. It is important for every person to reap out of each 24 hours the maximum of pleasures possible. Try not to live in recriminations of the past and in forebodings about the future. Just concentrate on achieving happiness in the here and now.

Accepting One's Social Role

Every adult has a responsibility in assuming a variety of social roles: as male or female, as husband or wife, as a parent, as a person who must relate to authority and on occasions act as authority, as a community member with obligations to society. Though one may feel immature, dependent, hostile, and hypocritical, the individual still must try to fill these roles as completely as possible. If the patient is destructively involved with another person with whom one must carry on a relationship, like an employer, for

example, he or she must attempt to understand the forces that serve to disturb the relationship. At the same time, however, one must try to keep the relationship going in a way that convention details so that personal security will not be jeopardized.

> *Th.* One way of trying to get along with people is to attempt to put yourself in their position and to see things from their point of view. If your husband [wife, child, employer, etc.] is doing something that is upsetting, ask yourself: "What is he [she] feeling at this time: what is going on in his [her] mind? How would I feel if I were in his [her] position?" At any rate, if you can recognize what is going on, correcting matters that can be resolved, adjusting to those that cannot be changed; if you are able to relate to the good rather than to the bad in people, you should be able to get along with them without too much difficulty."

The form by which the above guidelines are verbally or graphically communicated to the patient will vary, and each therapist may decide whether they are useful in whole or in part for specific patients. Reading assignments may also be given and suggestions for continued self-education made after therapy has ended. A full list of reading materials will be found elsewhere (see Ch 56, "Bibliotherapy").

IV
The Terminal Phase of Treatment

54
Goals in Terminating Treatment

Theoretically, psychotherapy is never ending, since emotional growth can go on as long as one lives. Consequently, it is necessary to employ some sort of yardstick in order to determine when to discontinue treatment.

The problem of goals in psychotherapy is one about which there are differences of opinion. On the one hand, there are those who believe that a definition of goals is vital in any psychotherapeutic program. On the other hand, there are many professionals who consider goals to be an extremely arbitrary matter—a manifestation of the authoritarianism of the therapist who seeks to impose on the patient artificial values and standards. "Goallessness" has been mentioned as the procedural stance essential to technical analytic work (Wallerstein, 1965). Nevertheless, therapists of different orientations aim at outcome targets that reflect their special conceptions of dynamics.

Psychological processes may be conceived of in many ways including:

1. As energy exchanges within various divisions of the psychic apparatus (the Freudian hypothesis).

2. As interpersonal events mediated by characterologic distortions (the neo-Freudian hypothesis).

3. As forms of faulty learning and conditioning (the Pavlovian hypothesis).

Goals in psychotherapy are fashioned by theoretical conceptions of personality. Thus, in Freudian theory the goal in therapy is genital maturity in which fixations of libido on pregenital levels that foster regression have been resolved. In neo-Freudian theory the objective is self-actualization that frees the individual in interpersonal relationships, enhances self-image, and expands creativity and productiveness. In conditioning theory it is the extinction of destructive old patterns and the learning-through-reinforcement of

new and adaptive ones.

Irrespective of how one feels about the uses made of them, goals are understandably of concern to the psychotherapist, for success or failure in the treatment effort can be gauged only in the context of set objectives. Before describing goals, however, we must admit that judgments of "success" in psychotherapy are really a matter of definition and may be viewed differently from the standpoints of the patient, society, and the therapist.

SUCCESS JUDGMENTS

From the Standpoint of the Patient

There is a story about a man who confided to a friend that he had just successfully completed an extensive course of psychotherapy. "Why did you need psychotherapy?" asked the friend. "Because," revealed the man, "I thought I was a dog." "Was the treatment successful?" queried the friend. "Decidedly," replied the man, "feel my nose."

Estimates by the patient as to what has been accomplished in therapy are in themselves not a reliable index of therapeutic success. Most patients regard symptomatic relief as the best measurement of positive gain. This index, however, is not a completely valid one in assaying the effectiveness of treatment.

Symptomatic improvement may be achieved in several ways. First, it may be associated with the giving up of vital aspects of personality functioning. For example, where anxiety and guilt are aroused by sexual impulses, the abandonment of all forms of sexual expression may relieve symptoms. Or where close interpersonal relations are conceived of as dangerous, the patient may, in the course of therapy, detach from people, the bargain that the patient makes with anxiety here cannot be regarded as successful therapy, even though suffering is relieved. Second, the patient may, during treatment, propitiate certain neurotic drives, gaining thereby a spurious kind of security. Thus, one may make oneself dependent on the therapist, acquiring a regressive fulfillment of security needs. Symptoms will abate as long as one conceives of the therapist as a

bountiful, loving, and protecting parent. This happy situation may, nevertheless, be placed in jeopardy whenever the therapist fails to live up to the patient's expectations. Under these circumstances we cannot consider the surcease of symptoms a sign of cure. Third symptom relief may be produced by the repression of damaging conflicts. Many annoying but relatively innocuous symptoms may be blotted out of awareness in the course of supportive therapy, only to be replaced by substitutive symptoms of a more serious nature. Thus, the symptom of anxiety may be relieved during therapy by repressive techniques of one sort or another. Anxiety equivalents may, however, appear in the form of psychosomatic complaints. Damage to viscera may later eventuate, of which the patient is not conscious until an irreversible somatic ailment develops, perhaps years after the presumed "success" in therapy had occurred.

The patient's estimates of failure in therapy must also not be accepted at their face value, since concepts of failure are based on a false premise. Thus, one may consider treatment unsuccessful where hoped for ideal traits have not been achieved. For example, one patient may have secret notions of being a genius, that are now latent but that will be released through therapy. Another patient may regard therapy as unsuccessful unless one has developed complete equanimity and the ability to remain tranquil, to endure tension, and to vanquish discomfort, even in the face of the most devastating environmental conditions. The failure to develop these and other traits, which are, in the patient's mind, considered indices of health, security, and self-esteem, may cast a shadow on even estimable therapeutic results.

From the Standpoint of Society

Judgments as to success in therapy from the standpoint of social standards must also be held suspect. The patient's family, mate, or friends may have ideas about the kind of individual that they want the patient to become that may not correspond with standards of mental health. For instance, parents may expect and even demand that the therapist mold the patient into a creature who is cooperative and pleasant at all times and who never challenges parental authority. A mate may insist that the patient develop a

personality that tolerates his or her own shortcomings and never gives vent to resentment. Friends may have stringent standards of character that might apply to themselves but not necessarily to the patient.

The culture or subculture may also impose arbitrary norms that differ from those of the patient or of the therapist. Political and economic forces in one group may make for a value system that is not accepted by, or acceptable to, another group. Thus, a "normal" individual in a totalitarian framework would be expected to submit willingly to the yoke of dictatorship and to subordinate personal freedom for the welfare of the state. In another cultural framework the individual's personal rights and the ability to make one's own choices would be paramount; one would not be expected to yield completely to authoritative demands. It is accordingly, important not to regard as goals of normality traits and drives that, though culturally condoned, may prove to be at variance with mental health.

From the Standpoint of the Therapist

The therapist may fashion therapeutic goals around certain set standards and values. These may relate to personal concepts of normality or to a general ideal of mental health.

One may, reflecting cultural concepts, pronounce certain traits as normal believing that the patient must acquire these before being considered emotionally balanced. Another therapist may personally operate under a cherished set of attitudes that constitute for one the highest goal. Thus, if a value is put on ambitiousness, perfectionism, detachment, dependency, narcissism, or power devices, one is apt to consider these real assets toward which one must aim the therapeutic sights. A word of caution must especially be voiced in regard to that group of attitudes collectively embraced under the term of compliance. A reasonable compliance to authority is a necessary thing, but compliance is too often utilized by neurotic persons as a form of security. This is most often the case in those cultures in which the child is considered a relative nonentity who is expected to submit without question and to yield without complaint to the dictates and

commands of the stronger, more authoritative individuals with whom the child lives. Where therapists themselves have been reared in an atmosphere that makes compliance tantamount with good breeding, they may expect the patient to adopt a submissive attitude. The patient may sense this trend in the therapist and try hard to please, even at the price of crushing self-strivings and needs for independent thought and action. Therapists may also, because of their own character structure, consider any aggression a sign of recalcitrance and ill will. They must be careful not to try to pattern their patients after their own image, for they, themselves, may be the victims of values that are basically faulty.

From the Standpoint of Mental Health Objectives

"Ideal" objectives of mental health are many. They require that the person be capable of deriving pleasure from creature comforts in life—from food, rest, relaxation, sex, work, and play. The individual is capable of satisfying these impulses in conformity with the mores of the group. Mobilizing whatever intellectual and experiential resources are required, one is able to plan creatively and realistically and to execute one's plans in accordance with existent opportunities. This involves an appraisal of one's aptitudes and limitations, and a scaling down of one's ambitions to the level of one's true potentialities. It includes the laying down of realistic life goals, an acceptance of one's abilities and a tolerance of one's shortcomings. Presupposed is a harmonious balance between personal and group standards, and those cultural and individual ideals that contribute both to the welfare of the self and of the group. The individual must be able to function effectively as part of the group, to give and to receive love, and otherwise to relate oneself congenially to other humans. One must be capable of engaging in human relations without indulging neurotic character strivings of detachment, needs to dominate or to be enslaved, or desires to render oneself invincible or perfect. One must be able to assume a subordinate relationship to authority without succumbing to fear or rage and yet, in certain situations, be capable of assuming leadership without designs of control or power. One must be able to withstand a certain amount of disappointment, deprivation, and frustration without undue tension or anxiety when these are considered to be reasonable, shared, or

necessary to the group welfare or when the consequences of impulse indulgence entail more than their worth in compensatory pain. One's capacities for adjustment must be sufficiently plastic to adapt to the exigencies of life without taking refuge in childish forms of defense or in fantasy. To achieve a healthy self-regard an individual must have a good measure of self-respect, the capacity to be comfortable within oneself, a willingness to face the past and to isolate from the present anxieties relating to childhood experiences. The individual must possess self-confidence, assertiveness, a sense of freedom, spontaneity, and self-tolerance.

Unfortunately, limitations are imposed by a variety of factors on the achievement through therapy of such ideal goals. Chief among these are obstacles within the patient, such as lack of incentives for change, diminished ego strength, and practical considerations of insufficient time and money. Additionally, society itself imposes insuperable embargoes on certain aspects of functioning. It supports many neurotic values that necessitate the maintenance of sundry defenses for survival reasons. A personality structure that is ideally integrated might actually serve as a source of conflict where the individual has to operate in the framework of a severely neurotic culture.

TOWARD A PRACTICAL GOAL IN THERAPY

Modem philosophers contend that achievement of enduring happiness, while worthy of pursuit, is undoubtedly a dream. Total adaptation must be measured against the backdrop of humanity's continuing involvement with violence, exploitation, and devastation of the earth's resources. These and other inescapable calamities are bound to disturb our equilibrium. Achievement of the most ambitious goal in therapy— reconstruction of the personality structure—would theoretically be most helpful in adapting to society's ills while sponsoring constructive efforts to rectify them. However, goals in therapy are more or less patient regulated. No matter how well trained and skilled the therapist may be, nor how extensive the desire to reconstruct the patient's personality, the latter is always in a position to veto the therapist's intentions. The patient is in a position strategically to thwart the ideal goal of personality maturation—the most

difficult of all objectives. Irrespective of how thoroughly conversant we, the therapists, may be with the technique of reconstructive psychotherapy, our efforts may prove unsuccessful.

Even where conditions are most favorable, reconstructive efforts may fail. The patient may be able to afford extensive psychotherapy and to make the necessary time arrangements; he or she may desire to achieve deep change, yet may gain little or no benefit from therapy. This fact has confounded many therapists as well as their patients who are wont, as a result, to regard reconstructive psychotherapy as ineffectual.

When we investigate failures in reconstructive therapy in patients who are adequately motivated, we find a number of operative factors. The patient may have sustained such personality damage during the formative years of life that the chances for complete growth are remote. The secondary gain factors may be so powerful as to make health a handicap rather than an asset. Environmental conditions may be irremediably destructive, and the patient may need some neurotic defenses in order to survive them. Disintegrative forces within the personality may be so strong as to threaten to break loose with the employment of uncovering procedures. Finally, neurotic symptoms or character distortions may constitute the only means of adjusting the patient to conflicts, even though one possesses insight into their nature.

There are some patients who can make an adaptation solely by employing such neurotic facades. While partially debilitating, they help prevent regression and the upsurge of disintegrative tendencies. Thus, a psychosomatic ailment may serve to drain off hostile and masochistic impulses which, deprived of a somatic expression, may shatter the ego and produce a psychosis.

While the ideal goal of absolute resolution of blocks in personality maturation, with achievement of complete functioning in all areas of living, is a cherished aim in every patient, in practice very few people if any can reach this objective. Lorand (1946) recognized this when he said that in doing psychoanalysis it is sometimes essential to satisfy oneself with "practical" though superficial results that permit the patient to get

along more satisfactorily than before therapy. Many other analysts years ago also recognized the impossibility of achieved ideal goals.

Clara Thompson (1950), in an excellent discussion of what constitutes a "cure" in therapy, describes the need for goal modification. She contends that the patient (1) must be relieved of neurotic suffering, (2) must also be able to relate to others with a minimum of unrealistically perpetuated attitudes that have their origins in early significant relationships, (3) must be capable of achieving as complete a development of personal powers as education and life circumstances will permit. If life situation and the culture in which functions are favorable, he or she will be most capable of relating to the group constructively; if not favorable, he or she may have to learn to endure relative isolation. As long as the person does not deceive oneself through neurotic escape mechanisms, one may remain reasonably healthy even under inimical conditions. However, since we live in a sick society, some neurotic compromises are necessary in order to function. An absolute cure is thus not possible. As long as the person is relieved of anxiety, inferiority feelings, and other destructive elements and is capable of coping effectively with life difficulties as they arise, this may constitute as much as can be done in treatment.

While classical analysts in theory contend that theirs is the only therapy that can regularly and deliberately bring about deep and permanent changes (Strachey, 1937; Menninger, KA, 1958; Wallerstein, 1965), they are not so confident that they can in practice always achieve these all-embracing results. Annie Reich (1950) considers that the bringing about through analysis of an absolute state of health "would appeal to the narcissistic omnipotence fantasies of the analyst." She adds that an analyst cannot hope to produce perfect human beings, that one should be content if one frees a patient from symptoms, enabling ability to work, to adjust to reality, to engage in "adult object relations," and to accept some limitations. Oberndorf (1942) speaks of a "practical success" of symptomatic relief, and admits that in many psychoanalytic cases "the structure of the disorder with recovery of infantile memories has not been worked out, to say nothing of being worked through." Wallerstein (1965) remarks, "Suffice it to say, that though the most ambitious of therapies in its overall outcome goals, in practice analysis

often achieves no more than other less ambitious therapeutic approaches."

These formulations actually repeat what Freud himself conceded were limitations in man's capacities for change. In "Analysis terminable and interminable" (1937) he stated that what analysis accomplishes "for neurotics is only what normal people accomplish for themselves without its help," namely, a "taming" of their instincts to bring them into harmony with the ego. Where the ego for any reason becomes enfeebled, as in illness or exhaustion, the "tamed" instincts "may renew their demands and strive in abnormal ways after substitution satisfaction." Proof of this statement is inherent in what takes place in sleep when in reaction to the lessening of the ego's forces there is an awakening of instinctual demands. In altering the character structure, Freud was pessimistic of the outcome. It was not possible, he said, to predict a natural end to the process. "Our object will be not to rub off all the corners of the human character so as to produce 'normality' according to schedule, nor yet to demand that the person who has been 'thoroughly analyzed' shall never again feel the stirrings of passion in himself or become involved in any internal conflict. The business of analysis is to secure the best possible psychological conditions for the functioning of the ego; when this has been done, analysis has accomplished its task."

R. P. Knight (1941) has condensed the aims of psychoanalytic therapy as follows:

1. *Symptom disappearance.*

2. *Improvement in mental functioning* with (a) understanding of the childhood sources of conflict, the part played by precipitating reality factors, the modes of defense against anxiety, and the specific character of the morbid process, (b) tolerance of the instinctual drives, (c) realistic self-appraisal with the ability to accept oneself objectively, (d) relative freedom from enervating tensions and crippling inhibitions, (e) liberation of aggressive energies required for "self-preservation, achievement, competition and protection of one's rights."

3. *Improved adjustment to reality* with (a) better interpersonal relationships, (b) more productive work capacity, (c) ability to sublimate more freely in recreation and avocations, and full heterosexual functioning.

A realistic approach to all forms of psychotherapy, including psychoanalysis, recognizes principles of goal modification. It acknowledges that we may have to content ourselves with the modest objective of freedom from disturbing symptoms, the capacity to function reasonably well, and to experience a modicum of happiness in living. The patient may continue to be burdened by outbursts of neurosis, which escapes control from time to time. Realistically, some habitual activities will have to be circumscribed, and certain protective devices developed that are a bit restrictive in certain areas. Yet one will be as well adjusted as most persons, which means that average life objectives can be reached while living with some handicaps.

In the process of modifying goals, cognizance is paid to the fact that while each person is capable of change, there are various levels of change—from the altering of relatively superficial attitudes to the modification of the deepest strata of personality. The strength of the ego in itself may bear no relationship to the extensiveness of goals approached during therapy. Thus, in many patients with strong egos, who have successfully dealt with infantile conflicts through repression, compensation, and sublimation and whose present illness consists of a breakdown of these defenses, the goals may advantageously be oriented around mediating the stress situation that has provoked collapse, restoring to the person the habitual defenses.

In patients with a weak ego who have dealt with infantile conflicts unsuccessfully, with a serious thwarting of maturation, one may also have to be content with the goal of restoring repression and of strengthening defenses to bring the person back to customary equilibrium.

There are, in general, three types of patterns that exist in all persons that influence potentialities for personality modification even with depth therapy.

1. *Conditionings acquired during the preverbal period of life that have become so integral a part of the individual that they continued to operate in a reflex way.* Reorganization of these paradigms may be unsuccessful even after prolonged reconstructive or conditioning therapy, especially where they fulfill important needs, promote gratifications, or serve as defenses.

Surviving in almost pristine form, they defy logic and resist corrective influences.

2. *Systems developed in early life that have been symbolized, then repressed and repudiated because they mobilize anxiety or foster such intense guilt that they cannot be acknowledged.* These patterns, often related to sexual, aggressive, and assertive needs, may break through periodically in direct or modified form rationalizations for them being elaborated. Alteration of these configurations may be possible once insight into their nature is gained, their pleasure or adaptive values harnessed, and motivation for their obliteration developed with substitution of more adaptive trends. Where pleasure gains are high and sacrifice of such gains is resented, or where substitution of more mature ways of behaving is resisted, insight will not remove or control their expression. Here selective reinforcements may be partially successful.

3. *Patterns developed in later childhood and in adult life of which the individual is aware.* One may be able to modify or to control these patterns through will power once one understands their nature and consequences. Yet one may also be motivated to retain these destructive modes because of their pleasure and anxiety-reducing values.

Amendment in all of these categories is possible. Some changes come about "spontaneously" in the medium of a rewarding, bountiful environment that does not repeat the frustrating upsetting experiences of the past. They may be the consequence of a constructive human relationship that acts as a corrective experience, rectifying distortions in past relationships. They occur most frequently, however, through a good psychotherapeutic experience with a skilled empathic therapist, the patient gaining some cognitive understanding of one's conflicts, drives, and defenses, and being helped to develop new ways of reacting and relating. In all persons some residues of the disturbed past will remain irrespective of how bountiful one's environment may be, how exhaustively one knows oneself, or how thoroughly one has relearned new patterns.

Were we, in summary, to attempt the definition of a practical goal in therapy, we might say that it is *the achievement by the patient of optimal functioning within the limitations of one's financial circumstances, existing motivations, ego resources, and the reality situation.* Such a goal would put upon the therapist the responsibility of resolving

the patient's resistance in working toward the ideal objective of personality reconstruction. It would, however, admit of the expediency of adopting modified goals, such as dealing with only those aspects of the patient's problem that can be practically handled during the present therapeutic effort.

55
Technical Problems in Termination

The conditions under which termination of therapy is indicated are

1. Achievement by the patient of planned treatment goals.

2. Decision by the patient or therapist to terminate on the basis of incomplete goals.

3. The reaching of an impasse in therapy or the development of stubborn resistances that cannot be resolved.

4. Countertransference that the therapist is unable to control.

5. Occurrence of physical reasons, such as moving of the residence of patient or therapist.

TERMINATING THERAPY UPON REACHING SET GOALS

Therapy may be terminated after the patient has achieved planned goals, such as the disappearance of symptoms, the mediation of environmental stress sources, the acquisition of greater happiness, productivity and self-fulfillment, the resolution of difficulties in interpersonal relationships, or the establishment of creative and productive patterns in living, with the evolution of greater emotional maturity. It is to be hoped that some intrapsychic structural changes will have occurred in which, through a reworking of infantile conflicts, new defenses crystallize and adaptive solutions for old conflicts take place.

With the accomplishment of the purposes of therapy, termination is best effectuated by discussing the possibility of ending treatment with the patient, handling any resistance displayed, warning of the possibility of relapses, and inviting the patient to return after therapy has ended whenever necessary or desired.

Discussing Termination with the Patient

In advance of the termination date it is wise to discuss with the patient the matter of ending therapy. A tapering-off period may be suggested, and a termination date set, which ideally should be from 6 to 8 weeks. The frequency of sessions may be reduced, and the intervals between visits steadily increased. The following is an excerpt from a session with a patient with a phobic disorder who has achieved adequate improvement in therapy:

> *Th.* It sounds as if you are reaching the end of treatment. How do you feel about stopping?
>
> *Pt.* Oh, of course I am glad that I am feeling so well, and I am very thankful to you, doctor.
>
> *Th.* Actually, you did the bulk of the work. Of course, we could go on with treatment indefinitely, reaching more extensive goals in your personality development, but frankly I don't see the need for that, unless you do.
>
> *Pt.* Well, I suppose I can benefit, but as you say, I am comfortable and happy now with Jim *[the patient's husband]* being so much better now to live with, and all these fears and things are gone now.
>
> *Th.* If you agree with me that we should begin to terminate, we can cut down our visits to a session every 2 weeks for the time being and then space them at intervals.
>
> *Pt.* All right, doctor.

During the tapering-off period, any relapses or resistances are handled, sessions being again increased, but only if the patient's condition demands this. In occasional cases it may be decided to terminate therapy abruptly without tapering off, in order to expose the patient to a complete break with the therapist. Forced to function on one's own, the patient may marshal inner strength more rapidly.

Handling Resistances to Termination

If the therapist has conducted the treatment sessions with the full participation of the patient, and if the therapist has avoided playing too directive a role, termination will not pose too great a problem in the average patient. In supportive therapy, however, where the patient has accepted the therapist as a guiding authority with whom he or she has conformed, or in insight therapy where the patient has, on the basis of a residual

dependency drive, made the therapist a necessary factor in adjustment, termination may present difficulties.

Termination of therapy is no problem in most patients who are adequately prepared for it, or who are characterologically not too dependent, or who are seen for only a few sessions and discharged before a strong relationship with the therapist develops, or who are so detached that they ward of a close therapeutic contact. It may, however, become a difficult problem in other cases. Patients who in early childhood have suffered rejection or abandonment by or loss of a parent, or who have had difficulties in working through the separation individuation dimensions of their development are especially vulnerable and may react with fear, anger, despair, and grief. A return of their original symptoms when the termination date approaches will tend to confound the patient and inspire in the therapist frustration, disappointment, guilt feelings, and anger at the patient for having failed to respond to therapeutic ministrations.

In some patients in whom no manifest dependency operates in the relationship with the therapist, termination may still be troublesome. The patient may be fearful of giving up the protective situation in the therapeutic relationship. Memories of past suffering and anxiety may cause a patient to want to hold on to the security achieved, even at the cost of continuing in therapy indefinitely. M. Hollander (1965) has pointed out "that the role of being a patient in psychotherapy, like being a student in school or a patient on a medical service, may become a way of life instead of a means to an end."

The therapeutic tasks prior to termination with all patients involve analysis of the dependency elements in the relationship, a search for needs in the patient to perpetuate dependency, and a helping of the patient to achieve as much independence and assertiveness as possible. A shift in the character of the relationship may be necessary where the therapist has operated in a directive manner. Here the therapist behaves non-directively with the patient, with the object of helping the patient establish new goals and values.

Resistances in the average dependent patient are multiform. Some patients bluntly

refuse to yield dependency, adopting all kinds of dodges, even to relapse in their illness, in order to demonstrate their helplessness. Other patients exhibit a profound fear of assertiveness, perhaps promoted by a neurotic equation of assertiveness with aggression. Resolution of such resistances may consume a great deal of time.

In some patients, and especially in the third phase of treatment (see Chapter 48) it may be necessary to interpret continuously to the patient the reasons for this self-paralysis and to emphasize the need to make one's own choices no matter how revolutionary these may seem. The patient may be told that if a person has never developed full confidence in oneself as an individual, the right to experience oneself as an independent being may be startling. The insidious operation of this dependency may be illustrated, and the patient may be shown how dependency has crippled efforts toward self-growth. In the relationship with the therapist it is natural for the patient to expect the therapist to give the answers and to make the patient's decisions. Should the therapist do this, however, the patient will never develop inner strength. The therapist may keep emphasizing the patient's need to take complete responsibility for personal decisions. The patient may be apprised of the fact that some of decisions may be wrong; but even though one makes mistakes, the very fact that they are one's own mistakes will teach more than being told what to do at all times. The therapist does not want to withhold support from the patient, but it is necessary to do so now out of consideration for the patient's right to develop.

When the patient accuses the therapist of being cold and distant, the therapist may say:

> The reason I'm not more demonstrative is that if I were to act like the traditional authority, it would eventually infantilize you; you would have to keep me around as a leaning post the rest of your life. You'd have to come to me for every decision with such queries as, "Am I doing something wrong?" or "Am I doing the right thing?" Rather, it's better for you to make mistakes, bad as they may be, and to feel that these are your own decisions than for me to tell you what to do.

A definition of the nondirective nature of therapy is given with the object of supplying the patient with an incentive to take responsibility. This will not serve to

liberate the patient completely from dependency demands. Neurotic attitudes and behavior patterns will continue to press for expression. The patient may still exhibit toward the therapist the same insecurity, submissiveness, and aggression that he or she always has manifested toward authority. Habitual ineptitudes in dealing with life and people, destructive acting out and continuing detachment may go on, but with a slight difference: doubts that these aberrations are really necessary.

The following excerpt of a treatment session with a patient resisting termination illustrates some of these points:

> *Th.* You want me to tell you exactly what to do, how to do it, and when. If you really feel that you just don't have strength to do things for yourself, I will do them for you, provided you understand it isn't going to be of help to you if I make your decisions. I'll leave it up to you to decide. If you really feel as bad as you say you do, and you haven't got the confidence to make your own decisions, I'll let you depend upon me, if you *really* want that. *[This statement is offered as a challenge to the patient. There are very few patients that take advantage of it. This patient actually has become quite assertive through therapy but is evincing a regressive dependency reaction to prevent termination.]*

> *Pt.* I do feel just as badly as I told you, but at the same time I can hang on to various little things, one of which is that I long ago accepted the idea that you know what you're doing and I don't want to go against it. [*She seems to doubt the wisdom of her desire to have me function as a parental image.]*

> *Th.* You don't want to go against what I have outlined as the best for you? What do you feel about making your own choices and your own decisions completely, with absolutely no help from me?

> *Pt.* Oh, I think it's great, except that there doesn't seem to be much I can do about it.

> *Th.* Well, what do you think would happen if I told you what to do, if I took you over and acted like a parent?

> *Pt.* I feel two ways about it. I feel, first of all, that it might be an excellent idea because I'm certainly amenable to letting you take me over. But the other way I feel about it is that all this time I've been trying to, more or less, cooperate with you. I trust your judgment and I can see very well that keeping throwing decisions at me is what will in the end make me self-sufficient. Yes, I can see it, but right now I just can't imagine it ever happening or my being able to stand on my own feet. I feel very much as if I have slipped constantly downward during the last few weeks. *[This is since termination was suggested.]* That's all. I mean it's not as if I don't have lucid moments every now and then, but they're very few and far between.

> *Th.* All right, then would you want me to play the role of telling you what to do on the basis that you can't come to decisions for yourself?

Pt. If it was making decisions, I might be able to do it; but I just can't see any decisions to make. There's nothing clear-cut. I don't know where I am at all.

Th. So that you'd like to just let yourself be taken care of by somebody?

Pt. It sounds nice, but I know perfectly well that it wouldn't be so good for me.

Th. You mean my making the decisions for you wouldn't be so good?

Pt. Well, certainly not.

Th. But some people seem to want that.

Pt. Grown people?

Th. Yes, grown people. Their feeling about themselves is so diminutive, their capacity to function so low that they want a parent watching over them all the time. If you'd like to adjust on this level all your life, you'd need to have me around to make your decisions for you indefinitely.

Pt. And then if I wasn't living here, I'd try to find someone else to do it, if I let you go ahead with this plan. *[This is a healthy reluctance to accepting dependency.]*

Th. If you don't develop strengths within yourself so you can figure things out and plan your life and follow it through, right or wrong, then you're going to need somebody around all the time.

Pt. I'd rather not depend on you then.

Because the therapist operates in a more passive role, the patient will be encouraged to act with greater assertiveness, to initiate actions, and to follow them through. There is increasing incentive to take personal responsibility for one's actions, to make plans and express choices. Failure may occur, but there will be successes too. And inner strength will grow on the bedrock of successes. New feelings of integrity and a more complete sense of self will be developed.

Ego growth will thus be catalyzed during the terminal phase, eventuating in the patient's desire to manage one's own life. Such growth is contingent to a large extent on the continued permissiveness of the therapist and the persistent encouragement of the patient's activity and self-expressiveness. The fact that the patient successfully figures things out during the session eventually shows the patient that he or she is not at all at the mercy of forces on the outside. Ultimately the patient comes to the conclusion that one can

live one's life, not because one is given permission, but because one has the right to do so. The patient feels equality with the therapist and a growing sense of self-respect. The self-confidence developed in therapy promotes an extension of assertive feeling toward the extratherapeutic environment.

The proper conduct of therapeutic sessions during the terminal phase of therapy requires that the therapist be so constituted that he or she can permit the patient to feel equality and to allow separation from treatment. The personalities of some therapists are essentially so authoritarian that they will not be able to function on equal terms with their patients. Automatically they will set themselves up as leaders, making judgments, giving directives, and setting goals for the patient that they insist must be followed. They may respond with hostility if challenged or abused by the patient. This is least apt to occur where the therapist has had personal psychotherapy and can analyze and control neurotic countertransference before it acts to interfere with the treatment situation.

Even the therapist who has undergone personal therapy may manifest attitudes that support the resistances of the patient to termination. There may be a compulsion to overprotect or domineer the patient and thus an inability to assume a nondirective role. Economics may play a part when new referrals are scarce, and the therapist anticipates hard times ahead. This may lead to interminable therapy, until the patient forcefully asserts himself or herself by the marshalling of aggression, and in this way violently breaks ties with the therapist.

In some instances the therapist may have to be contented with only partial reduction of the patient's dependence. Here the dependency is reduced as to innocuous a level as possible, by encouraging contact with an outside group or, in sick patients who require prolonged treatment, by maintaining a casual therapeutic relationship at extended intervals over an indefinite period.

Warning of the Possibility of Relapses

No matter how thoroughly the patient's neurotic patterns seem to have been

eradicated, particularly in reconstructive therapy, shadows of old reactions persist. One may be incapable of eliminating them completely, as one cannot obliterate entirely the recorded tracings in the brain of aspects of the patient's past. Under conditions of great insecurity, when the patient's sense of mastery is threatened, or during periods of disappointment, frustration, and deprivation, old defenses and strivings characteristic of past neurotic modes of adaptation are apt to be awakened.

Symptoms may return insidiously without the patient even being aware of having entered into the old conflictual situations that propagated them. Thus, migrainous attacks may recur in a man who, having learned to channel hostility constructively and to avoid competitive relationships that create damaging resentment, changes his job to one where he is judged solely on the basis of comparison of his productivity to that of other employees. A woman with a propensity for dependent involvements may experience a return of her helplessness and her symptoms when she falls in love with, and acts submissive toward, a power-driven individual who constitutes for her an omnipotent father figure. Unconsciously she has yielded to a childish yearning for complete protection, and she is again paying the price in shattered self-esteem and its attendant symptomatic penalties.

It is essential for the patient to realize that getting well does not guarantee further nonexistence of symptoms. Indeed when confronted with truly crucial decisions some patients respond with a return of complaints. Also when stress becomes too powerful to manage, a temporary relapse is possible. However, if the causes of any relapse are investigated and analyzed, not only will the patient have the best opportunity of subduing suffering, but will also be in a better position to forestall the future return of symptoms. Some therapists find it profitable to tell patients at termination that they do not consider a person cured until a relapse or two has occurred and been overcome. Such a warning may prevent a patient from classifying therapy as a failure should recrudescence of symptoms ensue. It alerts one to the insidious operation of inner anxieties and promotes continuing self-analysis. The ability to utilize lessons learned in therapy strengthens newly acquired traits and expands personality growth. The therapist may tell the patient:

You are apt to get a flurry of anxiety and a return of symptoms from time to time. Don't be upset or intimidated by this. The best way to handle yourself is first to realize that your relapse is self-limited. It will eventually come to a halt. Nothing terrible will happen to you. Second, ask yourself what has been going on. Try to figure out what created your upset, what aroused your tension. Relate this to the general patterns that you have been pursuing that we talked about. Old habits hold on, but they will eventually get less and less provoking.

Inviting the Patient to Return for Further Sessions

The therapist may advantageously invite the patient to return for additional interviews in the event of a relapse the patient cannot work out alone. Should the patient take advantage of this invitation, it will be possible for the therapist rapidly to help the patient gain insight into the patterns that have been revived, to connect this understanding with what the patient already has learned in therapy, and to analyze why the patient was unable to deal with the relapse through his or her own efforts. This review will usually occasion much relief in the patient and provide a greater sense of mastery. Relatively few sessions will be required to effectuate this objective.

The patient may also desire to return to therapy in order to achieve more extensive objectives. Growth is a never ending process, and the patient may be so dissatisfied with the present status that a more exhaustive self-inquiry will be insisted on.

For example, a patient in an anxiety state, mobilized by involvement in a love affair that she has been unable to control with her habitual character defense of detachment, may utilize the therapeutic situation to break the relationship with the young man of whom she has become so hopelessly enamored. Restoring her detached defenses and again functioning satisfactorily without anxiety, she may decide that she has accomplished her treatment objective. However, because she has become aware of a conflict that makes close relationships dangerous for her, necessitating withdrawal, she may develop, after she has stopped treatment, an incentive to return to therapy for more extensive work. She will do this with a new goal in mind; namely to be able to relate closely to a person without needing to invoke her defense of detachment. With this expanded motivation, a reconstructive approach may be possible.

A suitable way of terminating therapy is to consider the increased spacing of sessions part of the treatment plan. As soon as the therapist decides on treatment termination, the patient is instructed that it is important to extend the intervals between sessions as part of the treatment plan. A 2-week interval is followed by increasing intervals between sessions. When it becomes apparent that the patient is coping well, a yearly session is planned.

Encouraging the Patient to Continue Therapeutic Self-Help

A consistent application of what has been learned in psychotherapy is essential. The patient may be encouraged to engage in self-observation and to challenge neurotic patterns directly should they return, both by trying to understand what brought them back and by actively resisting and reversing them. In some cases the patient may be taught the process of self-relaxation or self-hypnosis to help reduce tension when upset and also to enable the patient, through self-reflection, to arrive at an understanding of elusive precipitating factors that have revived conflicts.

Even where there has been only supportive or a more superficial type of reeducative therapy, the patient may be inspired, as much as possible, (1) to utilize will power for the purpose of facing reality situations, (2) to push one's mind away from ruminative obsessional thinking and preoccupations, (3) to cultivate, if possible, a sense of humor about oneself and situation, (4) to develop the philosophy of living in the present rather than regretting the past and dreading the future, (5) to practice expressing controlled resentment in justifiable situations, and (6) to examine any tensions, anxieties, or irrational impulses in terms of possible meanings, connecting them with what one knows of one's basic neurotic patterns. These precepts and others contained in Chapter 53 on Homework Assignments may be extremely helpful. Self-help relaxation methods, meditation, the playing of an audio tape that the therapist prepares for the patient for purposes of relaxation and ego building, may be prescribed for some patients. See also Chapter 57.

TERMINATING ON THE BASIS OF INCOMPLETE GOALS

Therapy may have to be terminated prior to the achievement of planned goals. There are a number of reasons for this, most important of which is insoluble resistance. Thus, a patient may, with psychotherapy, lose certain symptoms, but other symptoms may cling to one obstinately. One may relinquish many neurotic patterns but continue to exploit a few without which one may feel oneself incapable of functioning. One may develop a number of new potentialities, yet be unable to progress to as complete emotional maturity as either the patient or the therapist may desire. Working on resistance accomplishes little, and the therapist may then deem it advisable to interrupt treatment.

A countertransference obstacle that may require resolution is a too strong ambition in the therapist who expects too much from a patient. Therapeutic objectives may have to be scaled down considerably in certain individuals. Thus, we may be dealing with a sick borderline patient who is on the verge of a schizophrenic break and who is insistent that he be brought in therapy to a point where he can be more normal than normal. This wish, while admirable, is not realistic, for the patient does not possess the fortitude to endure the rigors of a reconstructive approach. Because he does not have sufficient ego strength to work out a better adaptation, one may have to make a compromise with projected goals.

Sometimes therapy is started with a patient whose motivations are unalterably defective. For instance, a woman may have a tremendously arrogant notion of her capacities, and she may seek treatment solely because she has read somewhere that psychotherapy can bring out an individual's buried potentialities. The bloated self-image that the patient supports may be the only way she has of counteracting feelings of inner devastation or of rectifying a contemptuous self-image. Therapy with such a patient may be extremely difficult and may have to be terminated due to impenetrable resistance.

The therapist may be confronted with a patient whose life situation obstructs his or her progress. The environmental difficulty is so irremediable that possibilities of correction are remote, and hence the patient must be helped to live with it or be

desensitized to its effect. Or the patient's symptoms may possess so strong a defensive value that their removal will produce a dangerous reaction. Therapy may have to be terminated on the basis of only partial symptomatic relief.

It may be impossible, due to other obstructions, to get some patients to progress beyond a certain point in therapy. To continue treatment may prove discouraging to the therapist and undermining to the patient. It is better here for the patient to retain some neurotic drives than to be exposed to interminable and frustrating therapy to which, in all probability, the patient will be unable to respond.

As soon as the therapist decides that maximum improvement has been obtained or that a stalemate has been reached, the therapy may be brought to a halt by utilizing the techniques described for termination after the achievement of planned goals. The therapist will, however, have to explain the reason for termination in such a way that the patient does not arrive at the conclusion that matters are hopeless and that no further progress is possible. Thus, the patient may be told that therapy has alleviated some symptoms, has brought about an awareness of basic problems, and has pointed the way to a more productive life. Because the patient's difficulties have existed a long period, resistances may persist for awhile. Putting lessons learned in therapy into practice, however, will provide the best opportunity to achieve a more complete development.

The mere mention of termination, and the discussion of resistances that seem to have blocked progress, may stimulate incentives to break through these hindrances. If a termination date has been set, the patient may work through resistances prior to the expiration date. On the other hand, the termination techniques may not resolve the many impediments to further change. Yet, after the patient has left treatment, spectacular progress may be experienced. The fact that no headway was made while in therapy may have been due to the operation of a subtle transference situation that acted as resistance. For example, hostility toward the therapist may have expressed itself in a refusal to go forward; or dependence on the therapist may have taken the initiative away from the patient. Once the patient is functioning away from therapy under one's own power, such

resistances diminish and a spurt in development is possible.

Planned Interruption of Therapy

Instead of outright termination, a vacation from treatment may be suggested. During this period the learnings from therapy should be put into practice. The interruption can serve as an opportunity to observe the exact manner that one's personal problems interfere with proper functioning and to analyze what hindrances come up in trying to cope with such problems on one's own. The proposed interruption may be presented to the patient as in the following excerpt:

> *Th.* It seems to me that we have reached a plateau in your therapy and that a vacation from treatment may be indicated. How do you feel about that?
>
> *Pt.* I just can't seem to get any further. I've been thinking of that. How long would you suggest?
>
> *Th.* Suppose we plan on a month's vacation. After a month call me, and we'll arrange an appointment.
>
> *Pt.* Do you believe that will be of help?
>
> *Th.* I do. You might observe yourself during this period and see if you can determine what is happening, what stirs up your symptoms and what alleviates them. We might learn something important, and the interlude may help pull you out of the plateau.

Transferring the Patient

Sending the patient to another therapist may sometimes be preferable to outright termination. Where one seems unable to deal with the patient's resistances, or where one cannot control destructive countertransference, or, for any other reason, feels incapable of helping the patient any more, the decision may then be that the patient will do better with a different therapist. Sometimes a transfer is arranged when it is presumed the patient will benefit by a kind of therapeutic experience other than that provided by the present therapist. For instance, a therapist trained mainly in reconstructive approaches may feel that the patient needs supportive therapy and may consequently want to refer the patient to a professional person who is highly skilled in supportive techniques. Or a change to a therapist of the opposite sex may be considered advisable. Should a transfer be indicated,

the therapist may discuss the matter with the patient as illustrated in this fragment of a session:

Th. For some time I have felt that we haven't been making very much progress.

Pt. Yes, I was worried about this. I wondered if you were getting impatient.

Th. Of course not, except that sometimes a snag like this does happen, and a person may be able to work it out better with another therapist.

Pt. You mean you want me to see somebody else?

Th. My desire is for you to get well. What would you feel about seeing someone I would recommend and who I believe can help you? I have a feeling you may do better with another type of technique, and Dr.＿＿＿ is very excellent at this.

Pt. Well, I don't know.

Th. Why don't you talk to Dr.＿＿＿ after I determine that he has the time for you? Then, after a couple of sessions you can see how you feel.

Pt. If you think this is best, I'll do it.

Th. I do, and I'll make all the arrangements and call you.

TERMINATION NOTE

At the time of termination a note should be entered in the patient's case record indicating the reasons for termination, the patient's condition of discharge, the areas of improvement, the patient's attitude toward the therapist, the recommendations made to the patient, and the final diagnosis. A form, such as in Appendix H may be found useful.

FOLLOW-UP

Prior to discharging the patient, then it is advisable to ask whether he or she would object to receiving an occasional letter from the therapist asking regarding one's progress. Most patients are delighted to cooperate and consider the therapist's gesture a mark of interest in their development. Follow-up letters, briefly inquiring into how things have been progressing, may be sent to the patient yearly, preferably for at least 5 years. This enables the therapist to maintain a good check on what has been happening over a

considerable period of time. The patient's replies to the follow-up inquiry may be entered in the case record, and, if necessary, a brief notation may be made of the contents.

Follow-up is an essential practice where one wishes to determine the efficacy of one's clinical activities. It is an important aspect of outcome research. In doing follow-up we must remember that a single contact may not tell us too much. A person does not live in a vacuum after completing psychotherapy, and many intercurrent events can temporarily augment, detract from, or destroy the benefits of treatment. Thus an individual who has achieved a good result and has left therapy in a satisfactorily improved state may be subject to catastrophes that are beyond one's power to avoid or resolve. One may be in a state of depression at the time of follow-up but can later rally and pull oneself out of despair. This may not be evident unless provision is made for further contacts. Personal interviews are far more useful for follow-up than,, communication by mail, although practical considerations, such as changes in domicile to a remote area, may pose problems. Sometimes follow-ups done over the telephone may be much more satisfactory than by mail. However, patients tend to be more guarded here than in private interviews even where they have had a good relationship with their therapists.

Ideally, appraisals of the patient by other persons with whom the patient is living or working can be helpful, but this may be difficult to arrange. A simple statement of "feeling better" or "worse" means little unless areas of improvement or decline are delineated. Unless the case record has detailed categories of problems and deficits existing at the start of treatment estimates of change may be inaccurate. Researchers who have had no personal contact with a patient are especially handicapped, but even the primary therapist may without recorded backup be prejudiced by optimistic hunches.

PATIENTS' REACTIONS TO THE END OF THERAPY

What follows are some reactions voiced by patients when they finished therapy:

1. All people have problems, and I know now that mine are no worse than anybody else's.

2. I realize I considered my symptoms a sign of weakness. I realize they aren't. I don't pay attention to them and they pass. They aren't such a big deal now.

3. One of the big problems I had was considering myself the center of the universe. It now isn't so important for me to feel so important.

4. When I was so full of guilt, I felt I would burst. When I talked things out, I realized my standards were a lot more strict than those of other people. As a matter of fact, I would purposefully do things to prove I was bad; now I don't have to.

5. The price I would pay for my indulgences was just too high. So I don't burn the world up! So I don't get as much of a bang out of doing ridiculous things! The quietness I feel more than compensates for the high life I was leading.

6. Why knock yourself out climbing on top of the heap? You're nowhere when you get there. You kill yourself trying. I was so ambitious and perfectionistic that I had no time for living. Now I try to find pleasure in little things, and it works.

7. I don't have to blame my parents anymore for my troubles; whatever happened, happened. Why should I let the past poison my present life? I feel I can live now for what life has to offer me right now.

8. I used to torture myself about the future. Worry about it so much I couldn't enjoy anything. I knew I was silly, but I couldn't stop it. Now I just don't care. I do the best I can now and I know the future will happen as it will happen no matter how much I worry about it. I take things as they come.

These ideas are not capricious whims. They are formulations developed after a working through of important conflicts. They indicate an attempt at solution of basic problems, which permit of a style of living more in keeping with reality.

Interestingly, the essence of such precepts may be found in proposals and rules of living laid down by poets and philosophers from the earliest times that humans recorded their hopes and fears and formulated ways of resolving them. Sometimes individuals arrive at such philosophies spontaneously without therapy, usually during emotional

crises that force upon them adaptive ways of thinking and behaving. Sometimes the philosophies are evolved as a result of authoritative pressures or out of respect for leaders whom the individual elevates to a protective or powerful position. A good psychotherapeutic experience, however, will give the individual the best opportunity to remold values and to arrive at a more constructive way of being and living.

Part V.
Special Aspects

The principle adjuncts in psychotherapy are relaxation exercises, biofeedback, somatic therapy, hypnosis, narcotherapy, videotape recording, and bibliotherapy.

RELAXATION EXERCISES AND MEDITATION

A certain amount of tension is a normal phenomenon, and every human being experiences it as a concomitant of daily living. It is probably helpful to problem solving and creative adaptation. In psychotherapy it acts as a stimulant to experimentation with new modes of defense and behavior. In excess, however, like too much anxiety, it paralyzes productive work and provokes a variety of physiological and psychological symptoms that divert the victim from concentrating on therapeutic tasks. Its control, consequently, becomes an expedient objective. While the therapeutic relationship serves to solace the patient, it may not be sufficient to subdue pathological tension. Minor tranquilizing drugs are effective, but they have side effects and may, in susceptible persons, lead to habituation. Fortunately, there are other available modes of tension control that can serve as an adjunct to psychotherapy.

As explained in a previous chapter, there are a number of ways that relaxation may be achieved, including meditation, Yoga practices, self-hypnosis, Zen, autogenic training, biofeedback, and simple breathing exercises. In all of the foregoing similar general principles prevail (Benson et al, 1974).

In meditation there is a *control of external stimuli.* This is achieved by a quiet environment devoid of distractions. An isolated room, a secluded seashore, or quiet woods can suffice. Other people may be present provided that they too participate in the relaxation experience, maintaining strict silence. Experienced meditators are able to "turn off" in almost any environment, withdrawing into themselves, but this will not apply to the

great majority of people. Second, *attention is focused* on a simple sound, the repetition of a word or monotonous phrase, or gazing at an object. Some subjects utilize a metronome or listen to their own quiet deep breathing; some stare at a spot in the ceiling; still others recite to themselves a syllable or meaningless expression ("mantra"). Whenever the attention wanders and thoughts and ideas invade one's mind, the subject is enjoined to return to the fixation stimulus. Third, a free-floating, unpressured, languid, unresisting attitude must prevail: the *individual surrenders to passivity.* As images, reflections, ruminations, sentiments, and varied thoughts emerge from inner mental recesses, the subject lets them drift by without concentrating or being concerned with them. This is probably the most difficult task for the subject to learn, but with practice there is less and less focus on performance and greater ability to let things take their own course. Fourth, *a comfortable position* is essential, such as sitting in a chair or, if one is nimble, kneeling. Lying down is conducive to sleep and may defeat some of the aims of the experience.

The specific technique that one employs to achieve the relaxation experience is largely dependent on what is most meaningful for the individual. Some persons are so impressed with the mysteries of the esoteric Eastern philosophies that they are especially attracted to these.

In the practice of Zen Buddhism the meditation experience (Zazen) plays an important part. This, performed in a quiet atmosphere, with eyes open, the mind drifting while focused on breathing, produces a unique kind of physical-mental experience. Strived for are episodes of deep clarity (samadhi), of enlightened unity (satori), and a buildup of energy (joriki). To learn this type of meditation, one practices in a group (sangha), preferably under the guidance of a Zen master.

Transcendential meditation is perhaps the most widely employed form of relaxation utilized in the United States. Introduced by a guru, Maharishi Mahesh Yogi, it resulted in a movement that had gained momentum over the years with development of a large number of societies distributed throughout the land. The method continues to be used by some individuals. It is taught by a trained instructor who designs a word, sound, or phrase

(mantra) presumably uniquely fitting to the subject, which is supposed to remain secret. This constitutes the fixation object.

Other forms of meditation include Yoga, Sufism, Taoism, Krishna Consciousness, and a wide variety of nonreligious practices focused on achieving a higher reality and greater knowledge than can be gathered through the senses. This is done by finding a "unity of being" in the quietness of inner tranquility. Each brand of relaxation has its devotees who attest to its singular usefulness. An excellent review of meditation is found in the book by Carrington (1977).

A description of the method designed by Dr. Maria Fleisch and Joan Suval, of basically two aspects of meditation therapy follows.

> One involves effort and concentration, focusing attention upon a particular object or sensation, and the other, a simple watchfulness and observation, allowing a free flow of perceptions. The aims of this approach to meditation are twofold; to give a "total rest to the mind," relieving tension and anxiety, and to clear the mind, so that it is more aware and better able to cope with everyday problems.

> The meditation therapist begins the group session by suggesting that the meditators close their eyes, take a deep breath, release it slowly, and allow their shoulders, chest, arms, legs, etc., to relax—to "let go completely." For a few moments focus will be on different parts of the body so that tension can be released in those areas. The therapist may then suggest that the meditators direct their attention for a while to the natural movement of their breathing, or to see if they can be aware of the various pulsations and sensations going on within the body. Other areas of focus could include listening to the sounds coming from the outdoors, or the footsteps in the halls, or the steady vibration of an air conditioner. The meditators are reminded throughout this part of the session that if certain thoughts distract their attention, they should simply observe that this is happening, refocusing their attention each time this occurs.

> After 10 to 15 minutes of this aspect of the meditation involving effort and concentration, the therapist then suggests that the meditators now allow their attention to move wherever it is attracted—to a sound, a sensation, a thought— permitting a free flow of perceptions, an "effortless awareness." The therapist reminds the group, from time to time, that it is fine if thoughts are coming and going easily without causing any disturbance, but if the meditator finds that he or she is becoming anxious because of *thinking* about thoughts, one should then focus attention for a few moments on an area such as one's breathing, sensations within the body, sounds outside, etc., until the thoughts have subsided and one feels calmer. Then the meditator can return to watching a free flow of perceptions. Sometimes the therapist will ask the meditators to open their eyes "halfway" so that their gaze is directed downward for a few moments. This allows the meditator to discover that

the watchfulness and effortless awareness can be going on even when the eyes are open. The therapist ends the meditation by once again suggesting that the meditators take a deep breath, exhale slowly, and gradually open their eyes.

Meditators are encouraged to schedule a 15-to 20-minute formal meditation period for themselves at home, either in the morning or the evening, or both, following the same procedure as outlined above. In addition, the therapist points out that this watchfulness and effortless awareness can go on while the person is involved in everyday activities—traveling on a bus, in a train, walking, listening to a conversation, observing the thoughts one has following an argument, etc. This allows one to be in closer "touch" with one's thoughts, feelings, what one actually IS at each particular moment of observation. Often when a meditator is simply watching a free flow of perceptions in this way, repressed thoughts can come to the surface. The meditation therapist stresses the importance of moving away from thought that creates tension and anxiety, calming the mind by focusing attention on an area that is not one of conflict, and then, when the mind is clear and quiet, allowing one to look once again at the thoughts or the situation that had caused the disturbance. When the mind is quiet and free from anxiety, it can see more easily which thoughts are negative and destructive and which are positive and constructive.

It should be pointed out that this approach to meditation is different from that of transcendental meditation, which limits itself to a formal meditation period, with the meditator concentrating attention on the silent or verbal repetition of an assigned "mantra" or Sanskrit word or phrase, so that one can enter into a state of relaxation. As indicated earlier, relaxation and concentration are important aspects of the meditation, but even more vital and beneficial is that this practical approach involves an effortless and choiceless awareness that the meditator can incorporate into daily life, enabling one to be in closer contact with oneself and to function more effectively in relationships.

In addition to the formal meditation period, the therapist answers questions that are asked and stimulates group discussion whenever possible. A strong supportive personality is an important requirement for the meditation therapist, who must also be watchful that there not be overdependency on the part of the meditators. The therapist can avoid this by encouraging individuals to meditate at home and throughout the day, modifying their approach according to their own needs and convenience.

Reprinted with permission of Dr. Maria Fleischl and Joan Suval

An outline such as that in Table 56-1 may also be given to the patient as an alternative method.

Meditation is employed not only as a means of tension control but also by some therapists as a way of facilitating imagery and free association. This is akin to the injunctions by early analysts to their patients to shut their eyes and allow themselves to relax completely, and then report the thoughts and phantasies that paraded themselves

before their minds. As an adjunct in psychoanalytically oriented psychotherapy, meditation, like hypnosis, may release transference feelings that must be dealt with as part of the treatment process.

Biofeedback is another way of achieving relaxation through the use of instrumentation. This allows an individual to recognize and influence certain internal bodily states, like muscle tension, that interfere with relaxation. Among the most useful instruments are the electromyograph and temperature machines. Except where certain pathological physiological states exist, like very marked hypertension, dangerous tachycardia, and arrhythmias and severe migraine, there may be little advantage over the simple relaxation exercises outlined above for tension control.

Schultz's autogenic training (Schultz & Luthe, 1959; Luthe, 1969) is another way of achieving tension control. An outline of modified autogenic training exercises is included at the end of the following section on biofeedback.

What all forms of relaxation correctly done achieve is a decrease in activity of the sympathetic nervous system with lowering of the heart rate, respiration, oxygen consumption, blood lactate level, blood pressure, muscle tension, and probably an increase in alpha brain waves. Where highly charged emotions and conflicts lay dormant, their upsurge into awareness may reverse these physiologic changes, but the proper technique will suppress such interferences. Hypnosis can be useful for the relaxation response, but where the object is to release repressed components through suggestion, cathartic liberation of emotions can occur. However, should strict tension control be the objective, there is no attempt made in hypnosis to probe for conflicts.

For many years this author has utilized hypnosis for simple tension control and has taught patients self-hypnosis (which can easily be learned), shying away from ego-building or exploratory suggestions so as to limit the extraneous suggestions and to focus the objective on relaxation. The technique is simple. The patient is enjoined to practice for 20 minutes, twice daily, sitting in a comfortable chair in a quiet room, shutting the eyes and breathing gently but deeply, concentrating on the sound of one's breathing. The

patient is then asked to relax muscles progressively starting with the forehead and working down to the fingertips and then shoulders to toes. The reverse can also be done, that is, starting with the toes and slowly relaxing muscle groups to the forehead. Finally, the patient counts very slowly from 1 to 20 listening to his or her breathing. After the count the patient is enjoined to let the mind become passively languid, avoiding concentrating on thoughts and ideas. Should these obtrude themselves, the patient is to revert back to listening to breathing. In a short period these exercises may be learned achieving what the more complex meditation practices accomplish without unnecessary adornments. In some instances this author has made a cassette recording for the patient utilizing the format outlined in the section on hypnosis later in this chapter, but eliminating the ego-building suggestions and summation of suggestions. Such relaxation practices have been extremely helpful to patients under excessive tension, without interfering with the psychotherapeutic process.

A letter written by a physician who personally tried meditation to reduce pressures and tensions explains some of the benefits to be derived from it:

> I'm getting back to meditating twice a day instead of just once (after four months of down to once a day). It really makes a big difference for me to have regular meditation. It certainly helps me see things in the larger perspective and less egotistically and egocentrically. Also it's a recharging of my mental battery, clearing the static of constant mental chatter out by tuning in to a clearer, more positive channel. You know, I actually feel much more "free-floating" after meditating—like the contrast between having all that subconscious mental chatter and no mental chatter brings the chatter back into acute focus. It seems like I then have greater access to my subconscious. I feel more creative, more in control, and less driven somehow.

BIOFEEDBACK

Through the use of electronic instruments it has been shown that an individual may become aware of changes in bodily functions of which one is usually ignorant, including skin temperature, blood pressure, muscle tension, and brain wave patterns. Changes in these functions activate the instruments designed to measure them and deliver signals (sounds or lights) to the subject permitting one to become aware of certain feelings or states of mind that influence alterations in the studied parameters. The subject gradually

learns how to reproduce such feelings or states to secure desired physiological effects. Body and mind become affiliated through this feedback process so that eventually the individual can reproduce reactions without the use of instruments. The full value of biofeedback must still be evaluated. It has certain substantiated uses, but whether it is superior for this purpose to other techniques (yoga, autogenic training, meditation, self-hypnosis, progressive muscle relaxation, drug treatment, psychotherapy) has not yet been determined. There are some individuals who are extremely impressed with and hence responsive to gadgetry. A powerful placebo effect accompanies biofeedback instrumentation (Frank, 1982) but this does not entirely account for the benefits.

The conditions for which biofeedback may be helpful are generally those of any relaxation training program, i.e., conditions associated with tension and anxiety, either their raw manifestations or the somatic consequences. Biofeedback also serves to induce a state of relaxation during the application of behavioral techniques such as systematic and in vivo desensitization. Finally, it has some use in psychodynamic psychotherapy by helping the patient develop initial rapport with the therapist on the basis that something positive is being done for one. The patient is provided with a technique of controlling anxiety and thus may be more willing to participate in the painful task of exploring repressed needs and dealing with repudiated ideas and conflicts. Moreover, the patient will react to the instrumentation and to the routines expected of one with usual characterologic manipulations and defenses that can provide the therapist with ample dynamic material for scrutiny. During interviewing biofeedback encourages the release of imagery. Anxiogenic themes may be verbalized, particularly by thermal and electrodermal instrumentation, facilitating the exploration of significant fantasies, memories, and conflicts.

Biofeedback is particularly acceptable to those who are fearful of the labels of psychotherapy and mental health, such as executives suffering from tension and psychosomatic symptoms who do not wish to compromise their chances for advancement by having it appear on their record that they received "treatment for mental illness." Usually a patient is seen once or twice a week by the therapist, and is also encouraged to

practice exercises at home each day and when symptoms occur. Twenty to forty formal sessions are usually required to learn tension reduction through instrumentation.

Biofeedback is being employed in Raynaud's disease, migraine, cardiac arrhythmias, hypertension, phobias, bruxism, torticollis, low back pain, cerebral palsy, peripheral nerve-muscle damage, upper motomeurone hemiplegia, some cases of tardive dyskinesia, Raynaud's syndrome, temperomandibular joint pain, insomnia, narcotic withdrawal, attention deficit disorder, tension headaches, asthma, irritable colon, fecal incontinence, chronic pain, seizure disorders, and neuromuscular ailments with reported promising results. But biofeedback cannot be recommended for everyone. It is valueless in serious psychiatric problems and it may create anxiety in some patients such as paranoid conditions. In combination with psychotherapy it proves most helpful, and therefore treatment should be executed or supervised by a trained psychotherapist. It requires time for learning, studied application, and practice, in which not all patients are willing to indulge. It requires also instruments that may be an expensive investment. In spite of these drawbacks, biofeedback is an area whose full possibilities and applications have opened up a fertile field of research (J. Segal, 1975). A number of volumes of collected research on feedback have already appeared as well as critical reviews of the literature (Basmajian, 1983; Gaarder & Montgomery, 1977; D. Shapiro & Schwartz, 1972; Blanchard & Young, 1974). A journal, *Biofeedback and Self-Regulation* has been published.

In the technique of biofeedback "a meditative state of deep relaxation is conducive to the establishment of voluntary control by allowing the individual to become aware of subliminal imagery, fantasies, and sensations" (Pelletier, 1975). This facilitates a link between physiological and psychological processes. The combination of relaxation exercises and biofeedback instrumentation facilitates identification of subjective imagery and physiological sensations that are quieting to the bodily organs.

Where a patient with a serious gastrointestinal, cardiovascular, migrainous, or psychosomatic illness is unable to achieve relief through psychotherapy with the adjunctive use of relaxation exercises, biofeedback training should be considered. Which

instruments to employ will depend on the illness and the learning capacities of the patient. Many practitioners have found the galvanic skin reflex (GSR) electromyograph (EMG) and temperature machines most useful.

In muscle tension retraining through the use of an EMG information may be obtained regarding muscular activity below the threshold of sensory awareness. One may measure the average intensity of neuron firing in microvolts on a meter. An audible feedback delivers sounds registering increases in muscular activity, and by utilizing a threshold control one may provide conditions for optimal training. Where muscle relaxation is the goal, the threshold is set at a high level to produce sound; and as the patient learns to relax, the sound lessens then disappears. The electrodes are in a band that fits around the muscle to be utilized for training purposes. The most useful location is the forehead, the electrodes being placed about 1 inch above the eyebrows.

Signals are picked up not only from the frontalis muscle, but also from other muscles in the head, face, and neck. Thinking activates anxiety thoughts, which can cause a rise in muscular activity. "Turning off thinking" causes a fall.

Relaxation of the frontalis muscle tends to generalize to the entire body. When the level reaches below 4 microvolts, the subject may report a feeling of weightlessness or floating and alterations in the body image. This may create temporary anxiety and increase muscle tension. Should this happen, the patient is reassured that these sensations are normal and to enjoy them. As tension decreases, those patients who are repressing anxiety strongly may experience a sudden burst of anxious thoughts and feelings. Should this happen, the patient is encouraged to verbalize them. In this way biofeedback may be useful in dynamic psychotherapy (Glucksman, 1981, Adler & Adler, 1972). Biofeedback can create a state of relaxation helpful in verbalization during psychotherapy and desensitization procedures in behavior therapy. The effect on the therapeutic alliance is generally a constructive one and the learning of self-regulation may have an influence on the establishing of inner controls.

When the subject has been able to maintain EMG activity below 4 microvolts for

about 15 minutes, one should instruct the subject to examine internal sensations and feelings associated with deep relaxation in order to recreate the state without the feedback unit. In this way muscle relaxation may be obtained rapidly without the use of instruments.

GSR gives data as to emotional arousal, and its control may help lessen tension. The blood volume may also be assessed by special machines, especially through temperature measurements, in this way redirecting the blood flow from one area of the body where blood engorgement causes symptoms (e.g., the brain in migraine attacks) to other areas (e.g., the hand). A blood pressure apparatus and an electrocardiographic (EKG) machine are also employed to control blood pressure and the heart rate. The electroencephalogram (EEG) is occasionally used in epileptic patients to teach them to increase the sensorimotor density rhythm in order to reduce the frequency of seizures. There is some evidence that penile tumescence, the operation of sphincters, repiratory activities, optic and stomach functions may be mediated through special instruments in this way, helping impotence, fecal incontinence, excess gastric acidity, asthma, and myopia. The work in these areas is still incomplete.

To control migraine, it is necessary to learn control of blood circulation in the brain to minimize engorgement of the blood vessels. Utilizing the thermal machine, one may learn to send the blood flow from the head to the hand. The machine has two probes that record the surface temperature (a measure of the blood flow). To monitor blood flow between the head and hand, one probe is placed on the forehead, the other probe on the middle finger of the right hand. The thermal unit (machine) detects minute changes in temperature differential. As a difference in temperature occurs between forehead and finger, a slowly pulsed audible tone will be heard in the earphones. The sound means the blood is flowing in the right direction. Training sessions after the relaxation exercises should last no longer than 5 to 10 minutes.

There is no reason why biofeedback cannot be utilized in combination with behavior therapy (e.g., systematic desensitization) and dynamic psychotherapy. In this way the

patient monitors their own anxiety level by EMG feedback and becomes more insightful of his or her fantasy material in an atmosphere of objective detachment (Budzynski et al, 1970).

A useful means of achieving relaxation prior to biofeedback instrumentation is Schultz's autogenic training or a modification of this as in [Table 56-2]. Practically no scientifically controlled studies exist that truly establish the effectiveness of biofeedback, but the clinical reports are optimistic, perhaps overly optimistic. There is danger in this overoptimism of misuse of the method, and of arousing false hopes that biofeedback is a panacea. Should this happen, we may expect a backlash reaction leading to the denigration and premature elimination of biofeedback as a viable technique. What is needed are carefully designed studies with adequate controls.

A good text is the one by Gaarder and Montgomery (1977). Affordable monitoring modules are now available that measure physiological activities with considerable accuracy.

SOMATIC THERAPY

In a previous chapter the rationale and indications for the somatic therapies have been detailed (Chapter 9). In this section we shall consider some practical applications helpful for the psychotherapist in deciding which patients require medicaments adjunctively and which drugs to prescribe. If the therapist is a non-physician, it will be necessary to work collaborated with the prescribing medical person, supplying the proper data in order that the most suitable drug be selected.

Somatic therapy has proven itself to be a great boon to patients suffering from schizophrenia, endogenous depressions, manic phases of manic-depressive psychosis, acute puerperal psychosis, and severe toxic confusional states. Moreover, somatic treatments have had a positive effect on the morale of patients and their families and have helped to increase discharge rates of mental hospitals (Freyhan, 1961). The prevailing attitude of the public regarding the hopelessness and incurability of severe mental illness

has given way to optimism that dread psychiatric diseases may now be interrupted and perhaps even cured. Employed in outpatient departments of hospitals and clinics, somatic therapy has brought early psychoses to a halt before they have progressed to a point where patients have had to be institutionalized. It has also helped in the rehabilitation of chronic psychotic patients.

Somatic therapy, particularly drug administration, has also exerted a beneficial effect in psychotherapy (Linn, 1964; Kalinowsky, 1965; Kalinowsky & Hippius, 1969; Hollister, 1973). While some therapists continue to shy away from the use of medications, situations do arise during psychotherapy when drugs may prove helpful, even in psychoanalysis (Ostow, 1962). An important factor is to prescribe drugs in sufficient dosage and over a sufficiently long period to test their efficacy.

Pharmocotherapy

Psychotropic drugs during the past two decades have proven themselves to be of incalculable value in dealing with the biological correlates of certain mental and emotional disorders. They have not replaced psychosocial interventions, which concern themselves with the developmental, conditioning, extrapsychic, interpersonal, social, and philosophic-spiritual links in the behavioral chain. Nevertheless, in rectifying biochemical and neurophysiological dysregulations, they have by feedback influenced positively the various other bodily systems in the interests of better adaption. While they do not cure the disease, they alleviate many of the symptoms. Thus they have influenced, beyond the placebo effect, a variety of unwholesome behavioral symptoms, such as hyperactivity, agitation, excitement, violent rage, listlessness, social withdrawal, thinking disturbances including hallucinations and delusions, depression, tension, eating disorders, panic and anxiety. Initial improvements have been sustained, and many patients on a drug regimen even for over 10 years have not been deprived of any of their vital functions (Redlich & Freedman, 1966). Drug therapy helps to keep psychotic patients out of hospitals and enables them to assume some productive role in the community. During psychotherapy it

permits of a modulation of anxiety, particularly where the individual is so immersed in dealing with its effects that one is unable to apply oneself to the tasks of psychological exploration and working through. It may make disturbed patients more accessible to psychotherapy. It also reverses some depressive reactions that drain energy and block initiative. All patients on psychoactive drugs should be under close medical supervision.

The exact action of drugs is not entirely known; however, they appear to act both on the underlying disorder and on the secondary reactions (e.g., withdrawal, undermined self-esteem, etc.) of a patient to illness. They may dissociate symptoms from their attached emotional components; for example, the psycho-inhibiting medicaments, namely phenothiazines, can isolate delusional systems in schizophrenia. They may make available more psychic energy, thus enabling the patient to deal more readily with his or her conflicts. For instance, the energizing drugs vitalize the individual and increase general feelings of well-being. They may disrupt the psychic organization, giving symptoms a new meaning, as during psychedelic experiences with LSD. Tranquilizing and energizing drugs are sometimes employed singly or in combination (e.g., Trilafon and Elavil from two to four times daily), and with this alone (with no uncovering of dynamics and no insight) the patient may achieve a psychological balance. Lowinger et al. (1964), in a follow-up study on drug treatments as the exclusive therapeutic agency, found that the favorable outcome rates were comparable to other treatment approaches in similar patients. After a short period of time on medication some patients will reconstitute themselves; others may require prolonged drug administration. The dosage should be reduced in elderly patients and children. In selecting alternate drugs, it is important to inquire as to what has been effective in the past with the patient and with relatives who were or are on medications (since genetic factors influence drug responses).

Among the impediments in utilizing psychotropic drugs are:

1. Their side effects, such as allergic responses—hepatocanalicular jaundice with the phenothiazines and tricyclic antidepressants, and agranulocytosis with the phenothiazines and occasionally imipramine (Tofranil) and amitriptyline (Elavil); pigmentary reactions in the skin, lens and cornea with phenothiazines; cardiac changes with certain phenothiazines and

tricyclic compounds (especially Mellaril and Tofranil).

2. Their tendency to produce adverse physical and behavioral reactions—for example, hypotension with the phenothiazines and MAO inhibitors; adrenergic crisis in the sympathetic amines (amphetamine, dextroamphetamine); hypertensive crises with MAO inhibitors when tyramine foods are eaten; dyskinesia and Parkinsonism with the neuroleptics; problems in males of impotence and retarded ejaculation and anorgasmia in females. Antidepressant drugs may be contraindicated in some cardiac arrhythmias and in pheochromocytoma, and used with great caution in thyroid disease, angle-closure glaucoma, prostatic hypertrophy and renal failure.

3. Properties that lead to habituation—for instance, the sympathetic amines (Desoxyn, Dexedrine), the barbiturates (Nembutal), meprobamate (Miltown), chlordiazepoxide (Librium), and diazepam (Valium).

Side effects and allergic responses are not too common and mostly are annoying rather than dangerous. They do not justify discontinuing drug treatments. They usually occur during the early states of administration and may be controlled by antagonistic substances (like Cogentin or Artane in Parkinsonism). A disturbing and lasting effect of phenothiazines on chronic psychiatric patients in long-term therapy is tardive dyskinesia, which may not respond to any treatment. Habituating drugs, such as sedatives and hypnotics, may be regulated and should be at least temporarily discontinued after their effects have registered themselves to the benefit of the patient.

Some psychiatrists avoid personal prescription of tranquilizers in reconstructive therapy when they are needed on the basis that this introduces a guidance-supportive element in the relationship. If tranquilizers are indicated, they recommend that the patient consult the regular family physician. Actually, the giving of tranquilizers need not interfere with the management of reconstructive therapy, for the patient's reaction to the therapist as a guiding authority may be handled as part of the treatment process. Prescribing tranquilizers, giving interpretations, sending monthly bills, canceling appointments, and any other active transactions will be utilized by the patient as vehicles around which ideas about authority are organized, providing rich material for study. The

non-medical therapist will certainly need the cooperation of a physician, preferably a psychiatrist, in the event that prescription of a drug is necessary.

In review, drugs are no substitute for psychotherapy. But, as has been indicated, drugs can provide adjunctive help during certain phases of psychotherapeutic management. Caution is essential in prescribing drugs for minor emotional illness, not only because of their potential side effects, and the existence of allergies and sensitivities in the patient, but also because the temporary relief from symptoms that they inspire may induce the patient to utilize them as the first line of defense whenever conflict and tension arise, to the neglect of a reasoned resolution of a developing problem. In certain personality types tranquilizing and energizing drugs may come to fashion the individual's way of life, dependence on them producing a habituation whose effects are more serious than the complaints that they initially were intended to subdue. These disadvantages should not act as a deterrent to the proper employment of such medicaments, which, in their judicious use, will tend to help, not hinder, a psychotherapeutic program. Side effects and tendencies to habituation may be managed if therapists alert themselves to developing contingencies. A great deal of prudence must be exercised in evaluating the worth of any drug, since, as more and more medicaments are introduced into the market, their virtues are flaunted with spectacular and often unjustified claims.

In the main, tranquilizing drugs are employed in psychotherapy during extreme anxiety states when the patient's defenses crumble or when the patient is so completely involved in protecting him or herself from anxiety as to be unable to explore its sources. In neurotic patients the principal medicaments employed for anxiety are Xanas, Librium, Valium, and Serax. In borderline patients who are decompensating (depersonalization, extreme anxiety, psychotic-like ideation) low doses of neuroleptics, e.g., Stelazine and Haldol may be temporarily tried. In schizophrenia associated with apathetic and depressive symptoms, Stelazine and Trilafon may be employed. In schizophrenic excitement, Thorazine is an excellent drug, although, in office practice, Mellaril is effectively used. In psychotic reactions with apathy and withdrawal, Stelazine and Trilafon are helpful. Manic phases of manic-depressive psychosis may be approached with lithium

and Haldol. For mood elevation in mild depressions, Ritalin may sometimes be employed, especially in older people. For moderate and neurotic depressions the monoamine oxidase (MAO) inhibitors, Nardil and Parnate, are sometimes utilized, recognizing the side effects and dangers that may accompany their use. Tofranil, Desipramine, and Norpramine apply themselves well to retarded depressions, while Elavil is often helpful in agitated depressions. For suicidal depressions electroconvulsive therapy is preferred. In drug addiction and alcoholism certain drugs may be valuable—for instance, methadone in the former and antabuse in the latter.

People react uniquely to drugs, not only because of their constitutional physiological makeup, but also because of their mental set, their attitudes toward the medication, and the specific lines of their expectation influencing both beneficial and side effects. Experimentation will be required in dosage and type of drug. The very young and the very old may exhibit a sensitivity to drugs that require either a reduction of dosage or contradict their use. Drug administration must be under the direction and control of a qualified psychiatrist who first examines the patient and then prescribes the best chemical adjunct. The psychiatrist should see the patient periodically thereafter to ascertain the results of drug treatment, to manage side effects, and to alter the dosage when necessary.

The monitoring by laboratory tests of blood levels of psychotropic medications may be important in patients who are not responding well to these medications. Patients show variations in their absorption of drugs from the gastro-intestinal tract as well as in the metabolism of the drugs. If drugs other than the principal one are being taken, these may influence the absorption process causing blood levels that are too low for clinical relapse or too high with precipitated toxicity. Many patients forget or refuse to follow proper drug intake regimens and monitoring of blood levels can detect whether too little or too much medication is being used in order to regulate side effects, and to ensure compliance. Standard therapeutic dosages do not influence all patients the same way, some under-responding and others experiencing toxic effects. Moreover, in patients with cardiovascular illness on antidepressants, for example, careful monitoring may enable maintaining the patient on a therapeutic level with the lowest drug concentrations to

reduce the risks. The monitoring of neuroleptic blood concentrations in schizophrenia helps identify the optimal plasma levels for good dopamine receptor binding at the lowest concentrations thus reducing extra-pyramidal effects and the danger of tardive dyskinesia.

ANTIPSYCHOTIC DRUGS (NEUROLEPTICS)

Neuroleptics are used to reduce or eliminate the symptoms of psychosis in conditions such as schizophrenia, psychotic depression, mania, schizoaffective disorder, delirium, drug-induced psychosis and paranoid disorder. Such symptoms include disordered thinking, delusions, hallucinations, suspiciousness, extreme anger, markedly aggressive behavior, and agitated excitement. Given in periods of remission from psychosis, antipsychotic drugs may prevent a relapse and social and cognitive deterioration.

How these drugs work is not yet clearly known, but it is believed that they regulate at the receptor level the activity of the neurotransmitter dopamine (which operates excessively in schizophrenia). These medications also block other receptors producing quinidine-like activity and calcium-channel blockade, which may produce some undesirable side effects.

There are five distinctive classes of antipsychotic drugs for clinical use in the United States that are equally effective in antipsychotic activity, but vary in their pharmacologic profiles. This is all to the good since different individuals respond better to some of these classes than to others. The first and oldest class of drugs are the phenothiazines, which are of low potency, and hence require high dosage to be effective. Three common forms are available which vary slightly in chemical composition and produce somewhat different side effects. For example, the aliphatic phenothiazines (like chlorpromazine or Thorazine) produce marked sedation and are often used in overactive and aggressive psychotic patients. They do, however, lower the blood pressure (hypotension) and moderately promote extrapyramidal symptoms such as tremors, rigidity and masklike facial expression (Parkinsonism), which may necessitate neutralization by an antiparkinsonian

drug. The second variant of phenothiazines is the piperidine phenothiazine group like thioridazine (Mellaril), which has the same effect as Thorazine but produces a lower incidence of extrapyramidal symptoms. The third variant is the piperazine phenothiazine group like trifluoperazine (Stelazine), perphenazine (Trilafon), and fluphenazine (Prolixin), which because of higher potency require lower dosage, hence produce less sedation and lowering of blood pressure (hypotension). Their disadvantage, however, is the higher incidence neurological (extrapyramidal) symptoms.

The second class of neuroleptics, the butyrophenones, have much the same effect as the piperazine phenothiziazines. The most widely used of these is halperidol (Haldol) which has a reduced tendency to cause undesired sedation, anticholinergic effects and hypotension, but a high incidence of extrapyrmidal symptoms. The third class are the thioxanthenes: Thiothixene (Navane) which has similar side effects as Stelazine, Trilifon, and Prolixin; and chlorprothixene (Taractan), which has some properties like Thorazine. The fourth class is represented by dihydroindolone Molindone (Moban) and produces moderate side effects. The fifth class consists of dibenzoxazapine or loxapine (Loxitane) which often produces sedation and extra-pyramidal symptoms, but only moderate hypotension and anticholinergic effects. New drugs will undoubtedly come into the marketplace that exercise antipsychotic effects without the danger of tardive dyskinesia. For example, an investigative drug, Clozapine, has been found effective without the side effects of the neuroleptics. But even Clozapine has its destructive side effects in some cases affecting the blood through production of agranulocytosis.

The present available drugs vary in their choice and degree of receptor blockage, and hence the propensity for side effects. Excessive dopamine receptor blockage results in extrapyramidal movement disorders and tardive dyskinesia; blockage of muscarinic acetylcholine receptors are anticholinergic causing urinary retention, constipation, dry mouth and memory dysfunction; histamine receptor blockage produces sedation, weight gain and hypotension, tachycardia and lightheadedness. By selecting drugs that have a lessened capacity for side effects, disturbing symptoms can be minimized. Since patients respond differently to medications and only a clinical trial can determine which

neuroleptic will best be tolerated. Some therapists start therapy with the older drugs like chlorpromazine (Thorazine), thioridazine (Mellaril), or fluphenazine (Prolixin), and only where uncomfortable side effects occur do they shift to drugs with a lower receptor affinity like molindone (Moban) and loxapine (Loxitane).

Given any of the commonly used antipsychotic drugs administered over an adequate period in proper dosage, they all exert approximately the same antipsychotic influence. Side effects may be different among the different groups and often the selection of a medication is determined by whether we want to eliminate a selected side effect. Thus he anticholinergic sedative reaction of drugs like Thorazine, Mellaril, and Taractan may be troublesome for some patients and here we would use the less sedating drugs like Haldol, Prolixin, or Stelazine. On the other hand extrapyramidal symptoms, like restlessness, (akithesia) muscle spasms (dystorila) and muscle rigidity (parkinsonism) are intolerable in susceptible patients and Mellaril, Navane, or Moban would be used, with less of an extrapyramidal effect. In elderly or cardiac patients, a selection of drugs should avoid those that lower blood pressure or depress heart action, e.g., Thorazine, Mellaril, and Taractin. If dangerous toxic reactions occur, the more innocuous drug Moban is best to use. It is important not to mix the different neuroleptics. In elderly patients who display disturbing or unmanageable psychotic symptoms as part of an organic brain syndrome, severe depression, mania, paranoidal condition, or schizophrenia, antipsychotics may be indicated, but because of susceptibility to toxic reactions in the elderly, the dose should be reduced to one-third to one-half of the usual adult dose. High potency medications in small amounts like Prolixin and Haldol are preferred, administered in divided small doses to avoid the anticholinergic sedative and autonomic effects of the low potency drugs. However, extrapyramidal neurological side effects may occur with high potency medications. Sometimes medium potency drugs, like Trilafon work well with older patients, and in cardiac conditions Moban and Haldol may be prescribed.

Since there are some patients who seem to respond better to some classes of drugs than to others, after trying one medication for a sufficiently long period with gradually increasing dosage and achieving no success, one may then experiment with a new drug. In

spite of some reports regarding the stimulating effect of the high potency antipsychotics like Prolixin, Permitil, and Haldol, there is little evidence for this and they should not be prescribed for this purpose. High potency neuroleptics like Prolixin, which have neurological (extrapyramidal) side effects and which may retard sexual functioning should be avoided where these effects are likely to upset a patient, for example, a paranoid individual. Too early use of long-term single dose injections (Prolixin Decanoate, Haldol Decanoate) may be responsible for noxious effects.

In adolescent schizophrenia, disturbed thinking and behavioral patterns may be helped by neuroleptics although the dosage must be monitored and adjusted in relation to the degree of impairment produced by side effects. The low potency sedating antipsychotics, like Thorazine and Mellaril are best avoided in favor of the high potency drugs like Stelazine, Navane, Prolixin, and Haldol, which are less sedating.

There is some evidence pointing to the positive effects of low doses of antipsychotics in certain borderline and schizotypal personality disorders. In patients with symptoms of "psychotism," illusions, ideas of reference, obsessive compulsive symptoms, and phobic anxiety, Goldberg, et al. (1986) found that Thiothixene (Navane) in an average daily dose of 8.7 mg produced favorable results. Soloff et al. (1986) discovered that an average dose of 7.24 mg of haloperidol (Haldol) relieved symptoms of depression, anxiety, hostility, "psychotism," and paranoid ideation in borderline patients.

Rapid intensive "neuroleptization" has not fulfilled promises of great effectiveness as compared to standard treatment. Time may be needed before results become apparent. Attempts to reduce this time by massive increases of dosage succeed in toxicity more often than in treatment success. After several weeks of studied treatment without results, trials with increased daily doses (like 1200 mg Thorazine or equivalent) may be in order.

Side effects are to be expected in all of the neuroleptics no matter which are chosen, and the patient should be told that they are usual and indicate the drug is having an effect. Should the patient continue to be drowsy, the bulk of the dose may be administered at night which will help sleep. Dryness of the mouth usually abates. Constipation may appear

in older people. Rarely, some female patients develop a secretion from the breasts; they may manifest a weight gain and amenorrhea. Because skin sensitivity is increased, patients should be warned not to expose themselves deliberately to the sun during summer months. If skin sensitivity to sun lasts, Narvane is the best drug. Should dizziness occur due to postural hypotension, the patient may be instructed to stand up slowly from a lying or sitting position. Parkinsonism is considered by some authorities to be a welcome sign, a guidepost to maximum dosage. If it or dystonia or akithesia occurs, the patient should receive Artane (1-6 mg daily) or Cogentin (1-2 mg two or three times daily), or Kemadrin (2.5-5 mg three times daily). A rare side effect is agranulocytosis, and if the patient complains of a sore throat, a white blood cell and differential count should be obtained. In the event agranulocytosis is present, the drug should be immediately discontinued, and a medical consultation obtained to forestall complications. Jaundice is not too important, occurring mainly in 0.5 or 1 percent of older people. Reactions of skin, retinal, and corneal pigmentation are very rare.

Some side effects can be especially distressing and are usually responsible for patients discontinuing medication. Such side effects should therefore be anticipated, discussed with the patient, and managed by prolonged supervision. Without supervision one can expect a high incidence of drug disuse and relapse of illness. Anticholingeric effects may be neutralized by some medications, like bethanechol (Urecholine) or in emergencies by physostigmine (Antilirium). Among recipients of high potency drugs, extrapyramidal neurologic symptoms are reversible with the discontinuance of medication or can be neutralized by appropriate drugs like benztropine (Cogentin), trihexyphenidyl (Artane), diphenhydramine (Benadryl), and amantadine (Symmetral). The muscle spasms of the tongue and mouth (dystonias), the "restless legs" and fidgetiness (akithisias), tremors of the extremities and difficulties in walking (parkinsonism) can alarm the patient and relatives, but are not really too serious since they can be alleviated readily with appropriate medications mentioned above.

One complication is serious and develops in about 20 to 25 percent of patients, especially older persons on prolonged exposure to antipsychotic drugs, although in some

cases it may develop in young patients after 3 to 6 months of therapy. This is tardive dyskinesia with peculiar movements of the tongue, jaws, face, and extremities. Withdrawal from drugs at first exaggerates the symptoms. No form of therapy has proven consistently successful. Another very serious but rare complication is the "neuroleptic malignant syndrome" that is not related to dose or drug interactions most likely to occur in young men, patients with brain disorders, and those subjected to heat stress, physical exhaustion, and dehydration. Long-term use (beyond 6 to 12 months) of neuroleptics is justified only when there are disturbing symptoms of schizophrenia, paranoia, and certain neurological diseases that do not respond to psychosocial treatments alone; short-term use (for up to 6 months) should be restricted to acute psychosis, severe mania, or agitated depression that are not relieved by alternate therapies. Where tardive dyskinesia appears, neuroleptic and anticholinergic medications should be discontinued. Low doses of benzodiazepines may be tried and psychosocial treatments intensified. Some patients, however, because of the severity of their illness, will still require neuroleptic therapy. In this case, a chemically dissimilar neuroleptic should be tried other than the one that precipitated the reaction. In view of possible malpractice suits, patients and relations should be appraised of risks and benefits in using and continuing neuroleptics, if they are required after a year, and record of notations of this filed in the case records. In all cases, psychosocial treatment should be utilized and neuroleptics lowered in dosage or stopped where the patient is capable of getting along without them.

Benefits from drug therapy do not usually occur immediately, but may require 3 or 4 weeks before results are seen. Side effects, however, may be experienced early in therapy and should not encourage premature termination of medication unless they are serious. A trial of 6 to 8 weeks with proper dosage is advisable and if some dysphoric side effects develop these should be treated with proper medications such as Cogentin.

Some caveats and routines are important to mention. Combinations of antipsychotic drugs are occasionally used to achieve a better balance between therapeutic and adverse effects, but this practice is generally avoided since psychotic drugs do not differ in their impact on target symptoms, and in combination may increase side effects. Neuroses,

character disorders, anxiety reactions, and alcoholic upsets should never be treated even in low dosage with this powerful class of medications because of the risk of side effects. Before using drugs, a complete physical examination, blood count, liver profile and electrocardiogram should be done. In starting therapy the dosage is best at a low level (equivalent of 100 mg of Thorazine) and the dosage titrated upward watching the therapeutic response and side effects. Since absorption of medication is delayed by food and decreased by antacids, administration should be between meals and 2 hours after antacids. Following a few days of therapy, the total dosage may be given at bedtime provided the blood pressure does not decrease too drastically. Megadoses of drug should be avoided, but adequate dosage must be maintained (e.g., the equivalent of 400 to 600 mg of Thorazine for an acute schizophrenic episode). Inadequate doses yield side effects without therapeutic benefits. Finally chronic schizophrenia with symptoms of withdrawal and apathy usually will not respond to any of the neuroleptics. Because of the complications occurring in drug therapy it is important that a psychiatrist experienced in pharmacotherapy be put in charge of this dimension of the treatment process.

Maintenance drug therapy may be required and should be given in the lowest dosage (usually about 20-30 percent of the acute treatment doses) to keep the patient in some kind of functional equilibrium. More than 50 percent of schizophrenic patients rapidly relapse in a psychosis without drugs as compared with less than 20 percent of those on antipsychotic agents. How long to continue medications is difficult to assess. One rule of thumb is to extend treatment with drugs for 1 year after the first attack, for 2 years after the second; and indefinitely after the third attack. "The safest guideline is to use the least medication for the shortest time necessary ..." Baldessarini (1977). In all cases the rule should obtain to reduce the quantity of drug slowly once optimal symptom control has been obtained. This may be accompanied by total abstinence once, then twice weekly to allow the patient to try to make a drug-free adjustment. Psychotherapy and environmental adjustment to relieve the patient from undue stresses should be coordinately instituted. Should symptoms return, the dose levels can be adjusted upward. There are some patients who will need periodic drug therapy for the rest of their lives. Yet it is at least theoretically possible to secure adjustment in most cases without medication,

provided adequate educational, rehabilitative, and psychotherapeutic facilities are available and utilized. Even hardcore institutional mental patients on long-term maintenance drug therapy have been withdrawn from medications with benefit where social-environmental treatment programs were organized (Paul et al, 1972). With the increasing incidence of malpractice lawsuits involving tardive dyskinesia, the prescription of neuroleptics has become more carefully controlled. The estimate that a large percentage of psychiatric and geriatric patients on psychotropic drugs for 2 to 3 years have some symptoms of this complication is inspiring a more conservative use of major tranquilizers and a more sensitive diagnosis of early signs of their devastating side effects. Many states are mandating the patient's right to informed consent as a prerequisite to the employment of psychotropic drugs. The fact that studies indicate a more benign course for schizophrenia than the hopeless outlook in past years, and an understanding of how improved community care, better work opportunities, and social integration can constitute the preferred treatment plan is sponsoring a more aggressive drug-free orientation (Warner, 1985).

Because some patients who require maintenance therapy are loath to use oral medications or forget to take them, parenteral long-acting phenothiazines (Prolixin Enanthate, Prolixin Decanoate, Haldol Decanoate) may be given. Such maintenance antipsychotic drugs have been found to play a crucial role in the prophylactic treatment of patients with schizophrenia who resist oral therapy. Nonmotivated patients may be brought in to the doctor's office by a relative. As a last resort, some reward, by arrangement with the relative, may be given the patient by the doctor (e.g., his allowance) each time he appears for an injection. In a sizable number of patients schizophrenia that has existed for years may "bum out," particularly where the environment poses few stresses and the adaptive level has improved. Should relapse follow on withdrawal, medications may be reinstated.

Mania. Lithium carbonate (300-600 mg taken three times daily) is an effective therapeutic and prophylactic agent (with no undue sedative effect) for bipolar disorders (manic-depressive psychosis) where manic attacks are part of the recurrent illness. It has

also been used in acute nonorganic psychosis where an affective element exists. Some depressions, unresponsive to antidepressants have been helped by administration of lithium. Certain cases of schizophrenia (Hirschowitz et al, 1980) and alcoholism (Merry et al, 1976) are said to be responsive. Since lithium acts slowly, an excited, manic reaction may require initial antipsychotics, like Haldol or Thorazine orally or parenterally. This use is temporary since side effects may occur with the combination. The patient may be started on 300 mg of lithium three times daily, serum levels being tested twice during the first week. The usual dose is 600 mg three times daily, but this must be individualized and regulated by the blood level response. Regular determination of lithium serum levels by a good laboratory at least every month to maintain the proper concentration is essential. The range of lithium levels is kept between 0.8 to 1.5 milliequivalents (mE_ql) but during maintenance can be as low as 0.6 or 0.4 mE_ql tested every 2 months. Side effects are tremor, dry mouth, stomach discomfort, muscular weakness, fatigue, and a metallic taste. Urinary, cardiac and blood problems may develop with sensitivity to lithium and overdose. Because of its effect on the kidneys and other organs, lithium should be prescribed and the patient closely observed by a psychiatrist skilled in its use. Where a manic patient fails to respond to lithium, alternative drugs like carbamazepine (Tegretol) and clonazepam (Clonopin) may be tried.

A thorough examination of kidney function is in order prior to lithium administration, since lithium is excreted through the kidneys and impairment of kidney function may lead to lithium toxicity. Lithium also affects the thyroid gland and an examination of this organ may avoid complications. Toxicity may occur at usual therapeutic serum concentrations of lithium, so monitoring of side effects is important especially in the elderly and brain damaged. Signs of toxicity include weakness, tremor, ataxia, drowsiness, tinnitus, nausea, vomiting, nystagmus, seizures, coma, urinary symptoms, gastric distress, hand tremor, and thyroid effects. Lithium should be avoided in severe renal or cardiovascular disease, and where there is dehydration and sodium depletion.

Antipsychotic drugs are considered non-habituating, and withdrawal symptoms are

rare. However long-term administration should be accompanied by periodic blood and liver studies (Bloom et al, 1965). Some therapists make it a rule to have their patients who are on substantial medication examined every three months neurologically, in order to forestall development of unfortunate complications.

<div align="center">ANTIDEPRESSANT DRUGS</div>

On the whole, antidepressant drugs are inferior to electroconvulsive therapy in the treatment of severe and suicidal depressions. They do have an important utility, however, in non-suicidal depressions provided that the selection of the drug is one that will fit in with the prevailing profile of symptoms. A caution to be exercised relates to the fact that antidepressants tend to intensify schizophrenic reactions and, especially in bipolar depression, to precipitate manic symptomatology.

Helpful in overcoming fatigue and oversedation is the sympathomimetic amine: dextroamphetamine   (Dexedrine) and methamphetamine (Desoxyn), which are not used much today due to the potential for abuse. Methylphenidate (Ritalin) and Pemoline (Cylert) are similar in their effects to the sympathomimetic amines, but relatively weaker. Hyperkinetic children (ages 6 to 14) with both organic brain syndromes and functional disorders respond well to d-amphetamine, which has a calming rather than stimulating affect on them (Zrull et al, 1966). Amphetamine dependency may have serious consequences in the form of restlessness, irritability, insomnia, weight loss, aggressiveness, and general emotional instability (Lemere, 1966). Personality changes may progress to outright psychosis, the form of disorder being patterned by existing inner psychological needs and mechanisms (Commission on Alcoholism & Addiction, 1966). Prolonged addiction may result in permanent organic damage to the brain. It is essential, then, that administration of amphetamines be very carefully supervised.

Imipramine (Tofranil) is particularly valuable in inhibited endogenous depressions, approximately one-third being arrested and one-third improved. It is probably not as effective as ECT (minimum of eight treatments), but it may be a substitute where for any reason ECT cannot be easily administered. Imipramine has also been found useful in

enuresis (Munster et al, 1961) panic reactions, and bulimia (Klein & Davis, 1969, Pope et al, 1983).

Since in some cases it may produce insomnia, Kuhn (1960) recommends that the first dose of imipramine be given at bedtime. If the drug helps the patient sleep, it may be taken throughout the day. If insomnia occurs, it should not be given after 3 pm. Starting with one 25-mg tablet three times daily, the dose is increased by one tablet each day until eight tablets daily are taken. When the symptoms remit, the dose is reduced by one tablet daily until a maintenance level is reached. Older people respond more intensely to imipramine and may do well on the smaller 10-mg tablets. Because agranulocytosis has been reported, occasional blood checks are recommended. Imipramine is contraindicated in glaucoma. Should side effects of a disturbing nature occur (skin itching, confusion, loss of appetite, etc.) the drug should be stopped and a phenothiazine substance administered. If an MAO inhibitor (Parnate, Nardil, Marplan) is being taken, this should be discontinued for at least 2 weeks prior to introducing imipramine, since the combination is dangerous. Kline, differing from the majority of opinion, claimed that small doses of one can be used in combination with the other (Kline, NS, 1966). This defection has now recently been substantiated by others who claim that some patients resistive to all conventional therapies have been helped by a combination of a tricyclic and MAO inhibitor drug (Ayd, 1986). Agitated depressions may require a neuroleptic like Thorazine or Trilafon in addition to imipramine or a sedative antidepressant like Elavil. Following ECT, imipramine may be prescribed for a period to reinforce the antidepressive influence. Anticholinergic side effects include dryness of the mouth, tachycardia, arrhythmia, sweating, dizziness, constipation, visual disorders, urinary retention, and, occasionally, agitation, which may be controlled by regulating the dosage. In many cases the total dose can be given at night. Imipramine can produce orthostatic hypotension and tachycardia, and prolong atrioventricular conduction time. It must be used with great caution in patients with bundlebranch disease of the heart. Side effects of arrhythmia may be treated with physostigmine (2 mg intramuscularly or intravenously very slowly injected).

The newer imipramine and amitriptyline substances—desipramine (Norpramine,

Pertofrane) and nortriptyline (Aventyl)—appear to be no more effective than the parent compounds. They do have more stimulating properties and hence appear best suited for retarded depressions. Since they aggravate preexisting anxiety and tension, they should not be used where these symptoms are present, except perhaps in combinations with a sedative- tranquilizer.

Amitriptyline (Elavil) is a useful antidepressant with more sedative features than imipramine. Benefits are usually felt within a few weeks (Feldman, PE, 1961; Dorfman, 1961). Depression, tension, loss of appetite, disinterest in the environment and insomnia may be reduced or eliminated in somewhat more than half of the patients to whom the drug is given. It is administered in 25 mg dosages three times daily, increasing the dose by 25 mg daily until a 150-mg daily intake has been reached. In some cases a dose of 200, 250, and even 300 mg will be required. Older patients do well with a smaller dose, 10-mg tablets being substituted for the 25-mg tablets. The side effects, the contraindications, and the incompatibility with the MAO inhibitors are similar to those of imipramine. Elavil potentiates alcohol, anaesthetics, and the barbiturates, and the quantities of the latter substances, if taken, should accordingly be reduced. Where a psychotic (delusional) depression exists, a combination of amitriptyline and a neuroleptic like perphenazine (Triavil for example) provides better results then either drug alone.

Monoamine oxidase (MAO) inhibitors, such as tranylcypromine (Parnate) and phenelzine (Nardil), while less successful than ECT, Tofranil, and Elavil, have some use, especially in the neurotic or hysterical depressions (Dysthmic Disorder) or where a tricyclic cannot be used as in glaucoma, cardiovascular disease, or prostatic enlargement with urinary retention. There is some evidence that they are especially useful in panic disorder, bulimia, and atypical depressions. If a patient has not responded to a tricyclic in 3 to 6 weeks, one can go from a tricyclic to a MAO inhibitor after a waiting period of 2 weeks. Beneficial effects may not occur for about 3 weeks. MAO inhibitors must not be given with other medicaments such as cold tablets, nasal decongestants, hay fever medications, "Pep pills," antiappetite medications, and asthma inhalants. Cheeses, pickled herring, chicken livers, beer, Chianti wine, coffee and tea in quantity, and over-the-counter

cold remedies must also be eliminated from the diet. Side effects with the MAO inhibitors are potentiation of other drugs (such as barbiturates and amphetamine), hypotension, constipation, dysuria, reduced sexual activity, edema, and occasional liver toxicity (Ayd, 1961a & b). Such side effects may require an adjusting of the dose. N. S. Kline (1966), differing from other authorities in this country, contends that oral amphetamines and monoamine oxidase inhibitors are not incompatible and that the combination often eliminates the abrupt letdown that is a drawback in using MAO inhibitors alone.

Doxepin (Sinequan) is a useful antidepressant that has fewer side effects than Tofranil or Elavil. It may be given for neurotic depression, depression associated with alcoholism, depression or anxiety related to organic disease, and psychotic depressions with associated anxiety including involutional depression and manic-depressive disorders. It is relatively safe for and well tolerated by elderly patients. The dose for mild or moderate depression is 25 to 50 mg three times daily and for severe depression 50 to 100 mg three times daily. It may be used when the patient is taking guanethidine for hypertension in contradistinction to other tricyclics.

In the event the tricyclics (Tofranil, Elavil, Sinequan) produce too great sedation, Ritalin (10-20 mg) after breakfast may be prescribed. A nonbarbiturate hypnotic, like Doriden or Noludar, may be used for insomnia. Birth control pills should not be taken since they depress the plasma level of tricyclics. Patients over 60 should not be given the total dose at nighttime. Rather, one-half the dose after the evening meal and one-half at bedtime should be prescribed. After recovery the total dose should be continued for 3 months, then gradually lowered over several months, and finally discontinued. If the patient fails to respond to tricyclics, a MAO inhibitor (Nardil, Parnate), as mentioned, may be tried with the usual precautions. Some patients find the anticholinergic effects of the standard antidepressants intolerable. When this occurs the therapist may try one of the newer tetracyclic drugs such as trazodone (Desyrel). Because of its sedative effect it may be given at nightime which can be valuable for light sleepers. Maprotiline (Ludiomil) and trimipramine (Surmontil) are other antidepressants sometimes tolerated well despite their anticholinergic and other side effects. In the event a depressed patient has a cardiac

illness, wellbutrin (Buprion) may be considered a good choice. This drug has few anticholinergic or sedative effects. Amoxapine (Asendin) is another medication that acts more rapidly than the other antidepressant and it has a wide range of actions useful in mild as well as psychotic depression.

Combinations of drugs have been developed for treatment of agitated and anxious depressions (Smith ME, 1963). For example, Triavil and Etrafon are mixtures of perphenazine (Trilafon) and amitriptyline (Elavil). This combination is supplied in several strengths, as outlined in Table 56-3. Other combinations are Parnate and Stelazine, Nardil and Trilafon, and Thorazine and Dexedrine, the doses being adjusted in accordance with which target symptom (depression, anxiety, agitation) is most in need of control. Such combinations are considered unnecessary by some authorities who advise giving single drugs in adequate dosage and adding accessory drugs only when it is necessary to control certain symptoms not influenced by the original drug.

It is advisable in prescribing antidepressants to instruct and reassure patients regarding possible side effects. The patient should be given a typewritten sheet, such as in Appendix T, including dosages and times to take pills. This is especially necessary for geriatric patients who have a tendency to forget. The patient should be instructed that no alcohol is to be taken for the first 2 weeks of using antidepressant medications. However, after this one can, if desired, drink moderately provided that the medication is not taken at the same time.

If a patient is coordinately using other medications for a physical condition, these medications may dictate the preferred antidepressant to use. For instance, in hypertension where guanethidine (Ismelin, Esimil) is being taken, doxepin (Sinequan) is a suitable antidepressant to use.

ANTIANXIETY DRUGS (ANXIOLYTICS)

It is unsound to assume that a high level of anxiety is needed to motivate a patient for therapy or to make greater efforts to explore one's problems. While tolerable anxiety

and tension may require no medication, there is no reason to withhold psychotropic drugs where the patient is in real discomfort. A double-blind study by Whittington et al. (1969) with an unrelated outpatient population experiencing anxiety showed a greater perseverance in and acceptance of treatment of those receiving psychotropic drugs as compared with those receiving placebos. The fact that the patient gets relief from medicaments prescribed by the therapists seemed to help the relationship and to give the patient greater confidence in continuing therapy. The main anxiolytics are the benzodiazepines that are among the most frequently prescribed substances and owe their popularity to their effectiveness in subduing anxiety, calming stress, and quieting psychosomatic symptoms. They attach to highly specific receptor sites in the brain potentiating the inhibitory effects of the neurotransmitter GABA (y-aminobutyric acid). In higher dosage they possess a high level of safety, but in sensitive persons and the elderly they may produce ataxia, and when mixed with alcohol the combination can be dangerous. On the whole, however, their beneficial influence far outweighs their untoward consequences and they have an important place in the therapeutic armamentarium. Tolerance to benzodiazepines is very much less than to other anxiety agents like barbiturates, prolonged use of which necessitates increased doses of the drug to secure the same effects.

There is some difference in the profiles of the different benzodiazepines due mainly to the duration of their half-life which is determined by their rate of elimination. Diazepam (Valium) acts rapidly and maintains its effect due to slow elimination. Chlordiazepoxide (Librium) acts more slowly and also has a long half-life. Chlorazepate (Tranxene), halazepam (Paxipam), and prazepam (Centrax) produce metabolites similar to Valium, and apart from their rate of absorption very much act in the same way. Alprazolam (Xanax) and lorazepam (Ativan) have the shortest half-life of the benzodiazepines.

Over the years some diazepines have been differently utilized, for example, chlordiazepoxide (Librium) for alcoholic withdrawal symptoms, lorazepam (Ativan) and alprazolam (Xanax) for anxiety with depression, hydroxyzine (Atarax, Vistaril) for allergic reactions and itching, alprazolam (Xanax) for some panic reactions and agorophobia, and

flurazepam (Dalmane), triazolam (Halcion), and temazepam (Restoril) for insomnia.

All of these drugs should be employed with caution since tolerance and habituation is possible with prolonged use. To prevent withdrawal reactions the drugs should be discontinued gradually in those who have used them for more than 2 months, or in some cases even less, especially short-acting varieties like Ativan, Xanax, Halcion, and Restoril. For example, in the use of Xanax, dose reduction of no more than 1 mg every 3 days is advisable. Withdrawal symptoms generally consist of anxiety, depersonalization, and various physical symptoms that may frighten the patient greatly. Where large doses of medications have been taken and withdrawal is sudden, symptoms similar to barbiturate withdrawal, e.g., convulsions, may occur.

In prescribing anxiolytics, symptoms can sometimes be used as a guide for determining which tranquilizers to use. Thus, inhibited, motor-retarded, and anxious patients may do best on diazepam (Valium); the overactive, anxious patients on chlordiazepoxide (Librium); and the hostile, anxious patients on oxazepam (Serax). Where anxiolytics fail to control anxiety in borderline patients, close to a breakdown, one may try neuroleptic drugs like Stelazine. Other than this one should never use neuroleptics in nonpsychotic patients. Occasionally, barbiturates like phenobarbital work better in some anxiety-ridden patients than any other drugs. There are some anxieties that do not respond to any psychotropic drugs. These are often found in obsessive individuals who cannot stand the emotional straightjacket that tranquilization imposes on them. Anxiolytics are sometimes used along with antidepressants and major tranquilizers where anxiety is great.

Of all the minor tranquilizers, diazepam (Valium), chlordiazepoxide (Librium), and alprazolam (Xanax) are probably most used. With the introduction of buspirone (BuSpar ® Bristol-Myers Company, Evansville, Illinois), which holds promise of being an ideal anxiolytic drug, and whose influence is not through sedation, we may possess an important therapeutic and research tool. Most neurotic anxieties can be treated psychotherapeutically without drugs. It is only where the anxiety is so intense that the

patient cannot function or because the anxiety interferes with psychotherapy that drugs should be used. In some cases where the patient as a result of psychotherapy is ready to face a fearful situation but avoids this, a drug can help to break through. There is, however, a tendency to overdose. One way of regulating the dosage of tranquilizers is suggested by Hollister (1974) with Valium. Two hours before bedtime the patient is enjoined to take 2.5 mg Valium and to make a note whether he or she falls asleep earlier than usual, sleeps longer, and has a slight hangover next morning. If these do not occur, 5 mg are taken the second night. Should the patient still not respond, 10 mg are taken the third night. The hangover effect may be sufficiently great to last the patient throughout the day. If not, one-fourth of the evening dose may be taken during day.

The indications for Valium and Librium besides anxiety are certain depressions that may respond to its mildly euphoriant effect. They are also valuable in treating the agitation of chronic alcoholics in alcoholic withdrawal, including delirium tremens. In *severe* anxiety relatively large doses of Valium may be necessary. The starting oral dose is 5 mg three or four times daily. The patient is asked to telephone in 3 days to report how he or she feels. If there is no effect, the dose is raised to 10 mg four times daily so that the patient takes a total of 40 mg. The patient should be seen 4 days later, and if the symptoms continue, the dosage may be raised to 20 mg three or four times daily. The evening dose may be the largest one in the case of insomnia. When the patient feels better (tranquilization, mild mood elevation, increased appetite), one dose may be removed; 2 weeks later, a second dose is removed; 4 weeks later, all but the evening dose is taken away. Such regulation of the dosage will tend to prevent addiction. With higher doses patients may become ataxic and drowsy. Should this happen, the dose is lowered (it requires about 4 days to eliminate the drug from the system; consequently side effects may last during this period). Rapid symptomatic relief in alcoholic agitation, acute delirium tremens, hallucinosis, acute anxiety, and acute phobic and panic reactions may sometimes be obtained with 50 to 100 mg of Librium injected intramuscularly or intravenously, repeating in 4 to 6 hours if necessary. Caution in the use of Librium is to be heeded in older people who may become ataxic with even moderate doses.

Meprobamate (Miltown, Equanil) is another drug that has anxiety-alleviating properties when given over a sufficiently extended period, but is now not used as frequently as before having been replaced by the more effective and less habituating benzodiazepines. Indications for meprobamate are similar to those of chlordiazepoxide, except that it should not be employed in depressed patients. It is particularly useful where skeletal muscle spasm is present. The symptom profile of anxiety and tension may be helped with 400 mg three or four times daily, which may slowly be increased to as much as 2400 mg daily, this high dose being maintained for only a short time. Allergic reactions (fever, urticaria, bronchial spasm, angioneurotic edema) should be treated by discontinuing the drug and administering antihistamines, epinephrine, and possibly cortisone. Dependence and habituation are possible, consequently meprobamates should not be used for more than 3 months. Withdrawal from high doses should be gradual over a 1- to 2-week period.

Other minor tranquilizers include oxazepam (Serax) and alprazolam (Xanax). Serax (15-30 mg three or four times daily) has been utilized to control anxiety, neurotic depression, alcoholic tremulousness and withdrawal. The agitated reactions of older people also may respond to Serax (10 mg three times daily). Xanax in recent years has proven itself to be an effective anxiolytic and has additionally antidepressant and antipanic effects.

These minor tranquilizers have a disadvantage of leading to addiction over a long-term period, although the addiction potential of the benzodiazepines has been exaggerated. In a study of the long-term use of Valium, Hollister et al. (1981) found that in 108 patients suffering from severe pain and muscle spasm due to musculoskeletal disorders of the spine, who had been treated with the drug over an average period of 5 years, with a median dose of 15 mg/day (ranging from 5 to 40 mg/day) 83 percent of patients claimed benefit and "...diazepam seemed to retain its efficacy and did not lead to any clear-cut abuse". Nevertheless, withdrawal symptoms do occur when stopping benzodiazepines even where therapeutic doses have been used no matter how gradual withdrawal takes place and the reactions can be distressing (Ayd, 1984). Where a person

has an addictive personality (alcoholic, barbiturate user, etc.), it is best not to prescribe anxiolytics. Some new investigational antianxiety agents are in the process of being tested. One such non-benzodiazepine substance, buspirone (BuSpar), which has recently been released is helpful in patients with a generalized anxiety disorder. It has few side effects, is nonsedating, and has less potential for withdrawal symptoms, and less abuse potential.

In obsessional individuals who cannot tolerate losing control or not functioning with top efficiency, lowering performance may prove so upsetting as to obliterate any benefit from these drugs. Such persons may be taught to monitor their own minimal doses while being given reassurance to quiet them down.

Benzodiazepines are diminished in effectiveness when antacids and anticholinergic drugs (often sold over the counter) are concomitantly used.

Propranolol (Inderal) in doses of 10-40 mg three or four times daily may be of value in anxieties associated with beta adrenergic overstimulation, as in psychocardiac disorders. Inderal and other beta blockers require high doses, in which case careful monitoring of the heart is necessary to prevent excessive depression of cardiac function. Studies have shown that beta blockers are less effective in chronic anxiety and with agoraphobic or panic attacks than diazepam (Valium) although there is a possibility of addiction with the latter drug when utilized over a long-term period.

SEDATIVES, HYPNOTICS. AND PSYCHOSTIMULANTS

Since the advent of the benzodiazepines barbiturates have suffered a setback in popularity. Yet, in a few selected cases, they may still be the best drugs to use as daytime sedatives. Butabarbital (Butisol), phenobarbital sodium, and Tuinal in small dosage may be utilized here. However, in most cases the benzodiazepines are being employed for sedation as well as insomnia.

Insofar as insomnia is concerned, many substances have been used, abused, and then discarded in mankind's quest for a harmless substance that can hasten and sustain

sleep. We still do not have such a substance, but currently the least harmful, though still not perfect are the benzodiazepines, which have now replaced alcohol, bromides, opiates, barbiturates, ethchlorvynol, glutethimide and methaqualone as the most frequently prescribed drug for insomnia. Chloral hydrate is still employed occasionally as a safe and effective hypnotic although some patients complain about its unpleasant taste and irritating effect on their stomachs.

Benzodiazepine hypnotics are useful aids if taken occasionally when stress distracts the normal sleep tendency. When taken regularly for sleep insurance, hypnotics eventually defeat their purpose by exercising a generally negative effect. Without a pharmacological "straight jacket" no sleep is anticipated with the feared consequence of not being able to function alertly or at all the next day. On the other hand, where benzodiazepines are not prescribed, a stressed individual may resort to alcohol or more dangerous drugs which cannot be monitored.

The most popular benzodiazepines are the long-acting flurazepam (Dalmane) with a half-life of 78 to 200 hours, the short-acting temazepam (Restoril) with a half-life of 9.5 to 12.5 hours, and the ultra short-acting triazolam (Halcion) whose half-life lasts only 1.5 to 2.5 hours. Elderly persons who require daytime alertness and good psychomotor performance are best given triazolam (Halcion) in dosage of 0.125 mg, which may be increased to a limit of 0.5 mg. It is also given to persons who require a short boost in sleeping like those with jet lag with awakening in the middle of the night. Temazepam (Restoril) in dosage 15 mg to 30 mg is helpful to those who anticipate sleep difficulties. Flurazepam (Dalmane) with a dosage of 15 to 30 mg is highest in sedation and may impair performance. It has a utility for individuals who require at least some sedation.

Psychostimulants are now very rarely utilized for depression and diet control because of dangers of habituation. Amphetamines (Dexedrene, Desoxyn), methylpheni-date (Ritalin), cocaine, and pemoline (Cylert) are easily acquired illicitly, and are used and abused by large groups of people for their stimulant effect, their control of overeating, and the relief of fatigue. Consistent use of agents such as amphetamines is likely to induce an

organic brain syndrome with manic and paranoidal symptoms.

Some of the stimulants are medically indicated being for the treatment of certain syndromes (Baldessarini, 1972; Wobraich, 1977, Sprague & Sleator, 1973). Attention deficit disorders of children, hyperkinesis, poor impulse control, low frustration tolerance, and emotional lability may often be helped by dextroamphetamine (Dexedrine) or methylphenidate (Ritalin). Since the response to stimulants varies from child to child, adjustment of recommended dosage upward or downward will be necessary. These drugs have a calming effect on a hyperactive child and lessen the risk of later emotional problems that evolve from the acting-out and defensive patterns developed as a result of the hyperkinetic and attention deficit symptoms. In narcolepsy the heightened drowsiness, loss of muscle tone, and uncontrollable need to sleep may respond to high doses of amphetamine and methylphenidate, reinforced if necessary by imipramine.

PSYCHODYSLEPTIC (PSYCHOTOMIMETIC) DRUGS

Employed for the setting of model psychoses (see Chapter 9) LSD-25, mescaline, and psilocybin were once advocated to induce perceptual and cognitive crises in patients, release emotions, promote abreaction, revive memories, and open up channels to the unconscious. The effect on the individual was influenced by the environmental setting, the existing relationship with the therapist and activity of the therapist. Some patients, frozen in their affects, suddenly were transported into a psychedelic experience which enabled them to restructure their value systems somewhat after the manner of a mystical experience (see Chapter 10).

The extraordinary perceptual and hallucinatory irregularities induced by these drugs unfortunately appeal to adolescents in rebellion, thrill seekers, and psychopaths who subject themselves to a wondrous "widening of consciousness" in quest of new insights and powers. "It permits you to see, more clearly than our perishing mortal eye can see, vistas beyond the horizons of this life, to travel backwards and forwards in time, to enter other planes of existence, even—to know God" (Wasson, 1963). Psychiatric patients, disappointed in psychoanalysis, hypnosis, drug therapy, and electroconvulsive therapy

(ECT), often express a demand for the drug on the basis of its vaunted effects on the psyche. Unfortunately, on the debit side of the ledger is the capacity of psychodysleptics, particularly in vulnerable borderline patients, of sweeping away defenses that keep the individual in some kind of functional relationship to reality. "Our accumulating day-to-day experience with patients suffering the consequences of the hallucinogens demonstrates beyond question that these drugs have the power to damage the individual psyche, indeed to cripple it for life" *(JAMA,* 1963).

Favorable reports on LSD therapy with almost every syndrome have been published by Abramson (1956a & b), Bender et al. (1962), Chandler and Hartman (1960), S. Cohen and Eisner (1959), Cutner (1959), Dahlberg (1963a & b), Eisner and S. Cohen (1958), Feld et al. (1958), Heyder (1964), D. J. Lewis and Sloane (1958), Martin (1957), Sandison and Whitelaw (1957), Savage et al. (1964), Schmiege (1963), Simmons et al. (1966), and Whitelaw (1959). The book, *Uses of LSD in Psychotherapy* (Abramson, 1960), published by the Josiah Macy, Jr., Foundation, has a wealth of experimental and clinical data. The paper by Spencer (1964) also contains material helpful in evolving a technique. A conference held at South Oaks, Long Island (NY), devoted to LSD therapy expounded its potentialities (Abramson, 1966). LSD has been particularly recommended in the treatment of alcoholism (Hoffer, 1965; Jensen, 1962; Kurland et al, 1966, 1971; McCabe et al, 1972; Mac Lean et al, 1961; Pahnke et al, 1970; Savage et al, 1969, 1973; Smith, CM, 1958).

Beneficial uses in group psychotherapy have been described by Bierer (1963) who claims good results for LSD (in combination with methedrine) in "acute neuroses and for some sex difficulties. In addition, our experience with LSD as one aspect of an individual and group psychotherapeutic program for psychotic patients has been sufficiently encouraging to merit its continued use on an experimental basis." Bierer insists that it is not dangerous to treat psychotic, psychopathic, and emotionally immature patients with LSD. Eisner (1964) has also described the facilitating use of LSD in group therapy.

More recent work has shown that beneficial effects with single large doses of psychodysleptic drugs, or multiple small dose usage are not sufficient to justify

recommending this therapy as adjuncts to psychotherapy. On the contrary, it may exert an adverse effect on the psyche in the form of an immediate "bad trip" and more insidiously repetitive frightening flashbacks.

This should not deter from continuing careful research on how psychodysleptic drugs influence mental functioning. The problem of evaluating the effect of these substances in psychotherapy is as great as, if not greater than, that of assessing any other adjunct in psychotherapy. Of basic importance is how the therapist (who must be with the patient for 5 hours or more) works with and relates to the patient who is under the influence of the drug. Where the patient becomes too upset, the psychosis may rapidly be abolished by intravenous administration of 50 mg of chlorpromazine. Motor activity is reduced by chlorpromazine, verbal objectivity lessened, anxiety resolved, feelings of unreality and depersonalization abolished, and though hallucinations or somatic delusions continue, the patient may not react to them adversely.

What is essential in utilizing hallucinogens experimentally is familiarity with the effects of the particular drugs employed. Sufficient time must be spent with a patient prior to the administration of the drug to establish a working relationship and a feeling of trust. The therapeutic surroundings must be congenial, and the therapist and preferably a psychiatric nurse should be with the patient during the period the drug is in effect (which may be as long as 10-12 hours) to render support if necessary.

Recently a new drug MDMA (3-4-methylene-dioxymethamphetamine) has been employed experimentally in the attempt to enhance psychotherapy (The Psychiatric Times, 1986). This drug is said to evoke a highly comfortable experience that invites intensification of feelings and self-exploration. The drug is taken in doses of 75-175 mg by mouth and its effects begin in 30-45 minutes. It is said to have few complications. Although the drug has been around for at least 15 years there have been few publications. It awaits further testing before its general use can be recommended.

ORTHOMOLECULAR PSYCHIATRY AND MEGA VITAMIN THERAPY

There is a theory that schizophrenia is the product of an endogenous hallucinogen that accumulates in susceptible individuals as a result of faulty metabolism. Implicated frequently, it is avowed, is adrenochrome, formed from oxidation of adrenalin and released in large quantities by the excessive methylation of noradrenalin. On the basis of this theory, Hoffer (1966, 1971) administered large quantities of nicotinic acid (3 g or more daily), which he and his associates believed could restore metabolic balances. The theory, as well as the cure, have been rejected by a number of scientific investigators who have been unable to confirm the chemical changes postulated. Nevertheless, a sizable group of psychiatrists (who call themselves "orthomolecular" psychiatrists, a term originated by Linus Pauling) have endorsed the value of large quantities of vitamins (nicotinic acid, nicotinamide, vitamin B6, vitamin C, vitamin B12, and pyridoxine) for schizophrenia in combination with other accepted therapies, such as phenothiazines, ECT, and psychotherapy.

A task force of the American Psychiatric Association was appointed to examine the claims and appraise the results of megavitamin therapy. The report rejected both the theory and practice of orthomolecular treatments (Lipton et al, 1973). The extravagant claims of the orthomolecular psychiatrists in the public media were considered unfortunate. According to the task force, it has been impossible to replicate the results of the advocates of this form of therapy. Other studies, such as a five year multihospital project sponsored by the Canadian Mental Health Association, have concluded that large doses of nicotinic acid (3000 mg per day or more), the cornerstone of megavitamin therapy, have no therapeutic value other than as a placebo.

Against these reports, the orthomolecular psychiatric group have claimed unfairness and bias. Members of the group cite their own research, including doubleblind studies, that substantiate the value of megavitamin treatments in acute cases, often in conjunction with ECT and other therapies (Hawkins & Pauling, 1973). They repudiate the results of attempts to replicate their findings on the basis that the research designs have been faulty. Hoffer claims that where the megavitamin program outlined by him has been followed exactly, all reports published have duplicated his original claims. Pauling (1974) insists

that "There is evidence that an increased intake of some vitamins, including ascorbic acid, niacin, pyridoxine, and cyanocobalamin, is useful in treating schizophrenia and this treatment has a sound theoretical base."

The controversy illustrates the difficulty of validating outcome research findings where faith or lack of faith in the modality, along with nonspecific therapeutic elements, are unavoidable contaminants.

Electroconvulsive Therapy

Public and legislative distaste for electroconvulsive therapy (ECT), distortions promulgated by movie depictions of the method, malpractice insurance rates 400 percent higher than rates where practitioners do not use this modality, and professional misunderstanding about its operations and utility have tended to cast a shadow on a technique that in syndromes for which it is intended is better, quicker, and in some ways less dangerous than pharmacotherapy. While few people are frightened by the use of electricity in converting an arrhythmic heart to alpha rhythm, applying electricity to the skull to regulate mental rhythms bring out visions of medieval torture, inhumane manipulations of the mind, and irretrievable brain damage that have not vanished with the publication of countless studies detailing the established virtues and safety of this most misunderstood intervention. The facts speak for themselves. ECT is more effective and safer than psychotropic drugs for serious debilitating and suicidal depressions. In the hands of competent operators it is painless and without danger. A convulsive seizure that lasts 15 seconds in an anesthetized, relaxed patient results in no pain, no discomfort, and no recollection of the procedure. Only four serious complications occur in 100,000 treatments and this figure includes the treatment of 90 year olds. Compare this figure with any current medical and surgical procedure existing today. The argument that it should not be used because we do not know how it works is preposterous. We do not know how aspirin works or how electricity works, but we utilize both with benefit. Misused, both can be dangerous, and ECT in the past has been misused by applying it indiscriminately to minor emotional problems that it could not possibly influence.

ECT cures three-quarters of depressed patients in contrast to the best antidepressant drugs that relieve symptoms in from one-half to two-thirds cases. It has saved many lives that otherwise would have been extinguished by suicide. "Clearly ECT has demonstrated its efficacy beyond doubt. It should not be permitted to fall into disuse; if it is abandoned, patients will suffer." (JAMA, 1979). A panel organized by the National Institutes of Health, conceding that the risks of serious side effects are relatively low, gave ECT an endorsement to the effect that "not a single controlled study has shown another form of treatment to be superior to ECT in the short-term management of severe depressions." (Science, 1985). The most bothersome side effect is, in most cases, temporary memory loss for the period immediately surrounding the period of ECT and "some patients suffer no memory loss at all." The panel noted that the complication rate was 1 in 1700 treatments and the mortality risk no different from that associated with the use of short-acting barbiturate anesthetics. The question then is why there is such persistent and fierce opposition to ECT. For example, not long ago the citizens of Berkeley, California voted overwhelmingly to ban the use of ECT within the city limits (Science News, 1982). Even some psychiatrists maintain a continuing prejudice despite new technical developments in the concomitant use of muscle relaxants, anesthesia, unilateral electrode placements, hyperoxygenation, and monitoring of seizures that reduce complications.

While ECT is effective in catatonia, its use in other forms of schizophrenia is controversial since antipsychotic drugs are usually adequate although blighted by the risk of tardive dyskinesia. In manic patients lithium has replaced ECT except in rare cases where violent excitement necessitates immediate intervention. In neurotic depression (dysthymic disorder), psychosocial and pharmacological approaches are the preferred treatment modalities rather than ECT. ECT has not been found useful for chronic schizophrenia, and adjustment disorders with depressant moods. Informed consent is required from the patient who is presented with the options available, the possible benefits and risks, and the sequelae of confusion and memory loss. Obviously the family must be involved in the decision-making process. Before treatment is started drugs such as monoamine oxidase inhibitors and lithium should be discontinued. A thorough physical

and neurological examination is essential and any cardiac problems are closely monitored. Agitated and excited reactions and intense chronic anxiety will require concentrated ECT sessions until the symptoms are under control. ECT has been employed as a preventive measure in manic-depressive psychosis, being administered bimonthly or monthly following full recovery. More commonly following ECT, the prescription of antidepressant drugs or lithium (in bipolar disorders) is usually carried out as a preventive measure.

Adjunctive drugs have been employed with ECT, although caution prescribes that drugs like neuroleptics be employed only after the course of ECT is ended except in severely resistant patients (with the caution that the morning dose should not be given prior to ECT).

It is essential in using ECT to make sure that an adequate number of treatments are given. In general, depressions and manic excitements require approximately six or eight ECTs.

For the most part, the therapist will refer patients for ECT who are severely depressed. An adequate number of treatments (generally three) are needed during the first week where the patient is a suicidal risk. Following this, one treatment at weekly intervals may suffice. A total of 6 to 10 ECTs are usually required. Intervals should be so spaced that the patient is prevented from developing confusion and excessive memory loss. Excited and panicky schizophrenic or borderline patients may also require referral. Here treatments on the basis of three times weekly may be needed, reduced only to control confusion or regression. The last few treatments are given once weekly. In a few cases "maintenance ECT" has been used on a prolonged basis to keep the vulnerable patient from dissociating. Usually, however, borderline patients with a depressive or panicky overlay which interferes with psychotherapy may be made more accessible and kept from memory impairment by one, two, or three or more ECTs spaced sufficiently apart (Kalinowsky, 1965). Memory loss for recent events generally reverses itself within a few weeks.

Unilateral ECT reduces the post-treatment confusion and memory loss of

conventional bilateral ECT by placing the treatment electrodes over one side of the head only: the nondominant hemisphere (usually the right side in a right-handed individual). Generalized seizures are obtained with this method, which is otherwise given with anesthesia and muscle relaxation exactly as bilateral ECT. The striking absence of memory loss with unilateral ECT permits treatment to be given on a daily basis (Abrams, 1967). The depression-relieving effects of unilateral ECT are less than for bilateral ECT (Abrams, 1972), however, and this observation has stimulated attempts to increase the therapeutic effects of unilateral ECT by giving more than one treatment in a single session (Abrams & Fink, 1972). If there is no pressure of time and no clinical urgency (e.g., suicidal risk, progressive weight loss, reckless overactivity), unilateral ECT should be given initially, changing to bilateral ECT only if improvement has not occurred after four to six ECTs. Unilateral ECT is also useful for ambulatory patients or those whose work requires unaltered memory function during the treatment course. Unilateral ECT may also be used to avoid cumulative memory loss (retrograde amnesia) in patients who have improved after receiving their first few treatments with bilateral ECT.

Concentrated regressive ECT in the form of two ECTs daily to produce an organic brain syndrome is not recommended. Following ECT treatments, antidepressants for unipolar or lithium for bipolar depression may be given to forestall relapse.

The immediate consequences of ECT are confusion, headache, and transient memory loss. The confusion and headache disappear shortly, but memory loss may persist for weeks.

Basic Suggestions for Proper Drug Usage: Summary

There is a general agreement among clinicians regarding the selection and use of psychotropic drugs although the methods of employment may vary depending on the degree of expertise and the nature of the patient population. Standard medications and practices do exist which have been tested and validated in rigorous trials. A number of basic rules are in order: (1) One should never allow oneself to be influenced by anecdotal accounts of "novel" drug therapies. More often than not the drugs are worthless if not

hazardous. (2) Nutrient supplements do not substitute for time-tested agents. (3) Non-medical therapists must refer patients in need of drug therapy to psychiatrists qualified in pharmacotherapy. (4) The patient should be informed about the likelihood of using medications at the beginning of treatment in the event there is a drug-responsive disorder. (5) A negative transference should be suspected where there is noncompliance with prescribing instructions (Sussman, 1983). (6) Should a patient fail to respond to properly selected and administered medications, referral for specialized help with experimental drugs should be made only to a practitioner or clinic with experience in new pharmacological agents.

The proper use of psychotropic medication should result in maximal benefits for the patient at a minimal degree of risk. There is much more involved in pharmacotherapy than knowing the proper drug to select and writing a prescription. The following suggestions may be helpful.

1. Take a history of each patient regarding previous and present psychotropic drug usage, including which drugs were effective, the dosage, and any side effects. Ask about the use of psychotropic medications by other blood relatives. Due to genetic factors, the patient may have similar reactions to the same drugs. Inquire into existing physical illness since certain conditions may be dangerously aggravated by some drugs. For example, if the patient is taking certain medications for illness, these may be incompatible with some psychotropic drugs, for example, guanethidine for hypertension and tricyclics for depression do not mix.

2. A diagnosis is important in order to prescribe the proper drug; thus neuroleptics would be used for schizophrenia, lithium for mania, and antidepressants for psychotic depression.

3. Try to avoid some drug combinations, like hypnotics and antidepressants; they can lower the desired effect. Where combinations are necessary, one should be aware that the total therapeutic effect may be reduced. Thus, benztropine (Cogentin) to eliminate parkinsonian symptoms may lower the plasma level of a neuroleptic drug so that psychotic symptomatology can reappear, necessitating greater dosage.

4. Side effects tend to be dose-related. However, some patients experience adverse

drug reactions at the lowest doses, while other patients tolerate extremely high doses with no unwanted effects. Management of intolerable drug related symptoms involve lowering the dosage to the lowest possible therapeutically effective level, or switching to a drug with a lower side effect profile. For example, a patient who experiences severe extrapyramidal reactions to haloperidol (Haldol), and is unable to tolerate the anticholinergic effects of an antiparkinsonian drug (Artane, Cogentin, Kemedrin), may be given chlorpromazine or thioridazine that cause extrapyramidal reactions far less frequently.

5. Adequate dosage over a sufficiently long period is essential to test the efficacy of a drug. Build up dosage as rapidly as possible and sensible. If a patient fails to respond to one class of drugs during a sufficiently long time, switch to one of the other classes, as from aliphatic phenothiazines (Thorazine, Mellaril) to the butyrophenones (Haldol), to the thioxanthenes (Navane), to the dihydroindolones (Moban). If the patient still fails to respond after two months of antipsychotic or antidepressant drug therapy, the chances are the individual is not a good candidate for pharmacotherapy. Failure to respond to a benzodiazepine antianxiety or hypnotic drug within the first week should raise doubts about the eventual efficacy of the drug. Patients who benefit from benzodiazepines experience some reduction of anxiety or insomnia, even at low doses, at the outset of treatment.

6. Since most drugs are retained in the body for relatively long periods, a single total dose at nighttime, once a therapeutic effect has been obtained, is preferable to multiple doses during the day. Sleep is enhanced, and there is less tendency to forget to take the medications.

7. If a patient has had a good premorbid personality, has related well to people, and has broken down only under the impact of extremely severe stress, psychological treatments are likely to be most effective. The use of drugs may only be necessary for extremely severe or recalcitrant symptoms. An "acute psychotic break," particularly in a young person, may really be an identity crisis, a consequence of drug abuse, or a phase of a seizure disorder. It is better, therefore, not to prescribe psychotropic medications routinely. In many cases hospitalization suffices to stabilize the patient. One may wait a few days and then institute psychotherapy and reassurance to see if the patient's inner strengths will suffice to bring about a remission.

8. Where possible, concurrent psychotherapy should be employed in a psychotropic drug regimen to help reduce destructive interpersonal patterns, to lower self-imposed standards impossible of attainment, to teach social skills, and to facilitate environmental adjustment. Psychotherapy will enable the patient to make an adaptation more rapidly without the need, or with a reduced need, for medications.

9. Patients should be informed of the nature of side effects associated with psychotropic drug use. When antipsychotic drugs are prescribed, patients and their families should be told of the nature of extrapyramidal symptoms, particularly acute dystonic reactions. The therapist should not fear that an open discussion of side effects will deter the patient from agreeing to take medication, particularly if it is made clear that the benefits of treatment outweigh the risks. Patients receiving short-acting hypnotic drugs should be warned of possible rebound insomnia on the nights immediately after medication is discontinued.

10. Several drug preparations are marketed that contain fixed combinations of compounds with different clinical indications. The most widely used combination drugs are Triavil and Etrafon (both of which contain antipsychotic perphenazine and antidepressant amitriptyline) and Limbritol, a combination of chlordiazepoxide and amitriptyline. These three combination drugs may account for 20 percent of all prescriptions of antidepressant drugs. Nevertheless, except in a few special circumstances, there is little rational basis for the use of these combinations since the mixture of the drugs in fixed doses exposes the patient to unnecessary amounts of at least one of the compounds. This, in turn, causes a higher incidence of side effects. Whether drugs are used alone or in combination, dosage should be individualized according to clinical response.

11. Every class of psychotropic medication has been shown to increase the risk of birth defects. Though evidence that antipsychotic drugs produce congenital malformations is contradictory, the teratogenetic effects of lithium, anxiolytics, and tricyclic antidepressants is documented. Considering the consequences of birth defects for the parents and offspring, it is strongly suggested that women who intend to become pregnant or who are pregnant be managed by nonpharmacological modalities. If the use of medication is being considered for psychotic women, hospitalization is advisable to see whether a structured secure environment obviates the need for drugs. In cases of depression during

pregnancy, ECT is preferable to antidepressant medication. However, at times drug therapy is unavoidable, particularly when the patient's illness threatens the lives of both herself and the fetus.

12. The therapist should be mindful of the fact that according to the law patients have a qualified constitutional right to refuse psychotropic and antipsychotic medications, and this right has been recognized by a number of federal courts. In cases of incompetency, judgment about drug treatment decisions must be entrusted to a court.

13. Discussion with patients who require maintenance drug therapy can be reassuring to the patient, even to schizophrenics when informed about tardive dyskinesia. No increase in relapse or treatment noncompliance need be anticipated. (Munetz & Roth, 1985).

14. A patient who consents to take a drug should be told the name of the medication, whether it is intended to treat the disease or relieve symptoms, and how important it is to take it regularly, how to tell when it is working, what to do if it is not working, when and how to take it (before or after meals), how long to continue taking it, side effects and what to do about them, possible effects on driving and work with precautions on what to do, and interactions with other medications. (Drug and Therapeutic Bulletin, 1981).

15. Useful texts in pharmacotherapy are: Appleton and Davis (1980), Baldessarini (1984a & b), Hollister (1978),Klein et al. (1980), Mason and Granacher (1980), Simpson (1983).

CONFRONTATION

Psychodynamic theory and psychoanalytic methods are often accused of helping patients avoid responsibility for their behavior, blaming inner conflicts foisted on them by their parents or by past experience over which they had no control. In confrontation techniques it is assumed that the patient must accept responsibility for actions and take the consequences for behavior that is counterproductive. The patient is exposed to a surprise or shock stimulus from which there is no escape and to which he or she must respond. Retreats into unreality and evasive defense are cut off. The patient is invited to explore the reactions with the aid of the therapist. He or she must justify aspects of

verbalizations and behavior that the therapist believes are significant. There are some people who learn best by being subjected to such psychological assault. This acts as an aversive stimulus to force a different mode of thinking and behavior, to doubt habitual coping devices, and to reach for new adaptations. The patient may then either be left to ingenuity to find alternative patterns, or possible solutions may be suggested in the hope the patient will grapple onto one of them. The effectiveness of this intervention will depend on the acceptance of the therapist as an authority whose injunctions must be incorporated at face value, as well as readiness for and ability to change. The timing of confrontation is important. We are all aware of how frequently the challenging of pathological character traits merely makes them more rigid. Careful empathic interpretation may have to precede forceful confrontation.

The selection of a proper area for confrontation will depend on the perceptiveness and diagnostic skill of the therapist. There are some therapists who, wedded to a special way of thinking about dynamics, impose this on the patient. Thus if therapists believe that masochism is a universal liability and at the bottom of all pathology, they will interpret the symptoms of the patient in this light. Lewin (1970), for example, believes that every symptom serves both self-tormenting purposes as well as a means of provoking others. Even character patterns are interpreted as a masochistic need to suffer and punish people. The patient is helped "to see what he wants to do and what his conscience forces him to do" and how the disparity creates difficulties. The contrast between a healthy conscience that guides while inhibiting destructive actions and the patient's existing sadistic conscience that viciously torments and punishes is pointed out. It becomes essential for the patient to recognize that an intemperate and merciless conscience is the *"common enemy* against which the therapist is his ego's strong ally." No immediate interpretations are made of specific conflicts. "The initial confrontations are confined to the patient's need for self-punishment and his masochistic responses to anger."

The universality of this concept about masochism may be doubtful but sometimes masochism *is* at the basis of an individual's problems. Accident proneness, obsessional self-torment, suicidal tendencies, and hypochondriacal self-torment, suicidal tendencies,

and hypochondriacal preoccupations, for example, may be indications of a generalized masochism. Where this is apparent, an explanation such as the following may be offered: "You feel angry at what your parents did to you as a child. But you also feel guilty for your anger and thoughts. So you punish yourself for these thoughts and feelings. Your symptoms and your behavior seem to me to be the results of your punishing yourself. Now what are you going to do about what you are doing to yourself?" Should these explanations and injunctions fail to produce results, some therapists resort to stronger challenges and confrontations.

While aggressive confrontation under these circumstances may prove profitable in some patients with good ego strength, it may not be applicable to sicker patients unless the confrontations are toned down to a point where they are executed in an empathic reassuring way. Even then it may be necessary to wait until a good working relationship has been established, and then only after it becomes apparent that masochistic maneuvers are obviously being employed by the patient in the interests of resistance—"You seem to be punishing yourself by refusing to get well."

Other explanations than masochism may be offered by therapists trained in specific schools of psychology or psychiatry. One universal basic cause is presented for all types of emotional illness, and this single etiological factor is tortured to fit in with *every* symptom and behavioral manifestation. Thus, the patient may be dazzled by brilliant explanations of the malfunctions of pregenital splitting, or of the Oedipus complex, or of the devalued self-image, or of subversive archetypes, or of conditioned anxiety, or of any of the countless theories around which current psychologically ideologies are organized. While such single explanations may not be accurate, they may be temporarily effective, especially when dogmatically stated. In the long run, however, they will not hold up.

Most therapists who utilize confrontation employ it in the medium of a wide assortment of eclectic methods like role playing, Gestalt therapy, psychodrama, transactional therapy, encounter therapy, existential therapy, and psychoanalytically oriented psychotherapy.

Utilizing a transactional model, Garner (1970) has developed a confrontation technique that "focuses on the patient's conflict between the unconscious or conscious desire to approach a certain goal and the avoidance tendencies." The technique is characterized by interventions in the form of frequent directive statements made to the patient, with the question, "What do you think or feel about what I told you?" The patient's response is studied, whether it be complete compliance, compliance with critical appraisal, or critical appraisal. In this way an attempt is made to probe *reactions* to statements and to avoid the parroting of insight. The challenging question of the therapist requires that the patient explore the role of the therapist and the interactional dynamics of the relationship. It forces the patient also to examine the stereotyped nature of thoughts and behavior. The patient is invited to work out a mutually satisfactory solution to conflicts.

The focus may be limited or may involve the resolution of a core conflict that existed in the early life of the patient. For example, patients with dependency problems or separation anxiety may be confronted with, "Stop believing you are incapable of taking care of yourself," or "You are acting like the most helpless, inept person in the world." After each of these statements there is added, "What do you think or feel about what I have told you?" The latter question acts like a lever to explore compliance or noncompliance tendencies and to engage in problem-solving activities.

The confrontation formulations may be employed adjunctively in any form of insight therapy when a clearly defined conflict is exposed. They may be employed to reinforce a constructive defense or to challenge a neurotic defense, as in peer groups with addicts (Adler, G, & Buie, 1974). Among their uses is testing how thoroughly the patient has understood a point stressed by the therapist. In this way misinterpretations may be immediately corrected. Confrontation may also be used as an adjunct to behavioral and other educational methods as a wedge into cognitive areas. Obviously, sicker patients, such as borderline cases and schizophrenics, do not respond well to the technique.

GESTALT THERAPY

Establishing its position in the Human Potential Movement, Gestalt therapy (see Chapter 11) gets its inspiration from Gestalt psychology, existentialism, psychodrama, and psychoanalysis (particularly character analysis). It stresses the immediacy of experience in the here and now and nonverbal expressiveness (Fagan & Shepherd, 1970). It describes itself as a philosophy of living in the present rather than the past or future, of experiencing rather than imagining, of expressing rather than explaining or justifying, or avoiding the "shoulds" or "oughts," of taking full responsibility for one's actions, feelings, and thoughts, and of surrendering to "being as one is" (Naranjo, 1971).

By observing the patient's positive gestures and bodily movements, Gestalt therapists attempt to discern aspects that reflect unconscious feelings. The therapist points out these tendencies and asks the patient to exaggerate them, to express any feelings associated with them. The object is to expand the patient's awareness of the self, bodily sensations, and the world around one. Gestalt techniques are sometimes employed to catalyze other therapies. (Perls, 1973; Polster & Polster, 1973).

As to the actual techniques, Gestalt therapists have different ways of operating. Many follow the precepts of Fritz Perls (1969), particularly in working in the here and now, eschewing the "why" in favor of the "how." Since it is contended that review of the past cannot change what has happened, the past is avoided, the focus being on the immediate I-Thou therapeutic relationship. There is insistence on the patient taking full responsibility for the choices and decisions he or she makes. Only by self-acceptance, it is avowed, can meaningful contact be made with others. Closely observing ambiguous nonverbal behaviors and confronting the patient with these without analysis or interpretation may open up channels of repressed ideations and feelings. The patient may be asked to repeat or exaggerate unusual movements and amplify or adopt opposing modes of verbalization. "The whisperer experiments with yelling, the yeller experiments with whispering, the intellectual explainer who drowns everyone with words experiments with babbling sounds, enabling new awareness of sharing and holding back" (Kriesgfeld, 1979). An important objective is restoration to one's total being of split-off and dissociated aspects of the self. The person is consequently exposed to a group of

"therapeutic experiments" in order to come to grips with repressed and repressing aspects of oneself. A patient may be requested to hold conversations with various parts of the body that feel tense or painful, or with people and objects in dreams. One may project these parts, people, or objects onto an empty chair and engage in a dialogue with these. A number of texts are available detailing gestalt techniques (Perls, 1969; Smith, 1976).

The patient may be asked to observe things about the therapist's waiting room and to comment on them, particularly to speculate on the kind of a person the therapist is believed to be from this data. If the patient becomes aware of certain bodily sensations like heart beating, deep breathing, neck stiffening, etc., he or she may be asked to talk to the heart, lungs, neck, etc. The projective elements of anything that one says are inquired into by asking the patient to relate comments about others to oneself. The patient is encouraged to do, and even to exaggerate doing things that he or she avoids or is ashamed of, at first in fantasy and then slowly in reality. All aspects of the patient's dreams are considered part of the self, and the patient is asked to play these parts, dramatizing them while verbalizing feelings freely. Many of the Gestalt techniques lend themselves to groups as well as individual therapy. The techniques used for the most usual situations encountered in therapy are summarized here:

1. *Dealing with conflict:* When elements of a conflict are perceived (e.g., dominant desires versus passive impulses; masculine versus feminine, etc.), the patient is asked to play both roles in turn, utilizing the empty chair in which an imagined significant person is seated or the counterpart aspect of the self is seated.

2. *Unresolved feelings:* When detected, the therapist may insist that these be expressed.

3. *Difficulties in self-expression:* A game is often played wherein the patient makes a statement and ends it by saying, "And I take responsibility for it."

4. *Fear of offending others:* In a group the patient goes around expressing attitudes and feelings frankly to each member.

5. *Testing projections:* A patient who believes another individual has a problem or characteristic is asked to play a role as if the problem or characteristic is

one's own.

6. *Challenging reaction formations* (e.g., excessive prudishness): Here the therapist may ask the patient to play the opposite role deliberately (e.g., verbalizing sexual freedom).

7. *Managing anxiety:* The therapist says, "Why not let it build as far as it likes. Don't try to stop it. Emphasize your shaking. Try to bring it on."

8. *Tendencies to detachment and withdrawal:* The patient is asked to focus on the situations or inner feelings that cause withdrawal.

9. *Exploring the meaning of gestures or unusual verbal statements:* When these are noticeable, the patient is asked to exaggerate them and detail associations.

10. *Difficulties in making assertive statements:* The patient is encouraged to say before each statement, "Of course" and "It is certain that."

11. *Use of dreams:* Each aspect of the dream is believed to represent a part of the individual. The patient is asked to identify with each aspect of the dream and act out a role talking to various aspects of oneself.

12. *Dealing with distorted values:* The therapist often tries to act as a model by verbalizing and sharing with the patient his or her personal values and feelings.

HYPNOSIS

Trance phenomena have been utilized as part of religious and healing rituals in all ages and cultures since the earliest of recorded history. The loss of control by the subject in the trance, the bizarre muscular movements, and the vivid imagery that is released have suggested "possession" by spirits and extramundane forces that have led observers to link hypnosis with mysticism and the paranormal. It is only relatively recently that attempts have been made at scientific investigation of hypnosis in the effort to understand how it influences behavior and particularly its therapeutic potentials. Modem uses of hypnosis embrace its employment within the matrix of a number of paradigms, such as social influence, dissonance reduction, indirect metacommunications, employment of paradox,

imagery evocation, double binds and a variety of other interventions. Most recently the dramatic innovative techniques of Milton Erickson have been analyzed (Rossi, 1980; Zeig, 1985a and b) with the object of distilling from them strategies that can enhance the therapeutic process. Some new ideas have emerged from this contemporary work including "neuro-linguistic programming" (Bandler & Grinder, 1975) through which an attempt is made to manipulate unique individual thought processes in order to effectuate changes in behavior and feelings.

Such studies have shown that employed by reasonably trained professionals within the context of a structured therapeutic program, with awareness of limits of its application, hypnosis can make a contribution as an adjunct to any of the manifold branches of psychotherapy, whether these be supportive, reeducative, or psychoanalytic.

Most professionals who are fearful of hypnosis as a therapeutic tool, or exaggerate its virtues, either have never experimented with it for a time sufficient to test the method or else are victims of superstition, prejudices or naive magical expectancy. A number of spokesmen for hypnosis, some writing extensively, help to discredit it by overdramatizing the process, by exaggerating its powers, by participating in and publishing results of poorly conceived experiments, by engaging in naively organized therapeutic schemes, by offering therapeutic formulations that violate the most elementary precepts of dynamic psychology, or by promulgating its presumed dangers for which there is little basis in fact (Wolberg, LR, 1956).

How hypnosis aids in securing therapeutic effects is not entirely clear, but we may postulate two important influences. First, hypnosis rapidly produces a remarkable rapport with the therapist. Irrespective of the fact that this is probably linked to some anachronistic regressive dependency need, a strong impact is registered on the therapeutic working relationship. The placebo influence, a component of all therapies, is strongly enhanced. Suggestion, another universal component of all treatment processes, is so expanded in hypnosis that the patient responds sensitively and with dramatic readiness to both indirect, subtle persuasions by the therapist and to direct commands

and injunctions that are not too anxiety provoking. The relationship with the therapist, in a surprisingly short time, becomes one in which the therapist becomes endowed with noble, protective, and even magical qualities. The ultimate result of these combined forces can be substantive relief from tension, a restoration of homeostasis, and a recapturing of a sense of mastery, which in themselves may restore adaptive defenses and produce a symptomatic cure.

The second influence of hypnosis is upon the intrapsychic processes. Hypnosis promotes an altered state of consciousness. As such, repression may temporarily be lifted with exposure of emotionally charged impulses that have been denied direct expression and that have hitherto partly drained themselves off through substitutive symptomatic channels. This can lead to a release of vivid imagery and emotionally cathartic verbalizations. Such spontaneous outbursts usually occur only in persons who are strongly repressed while nurturing explosive inner conflicts. On the other hand, a therapist utilizing exploratory techniques to probe unconscious ideation may, by direct suggestion or regression and revivification, expose less highly charged but significant fantasies, verbal associations, and memories, thus opening roads to greater self-understanding.

Hypnosis as a relaxing agency has been employed in physical and psychological disturbances that are characterized by stress and tension. Since stress may have a damaging effect on all bodily functions, its amelioration can be important for healing (Wolberg, LR, 1957). Tension relief may, on the basis of suggestion during the trance state, be supplemented perhaps by self-hypnosis (Wolberg, LR, 1965) or by such techniques as autogenic training (Luthe, 1963; Schultz & Luthe, 1959; Luthe et al, 1963).

Where the symptom does not bind too much anxiety or where its pleasure and masochistic values are not too intense, it may be possible to alleviate it by hypnotic suggestion without symptom substitution. Not only may the ensuing relief initiate a better adjustment, but also it may set off a chain reaction that, reverberating through the entire personality structure, influences its other dimensions. Suggestive hypnosis may also be of

value in controlling the ruminations of chronic obsessive-compulsive patients whose preoccupations immerse them in interminable misery. By helping such victims to divert their thinking into more constructive channels, it may initiate relief of anxiety and a better adaptation. With caution hypnosis may be adopted as a suggestive instrument in controlling certain habits, such as overeating, excessive smoking, and insomnia. The phrasing of suggestions here is important.

Some therapists still use hypnosis like a magic wand to dissipate in thin air symptoms that hamper the adjustment of the patient. While symptom removal by hypnosis is justified where the symptom blocks therapy, as in emergencies or where more extensive therapy cannot be applied, one must realize its limitations. For so long as we depend solely upon the authoritarian powers with which the hypnotic situation automatically invests us, our therapeutic effectiveness will be no greater, and often will be less than miraculous healing. Christian Science, and other therapies dependent upon faith, magic, and prayer. Because of the evanescent effects of suggestive hypnosis, hypnotic therapy has historically enjoyed brief spurts of popularity followed by disappointment and abandonment of the method.

Hypnosis may prove itself to be singularly successful in overcoming resistance, exposing segments of the person's inner life that are deeply buried within and which have hitherto evaded detection. In rare instances this exposure of memories and experiences, as well as the related emotions, will result in the relief of a symptom. In my own work I have been able to remove isolated amnesias, motor paralysis, blindness, and anesthesias through the hypnotic revival of some early experience that resulted in these hysterical symptoms. This is what Freud did in his original work at the turn of the century, which resulted in his pioneer psychoanalytical discoveries. Hypnotic removal of symptoms should if possible be followed by further explorations for conflicts that have generated hysterical defenses.

The use of hypnosis in exploratory psychotherapy, such as in the insight approaches, is contingent upon the influence of hypnosis on unconscious resistance that in resolution

helps the individual establish closer contact with repressed needs and conflicts. It may thus be possible to bring to the surface significant memories and repressed impulses that expedite the analytic process. (Wolberg, 1964a; 1986)

Hypnosis is particularly useful in freeing verbalizations, in liberating transference, and in helping the patient to recall dreams. Where anxiety blocks speech, the mere induction of a trance may serve to release a verbal discharge. Moreover, the provocation of transference feelings may bring to the surface painful emotions as well as fantasies that sometimes burst through with intense violence. Where free associations have been blocked for one reason or another, hypnosis may suffice to restore this form of communication. Hypnosis may serve also as a means of stimulating dreams in patients who are unable to remember them or who have "dried up" in their analytic productiveness.

In behavior therapy hypnosis is useful in various ways. First, it establishes in the mind of the patient the authority of the therapist, who will act as the reinforcing agency. Under these circumstances positive counterconditioning, aversive conditioning, extinction, and other tactics will be catalyzed. Second, by promoting relaxation through hypnosis a positive stimulus is supplied that becomes affiliated with the conditioned stimulus and helps to extinguish it. Third, on the basis of suggestion, the objectives of the therapist, once explicitly defined, may be more easily accepted. The patient is encouraged to behave in emotionally constructive ways, in quest of reversing established patterns or correcting behavioral deficits. Thus, in the method of desensitization through reciprocal inhibition anxiety-provoking cues are presented in a climate of relaxation in progressively stronger form.

There is no way of predicting in advance the exact influence hypnosis may have on the patient or problems since each individual will respond uniquely to the phenomenon of hypnosis in line with the special personal meanings. The mental set toward hypnosis, the motivations to be helped, the depth and quality of resistances, the preparation for induction, ideas about the therapist and particularly the image conjured up of the

therapist, the skill of the therapist as a hypnotist, the quality of the suggestions administered, the management of the patient's doubts and oppositional tendencies, and the nature of the transference and countertransference will all enter into the responsive Gestalt.

Potentially, hypnosis may catalyze every aspect of the therapeutic process. Whether or not a therapist will want to employ it will depend largely on how much confidence one has in hypnosis and how well one works with hypnotic techniques.

Hypnosis is an intense emotional experience that may affect both patient and therapist. In the trance a dynamic configuration of many kinds of phenomena are constantly interacting in response to functional psychophysiological changes within the individual and the specific significance of the hypnotic interpersonal relationship. As attention is shifted from the external world toward the inner self, there is an expansion of self-awareness and a lifting of repressions, with exposure of certain repudiated aspects of the psyche. A regressive kind of relationship develops between the subject and operator, the latter being promoted into the post of a kind of magical authoritative figure.

Hypnosis may also release powerful feelings in the therapist, aspects of which, in the form of countertransference, may be inimical to the therapeutic objective. Particularly obstructive are omnipotent, sadistic, and sexual strivings. Only by experimenting with hypnosis can a therapist determine whether one is personally capable of employing it as a therapeutic adjunct. While one may be able to do good psychotherapy with the usual psychotherapeutic techniques, attempts at hypnosis may alter one's manner toward the patient in ways that will prove antitherapeutic. Thus, a therapist may act aggressively toward patients perceived to be in a helpless state. Coordinately, one may become suffused with feelings of grandiosity. Or one may, as a projected Svengali figure, find oneself sexually attracted to a patient whom one regards as passively seductive. Should these feelings arise in spite of measures to control them, it is best to pursue a pattern of caution and refrain from employing hypnosis in practice.

Hypnosis, then, is merely a device to facilitate the psychotherapeutic process rather

than to substitute for it. No problems need be anticipated in the induction of hypnosis, and in the application of hypnotic and hypnoanalytic procedures, if the therapist masters at least one of the standard techniques, applies it confidently, while constantly observing the reactions of the patient and of oneself. Protracted dependency reactions are no more common than in psychotherapy without hypnosis. It goes without saying that hypnosis is no substitute for careful training, extensive experience, and technical competence. It will not make up for lacks in judgment or skill. However, a sophisticated psychotherapist who has learned how to utilize hypnosis has available a most important adjunctive tool.

Induction of Hypnosis

Hypnosis is extremely easy to induce. The object is to bring the patient to a hyper-suggestible state. Toward this end the operator executes a number of maneuvers, the most common one being a state of muscular relaxation and the fixation of attention. Important rules to follow are these:

1. Engage the attention of the patient by assigning a task, (muscle relaxation, hand clasp, hand levitation), descriptions of which will follow.

2. Approach the induction with a confident manner. Any faltering or unsureness in vocal expression will influence the patient negatively. Adopt a persuasive, calm, reassuring tone of voice, droning suggestions rhythmically and monotonously.

3. Employ repetition in suggestions to focus the patient's attention.

4. Excite the imagination of the patient by building word pictures so that the patient practically lives and feels what is suggested. (In children one can engage their attention by asking them to imagine watching a television screen and observing their favorite programs.)

5. Use positive rather than negative suggestions. For example, where pain is to be deadened, do not say, "You will have no pain." Say, "The sensation will change so that instead of feeling what you have been feeling, it will feel dull, numb, and tolerable." If a hypodermic injection is to be given, do not say, "This will not hurt," but rather, "This will be like a tiny mosquito bite."

6. Should the patient at any time open the eyes and insist he or she is not hypnotized, put your fingers on the eyelids to shut them and say, "That doesn't matter, I just want you to relax." Then continue with suggestions.

7. Almost universally, patients, after the first induction, even those who have been deeply hypnotized, will insist they were not in a trance. Reply with, "Of course you weren't asleep or anesthetized. You were in a state of relaxation and this is all that is necessary. You may go deeper next time, but it really doesn't matter." Give the patient a typewritten copy of material describing some phenomena of hypnosis (see [Appendix U](#)).

8. Some operators find it important to tell the patient that all that will be achieved in the first session is not hypnosis but a state of relaxation that will help the patient quiet the symptoms: "If you fall asleep, that is fine; if you feel completely awake, that too is fine. The effect will still be there." To some people the word "hypnosis" has many unfortunate connotations. It often embraces expectations of an immediate miracle cure. When the patient fails to go into the depth of trance imagined he or she should achieve with the "hypnotic" indication, one may become upset, feel hopeless, and lose confidence in the therapist.

A simple technique that I have found valuable, particularly for suggestive-persuasive-reeducative therapy, involves muscle relaxation. This method lends itself to teaching the patient self-hypnosis to carry on suggestions by oneself. It is helpful in this direction to supply the patient with a tape recording (the patient may bring a machine and a recording may be made directly on it; or if the therapist's recorder is compatible with that of the patient, he or she may be given the recorded tape at the end of the session). The patient may be requested to lean back in a chair and shut the eyes (if preferred one can be supine on a couch) and the material below may be dictated, *slowly,* in a persuasive tone (the therapist may have to practice reading the material so that it does not come through in a stereotyped mechanical way). As a preliminary, I tell the patient, "I would like to teach you a simple relaxing technique that should help you." If the patient agrees, I continue.

Making a Relaxing and Ego Building Recording/h3>

Having prepared the recorder, the therapist, prior to dictating into the microphone

says:

All that will happen is that you will be pleasantly relaxed, no sleep, no deep trances, just comfortable. Now just settle back and shut your eyes. *[At this point the therapist may read the following material. If a recording is to be made, start the recording.]* Breathe in deeply but gently through your nostrils or mouth, right down into the pit of your stomach. D-e-e-p-l-y, d-e-e-p-l-y, d-e-e-p-l-y; but not so deeply that you are uncomfortable. Just deeply enough so that you feel the air soaking in. In . . . and out. D-e-e-p-l-y, d-e-e-p-l-y. In . . . and out. And as you feel the air soaking in, you begin to feel yourself getting sleepy and r-e-l-a-x-e-d. Very r-e-l-a-x-e-d. Even d-r-o-w-s-y, d-r-o-w-s-y and relaxed. Drowsy and relaxed.

Now I want you to concentrate on the muscle groups that I point out to you. Loosen them, relax them while visualizing them. You will notice that you may be tense in certain areas and the idea is to relax yourself completely. Concentrate on your forehead. Loosen the muscles around your eyes. Your eyelids relax. Now your face, your face relaxes. And your mouth . . . relax the muscles around your mouth, and even the inside of your mouth. Your chin; let it sag and feel heavy. And as you relax your muscles, your breathing continues r-e-g-u-l-a-r-l-y and d-e-e-p-l-y, deeply within yourself. Now your neck, your neck relaxes. Every muscle, every fiber in your neck relaxes. Your shoulders relax . . . your arms . . . your elbows . . . your forearms . . . your wrists . . . your hands . . . and your fingers relax. Your arms feel loose and limp; heavy and loose and limp. Your whole body begins to feel loose and limp. Your neck muscles relax; the front of your neck, the back muscles. If you wish, wiggle your head if necessary to get all the kinks out. Keep breathing deeply and relax. Now your chest. The front part of your chest relaxes . . . and the back part of your chest relaxes. Your abdomen ... the pit of your stomach, that relaxes. The small of your back, loosen the muscles. Your hips . . . your thighs . . . your knees relax . . . even the muscles in your legs. Your ankles . . . your feet . . . and your toes. Your whole body feels loose and limp. *[Pause.]* And now, as you feel the muscles relaxing, you will notice that you begin to feel relaxed all over. Your body begins to feel v-e-r-y, v-e-r-y relaxed . . . and you are going to feel d-r-o-w-s-i-e-r, and d-r-o-w-s-i-e-r, from the top of your head right down to your toes. Every breath you take is going to soak in deeper and deeper and deeper, and you feel your body getting drowsier and drowsier.

And now, I want you to imagine, to visualize the most relaxed and quiet and pleasant scene imaginable. Visualize a relaxed and pleasant quiet scene. Any scene that is comfortable. *{[The following may be introduced at the first, and perhaps the second induction to give the patient an idea of the kind of imagery that is suitable. Once the patient selects a scene, these suggestions need not be repeated. If a recording is being made, the recorder should be turned off at this point to eliminate the remainder of this paragraph.]* It can be some scene in your past, or a scene you project in the future. It can be nothing more than being at the beach watching the water breaking on the shore. Or a lake with a sailboat floating lazily by. Or merely looking at the sky with one or two billowy clouds moving slowly. Any scene that is quiet and pleasant and makes you feel drowsy. Or a sound like Beethoven's sonata, or any other selection that is soothing.) Drowsier and drowsier and drowsier. You are v-e-r-y weary, and every breath will send you deeper and deeper and deeper. *[The recorder may now be turned on again.]*

As you visualize this quiet scene, I shall count from one to twenty, and when I reach the count of twenty, you will feel yourself in deep. *[The count should be made very slowly.]* One, deeper, deeper, Two, deeper and deeper and deeper. Three . . . drowsier and drowsier. Four, deeper and deeper. Five . . . drowsier and drowsier and drowsier. Six . . . seven, very very, very

relaxed. Eight, deeper and deeper. Nine . . . ten, drowsier and drowsier. Eleven, twelve, thirteen; deeper and deeper. D-r-o-w-s-i-e-r and d-r-o-w-s-i-e-r. Fourteen, drowsier and drowsier and drowsier. Fifteen . . . sixteen . . . seventeen, deeper and deeper. Eighteen . . . nineteen . . . and finally twenty.

The following "ego-building" suggestions of Hartland (1965) may be employed in supportive and some reeducative approaches. They are introduced at this point.

As I talk to you, you will absorb what I say d-e-e-p-l-y into yourself. "Every day . . . you will become physically *STRONGER* and *FITTER.* You will become *MORE ALERT . . . MORE WIDE AWAKE . . . MORE ENERGETIC.* You will become *MUCH LESS EASILY TIRED . . . MUCH LESS EASILY FATIGUED . . . MUCH LESS EASILY DEPRESSED . . . MUCH LESS EASILY DISCOURAGED.* Every day . . . you will become *SO DEEPLY INTERESTED IN WHATEVER YOU ARE DOING . . . SO DEEPLY INTERESTED IN WHATEVER IS GOING ON . . . THAT YOUR MIND WILL BECOME MUCH LESS PREOCCUPIED WITH YOURSELF . . . AND YOU WILL BECOME MUCH LESS CONSCIOUS OF YOURSELF . . . AND YOUR OWN FEELINGS.*

"Every day . . . YOUR NERVES WILL BECOME STRONGER AND STEADIER . . . YOUR MIND WILL BECOME CALMER AND CLEARER . . . MORE COMPOSED . . . MORE PLACID . . . MORE TRANQUIL. You will become MUCH LESS EASILY WORRIED . . . MUCH LESS EASILY AGITATED . . . MUCH LESS FEARFUL AND APPREHENSIVE . . . MUCH LESS EASILY UPSET. You will be able to THINK MORE CLEARLY . . . you will be able to CONCENTRATE MORE EASILY . . . YOUR MEMORY WILL IMPROVE . . . and you will be able to SEE THINGS IN THEIR TRUE PERSPECTIVE . . . WITHOUT MAGNIFYING THEM . . . WITHOUT ALLOWING THEM TO GET OUT OF PROPORTION.*

"Every day . . . you will become EMOTIONALLY MUCH CALMER . . . MUCH MORE SETTLED . . . MUCH LESS EASILY DISTURBED.*

"Every day . . . you will feel a GREATER FEELING OF PERSONAL WELL-BEING . . . A GREATER FEELING OF PERSONAL SAFETY . . . AND SECURITY . . . than you have felt for a long, long time.*

"Every day ... YOU will become . . . and YOU will remain . . . MORE AND MORE COMPLETELY RELAXED . . . AND LESS TENSE EACH DAY . . . BOTH MENTALLY AND PHYSICALLY.*

"And, AS you become . . . and, AS you remain . . . MORE RELAXED . . . AND LESS TENSE EACH DAY . . . SO, you will develop MUCH MORE CONFIDENCE IN YOURSELF.*

"MUCH more confidence in your ability to DO . . . NOT only what you HAVE to do each day, . . . but MUCH more confidence in your ability to do whatever you OUGHT to be able to do . . . WITHOUT FEAR OF CONSEQUENCES . . . WITHOUT UNNECESSARY ANXIETY. . . WITHOUT UNEASINESS. Because of this . . . every day . . . you will feel MORE AND MORE INDEPENDENT . . . MORE ABLE TO STICK UP FOR YOURSELF, . . . TO STAND UPON YOUR OWN FEET . . . TO HOLD YOUR OWN . . . no matter how difficult or trying things may be. And. because all these things WILL begin to happen . . . EXACTLY as I tell you they will happen, you will begin to feel MUCH HAPPIER . . . MUCH MORE CONTENTED . . . MUCH MORE CHEERFUL . . . MUCH MORE OPTIMISTIC . . . MUCH LESS EASILY DISCOURAGED . . . MUCH LESS EASILY DEPRESSED."*

These are broad suggestions that cover most problems. The therapist may interpolate specific suggestions in accord with the special needs of the patient.

> Now relax and rest for a minute or so, going deeper, d-e-e-p-e-r, d-e-e-p-e-r, and in a minute or so I shall talk to you, and you will be more deeply relaxed. *[Pause for one minute.]*

> In summary, there are four things we are going to accomplish as a result of these exercises, the 4 S's: symptom relief, self-confidence, situational control and self-understanding. First, your various symptoms *[enumerate]* are going to be less and less upsetting to you. You will pay less and less attention to them, because they will bother you less and less. You will find that you have a desire to overcome them more and more. As we work at your problem, you will feel that your self-confidence grows and expands. You will feel more assertive and stronger. You will be able to handle yourself better in any situations that come along particularly those that tend to upset you *[enumerate]*. Finally, and most importantly, your understanding of yourself will improve. You will understand better and better what is behind your trouble, how it started and why your symptoms developed. Whenever you feel your symptoms coming on you will be better able to understand what is bringing them about, and you will be able to do something constructive about this, more and more easily. You will continue working on what is behind your problem. *[Pause.]*

> You should play the recording at least twice daily. The time is up to you. Remember it makes no difference if you are just pleasantly relaxed, or in a deep state, or asleep, the suggestions will still be effective. *[Pause.]*

> Relax and rest and, if you wish, give yourself all the necessary suggestions to *yourself* to feel better. Using the word "you." Take as long as you want. Then you can go to sleep or arouse yourself. When you are ready, you will arouse *yourself* no matter when that is, by counting slowly to yourself from one to five. You will be completely out of it then—awake and alert. Remember, the more you practice, the more intense will be your response, the more easily will your resistances give way. Keep on practicing. And now go ahead—relax—and *when* you are ready—wake *yourself* up.

If a recording is being made, the machine may now be turned off. The patient may be able to arouse himself or herself as desired, or, if too long a period transpires, the patient may be aroused by saying:

> Now, when I count to five, you will be awake. Your eyes will open, you will feel alert and well. One . . . *[pause]* . . . two *[pause]* . . . three . . . *[pause*] . . . four . . . *[pause]* . . . five . . . Lift your eyes.

The above induction may prove invaluable in short-term therapy and if it is recorded on an audiotape and given to the patient to talk about the posthypnotic feeling gains made during the active period of therapy. Understandably, as directive as it is, hypnosis will stimulate transference responses, positive and negative. Asking the patient to talk about the posthypnotic feelings may elicit material that can be useful to work productively with

resistances and defenses. A dynamically oriented therapist may ask for dreams and associations and often the reactions of the patient to the hypnotic induction will open up interesting areas for exploration. Suggestions given a patient to dream will usually expedite dream reporting. This is especially helpful in patients who do not remember their dreams. Sometimes a suggestion to redream a forgotten dream during hypnosis may restore the memory; while dreams distorted by secondary elaborations may be corrected, or forgotten fragments reassembled. During hypnosis a patient may be directed to dream about selected subjects such as feelings about certain people, including the therapist.

Other Induction Methods

Other induction techniques may be employed although the foregoing induction method may be all that the therapist needs to use. Elsewhere, detailed accounts of trance induction have been elaborated (Wolberg, LR, 1948, pp. 98-185; 1964a, pp. 31-67). In brief, the required steps are these:

1. Promoting motivations that will lead to hypnosis by associating the desire to get well with cooperation in the hypnotic process.

2. Removing misconceptions and fears about hypnosis by explanation and clarification.

3. Introducing a suggestibility test, like the hand clasp test, to demonstrate that the patient can follow directions.

4. Giving the patient a short preparatory talk to the effect that the patient will not really go to sleep, even though sleep suggestions will help one relax, and that one will not be asked embarrassing questions or forced to do anything one does not want to do.

5. Inducing a trance by any chosen method.

6. Deepening the trance by suggesting more and more complex hypnotic phenomena.

7. Making therapeutic suggestions.

8. Awakening the patient.

9. Discussing with the patient his or her trance experiences.

One of the easiest ways of inducing hypnosis is by means of the suggestibility test of the hand clasp. To do this, the patient is made comfortable in an armchair and asked to relax the body progressively, starting with the muscles in the forehead, then the face, neck, shoulders, arms, back, thighs, and legs. Following this, the patient is enjoined to clasp the hands, a foot or so away from the eyes. With eyes fixed on the hands, the hands are clasped together more and more firmly as the therapist counts from one to five stating that then, it will be difficult or impossible to separate the hands. After the patient has cooperated with this suggestion, the patient is to stare at the hands while the eyes begin to feel tired and the eyelids heavy. The eyelids progressively will get heavier and heavier until the eyelids feel like lead. The eyes will soon close and a pleasant sense of relaxation will sweep over the patient. These suggestions are repeated over and over in a monotonous cadence and in a firm, reassuring tone until the eyes close. The hands are then unclasped with or without the help of the therapist.

An effective way of inducing a deep trance is by means of hand levitation (Wolberg, 1948). This method is more difficult to master than the other techniques and calls for greater effort and persistence on the part of the therapist. With the patient's hands resting lightly on the thighs, the patient is asked to concentrate attention on everything the hands do. Sensations will be noticed, such as the warmth of the palms of the hands against the thighs, the texture of clothing, and perhaps the weight of the hands pressing on the thighs. Then the fingers will wiggle a little. As soon as this happens, the finger that moved first should be raised. Then the patient is commanded to raise the finger that moved first. Thereafter, gazing at the right hand it is anticipated that the fingers will fan out, the spaces between the fingers getting wider and wider. When this happens, suggestions are made that the fingers will slowly lift from the thigh; then the hand will rise as the arm becomes lighter and lighter; the eyes will become tired and the lids heavy. However, much as he or she wants to, the patient is not to fall asleep until the arm rises and the hand touches the face. As one gets more and more relaxed, and the lids get heavier and heavier, the arm and

hand will get lighter and rise higher until it touches one's face. When it touches the face, the patient will be relaxed and drowsy and the eyes will be firmly shut. Suggestions are repeated constantly until they are acted on by the patient. Asking the patient to imagine a string tied around one or both wrists with a balloon at the free end which rises and pulls the hands up until they touch the face, at which point one will fall asleep, is sometimes also effective.

The traditional method of hypnosis through staring at a fixation object continues to be useful. Here a coin, pencil, or shiny object is held above the head, the patient being asked to stare at it while suggestions are made to the effect that one is getting sleepy, that one's eyes begin to water, and one's lids blink until one no longer can keep the eyes open.

As soon as the eyelids close by the use of any of the above methods, the trance may be deepened by suggesting, progressively, heaviness and stiffness of the left arm (limb catalepsy), heaviness of the lids until the patient cannot open them (lid catalepsy), inability to move the extremities or to get out of the chair (inhibition of voluntary movements), hyperesthesia of the hand, anesthesia of the hand, and, perhaps, auditory and visual hallucinations. Some therapists do not go through the formality of deepening hypnosis (the first method of trance induction through muscle relaxation described above illustrates this). However, if probing techniques are to be employed, it is wise to induce as deep hypnosis as possible (see Wolberg 1948, 1964a). As to the actual syndromes helped by hypnosis, many therapists find that is valuable in the following ways:

1. As a means of removing certain conversion symptoms, like paralysis, aphonia, and some psychophysiologic reactions.

2. As a way of controlling the drinking urge in some alcoholic patients.

3. As a vehicle of establishing the authority of the therapist, which the patient does not dare to defy, thus inhibiting acting-out, especially in psychopathic personalities.

4. As a means of bolstering persuasive therapy in obsessive-compulsive reactions.

5. As treatment for certain habit disorders, like smoking, sexual difficulties,

insomnia, overeating, and nail biting.

6. As a mode of reinforcing desensitization and counterconditioning in behavior therapy, as in phobias.

During insight therapy hypnosis may result in the following:

1. Removal of amnesia in post-traumatic stress reactions with release of repressed memories and emotions.

2. Lifting of repression in conversion and dissociative reactions.

3. Resolution of repression in the treatment of other conditions, like anxiety reactions and phobic reactions.

4. Dissipation of certain transference and content resistances.

5. Facilitation of dreams and free associations.

In supportive therapy, where an authoritarian relationship cannot be set up with facility, hypnosis may put the therapist in a sufficiently omnipotent position to produce better results.

There is another use of hypnosis that has not received the attention it deserves, that is, as an experience in relationship. All therapy requires the establishing of a working relationship between therapist and patient. It is impossible, without good rapport, to help the patient to an understanding of the problem and to the resolution of the manifold resistances in utilizing insight in the direction of change. The mere induction of a trance produces a feeling of closeness and trust in a remarkably short time, resolving certain transference resistances and enabling the patient to proceed toward the exploration of anxiety-provoking inner conflicts. In some patients one may employ hypnosis at the start of therapy, and once a relationship has crystallized, one may go on to implement the traditional psychotherapies without hypnosis. This may cut down on the time required for the establishing of a working relationship.

Another technique utilized occasionally during the exploratory phase of therapy is

the training of the patient in self-hypnosis, suggesting that one will investigate spontaneously, through dreams and fantasies in the self-induced trance state, puzzling aspects of the problem and also that one will work out various resistances that may arise. In this way the patient actively participates in the investigative process and time may be saved. The first induction method above may easily be adapted to self-hypnosis. More details may be found elsewhere (Wolberg LR, 1964a). Self-hypnosis may be employed on a maintenance basis where necessary. Qualms about its use need not be felt; addiction to and dependency on self-hypnosis has not occurred in my experience. Appendix V contains an outline for self-relaxation that may be given to the patient. Practice may result in the capacity for self-hypnosis.

Symptom removal through hypnosis should not pose undue risks. The consequences will depend on the way the removal took place and the attitude of the hypnotist. One does not rush into a complex psychiatric picture like a bull in a china shop. Unfortunate aftermaths are usually the product of a disturbed relationship rather than the result of hypnosis. Unsettling reactions to hypnosis do not seem to be greater than untoward responses to any other therapeutic relationship. A study by Litton (1966) of 19 cases of hysterical aphonias was undertaken to test the hypothesis that rapid removal of a symptom will eventuate in substitutive symptoms or in the precipitation of a breakdown in homeostasis. Removal of the symptom through hypnosis was successful in 14 cases and resisted in 5. Follow-up showed no unpleasant sequelae. In 2 cases there was a return of the symptom after 7 months, and in 1 case after 12 months. Readministration of hypnosis rapidly removed the symptom. As explained before, hypnosis provides a dynamic interpersonal situation that evokes processes in the patient that may be productively examined as a biopsy of how the patient responds to an intensive interpersonal relationship. The patient will project into the hypnotic situation his or her basic defenses and demands. Responses to hypnotic induction, and to the trance experience itself, may constitute the material around which the therapeutic work is organized. The specific meaning to the patient of being put into a trance can bring forth various irrational defenses and fears. For instance, a patient with frigidity was referred to me by her psychoanalyst for some hypnotic work. After the third induction, the patient revealed that

she was aware of her need to keep her legs crossed during the entire trance state. So tightly did she squeeze her thighs together that they ached when she emerged from the trance. Prior to the next induction, I instructed her to keep her legs separated. As I proceeded with suggestions, she became flushed, opened her eyes, and exclaimed that she knew what upset her. I reminded her of her grandfather who, on several occasions, when she was a small child, tossed her into bed and held her close to his body. She had felt his erect penis against her body, which both excited her and frightened her. It became apparent that the hypnotic experience constituted for her an episode during which she hoped for and feared a repetition of this sexual seduction, and her leg crossing constituted a defense against these fantasies. Continued trance inductions desensitized her to her fears and were followed by an improved sexual functioning with her husband.

The hypnotic situation may also enable the patient to recall important past experiences. A man of 45 years with a claustrophobic condition of 10 year's duration was referred by an analyst who had treated the patient for several years. While his analysis (four times weekly for *2½* years) had enabled the patient to mature considerably in his relationship with people, the phobic problem remained as an obstinate block to the financial success he potentially could achieve in his business. The phobia made it impossible for him to dine with people, and, whenever he was forced in a situation in which he had to eat with others, he excused himself several times during the meal so that he could go to the bathroom to disgorge his food.

The patient was inducted into a hypnotic state, and the suggestion was made that he would go back to the period in his life when he had first experienced a feeling similar to that in his phobia. After several minutes had gone by, it became apparent from his sweating, bodily movements, and moaning that the patient was undergoing a profound emotional reaction. Asked to talk, he murmured, in a voice scarcely audible:

> I have a peculiar feeling; the chair is narrow and you are closer. I get a good feeling, a secure feeling *[breaks out into crying]'*, my father, I hated him. He rejected me. He was very critical. He never praised me for anything. There was something in him that wouldn't permit him to like me. I hate him. I hate him. *[The patient beats the side of the chair.]* I feel all choked up. I think of my mother. I am little. I see her *[compulsive crying]*.

The patient's recall of his early traumatic incident enabled us to get into other intimacies. An important one was his relationship with his analyst. It became apparent that he had become bogged down in transference resistance. Discussing this appeared to change his feeling toward his analyst, from one of resentment to that of gratitude that he had been helped significantly in many dimensions. Soon he desensitized himself to the phobic situation.

In working with resistances to giving up symptomatic complaints, the way suggestions are made may help avoid precipitating too much anxiety. If the therapist feels the patient is unable to tolerate recovery for the moment, one may say: (1) "Perhaps there is some information you do not wish to tell me at this time. It is all right to hold this back until the next time you see me or whenever you are ready." Or (2) "I wonder how long it will be before you will want to let yourself give up these uncomfortable symptoms. I do not want you to give them up all at once. Try hard to hold on to one bit of your symptom and not to let it disappear for at least a week or so after you feel comfortable."

In reconstructive therapy hypnosis may be employed to expedite free association in patients who are blocked. It may also foster dream recall. A patient came to me for hypnosis to help her recover a dream that kept eluding her, but which she felt was significant. It had first appeared, she claimed, a long time ago during her psychoanalysis, but she had forgotten it. Try as hard as she could, she was not able to bring it back. Years had gone by after she had stopped her analysis, but periodically she had the impression

that the dream returned, only to vanish with daylight. The situation intrigued her and she asked for referral for hypnosis, during which I told her that if she had a spontaneous dream, she would remember it. On awakening she revealed that a most interesting thing had happened to her while she was relaxing. The meaning of the forgotten dream had flashed through her mind.

"All of a sudden I realized that the dream was that I was all alone and I don't want to be alone. I don't want to be alone. I shed copious tears." This experience brought about a "heavy sadness" which haunted the patient for several days. A spontaneous dream followed: "I go over the rooms that we lived in as a child. The rooms are empty. I'm all alone. Where is everybody? My mother, father, sister, brothers, where are they? There is nobody there. Ours was a busy house. Copious tears." Burdened by an even deeper depressive feeling to which she could not associate in the waking state, the patient was rehypnotized and requested to say what was on her mind. She replied: "Please everybody, please everybody, come back, come back. Don't leave me alone again.

What did I do, what did I do that this should happen." In bitter tears she revealed a memory of having as a tiny child been sent to a hospital after burning herself. Separation from her mother for a protracted period had initiated fear that she would be punished and sent away if she did "anything bad." The traumatic incident (which was validated) was followed by separation of her father from her mother when she was 3 years of age, for which the patient blamed herself unfairly. Therapy including teaching the patient self-hypnosis, during which she was enjoined to revive these images, to master the emotions related to them, and to revalue them in her mind. It was through this means that she desensitized herself. Ultimately her depression was resolved. Hypnotically induced dreams may, in this way, where insight is fragmented, serve to weave unrelated mental threads into a meaningful fabric.

A case illustration of how hypnosis may aid in the uncovering process, with a recording of hypnosis through the handclasp method, may be found in Chapter 44.

NARCOTHERAPY (NARCOSYNTHESIS, NARCOCARTHARSIS, NARCOANALYSIS)

The difficulty of inducing hypnosis in certain subjects, the relatively long time required to produce a trance even in susceptible persons, and the inability on the part of some therapists to acquire skill in trance induction, some time ago brought into prominence a simple technique of promoting hypnosis by the intravenous injection of a hypnotic drug, such as, Sodium Amytal (sometimes called the "Amytal interview") or Sodium Pentothal (Horsley, 1936, 1943; Grinker & Spiegel, 1945; Sargant & Shorvon, 1945; Hoch & Polatin, 1952). It was most prominently used for the therapy of traumatic neurosis (Posttraumatic Stress Disorder) during and after World War II.

Injected narcotic substances produce a cortical depression with relaxation and heightened susceptibility to suggestion, reassurance, and persuasion. The name given to this combined use of narcosis and supportive therapy is "narcosuggestion." The psychologic regression in narcosis, as in hypnosis, incites archaic dependency feelings toward the therapist and expedites authoritative supportive procedures. Acute anxiety reactions, some manic and catatonic reactions which constitute emergencies, or assaultive or self-destructive tendencies may sometimes be approached by narcosuggestion as may other conditions that call for supportive measures. In very resistent phobias the patient, in a light state of narcosis, may be exposed to counterconditioning techniques of behavioral therapy, for instance to Wolpe's "reciprocal inhibition" technique (see Chapter 51). As a diagnostic aid narcotherapy is sometimes employed to unmask a schizophrenic tendency that is concealed by defensive reactions in the waking state. This can help in treatment planning.

Releasing of cortical inhibition liberates charges of pent-up emotion that have been kept from awareness by repression. The result is an emotional catharsis. This effect may also be facilitated in narcosis by suggestion, by persistent questioning and probing, and by encouraging the patient to explore painful areas of his or her life. Recollection of repudiated traumatic memories and experiences may remove mental blocks, flurries of anxiety, depression, and psychosomatic symptoms associated with the repression of such harassing foci. These effects have been found helpful in the treatment of certain emotional problems, particularly acute stress reactions, (transportation and industrial accidents,

catastrophes like floods and fire, and war neuroses), and some anxiety and hysterical reactions. In the war neuroses, particularly, beneficial results are possible especially in cases of recent origin treated before rigid defenses have organized themselves. The working through of the repressed or suppressed material in both narcotic and waking states helps to insure the permanency of the "cure." In chronic war and civilian neuroses, however, the patient does not seem to benefit so readily, since the illness has structuralized itself and stubborn resistances block progress. Another effect of drug interviews is to release pleasant positive feelings, which I. Stevenson et al. (1974) have found is conducive to symptomatic improvement. The effect of narcosis consequently can be both emotionally releasing as well as sedating depending on whether exposure is to challenging confrontations or calming suggestions.

While narcotherapy is principally employed for purposes of short-term therapy, it is sometimes introduced during the course of long-term insight psychotherapy where little material is forthcoming or obdurate resistance blocks the exploratory effort. Here one may occasionally save a treatment situation that has come to a stalemate by inducing narcosis and liberating repressive forces through concerted probing. Transference phenomena that have evaded both patient and therapist sometimes become dramatically operative as emotionally charged material is released. An emergency use of narcotherapy is in the sedating of acute uncontrollable anxiety and panic states that occur during the course of long-term therapy. These symptoms may be so severe that they threaten the therapeutic relationship. In obsessional neurosis, for instance, occasional sessions of light narcosis may prevent alarming reactions at phases when defensive forces subside too rapidly. The secret of narcosynthesis in chronic neurosis lies in the facilitated communication that it induces in severely repressed patients.

Where repressed incidents are of relatively recent origin, cathartic release may provide a dramatic improvement or cure. However, in most cases a structuralization of traumatic events has occurred, barricaded by many defenses, including protective character traits, so that the exposure during narcosis (no matter how dramatic the results) seems to do little for the patient. It is essential, therefore, as soon as the patient is

capable of remembering seemingly important events to subject this material to repeated examination in the waking state, particularly probing for associated emotions. During this process periodic sessions with narcosis may be helpful. Should anxiety be strong or repression too interfering, the anxieties and defensive reactions may yield, and the need for narcosis will then be unnecessary.

Another use of narcosis is to expedite the induction of hypnosis in resistant subjects. During narcosis it may be possible to give patients suggestions to the effect that they will be susceptible to hypnosis. Suggestions must be detailed and specific, covering every aspect of the induction process. For example, the patient may be told when shown a fixation object, the eyes will water, lids will get heavy, the breathing will deepen, and sleep will get deeper and deeper. They will be as deeply asleep as at present. These suggestions should be repeated and the patient may be asked if he or she understands what to do. If confusion exists, the suggestions should be repeated when the drug effect is not so pronounced. As soon as the patient understands what is expected, he or she is asked to repeat what will happen at the next session. After the narcotic session, and before the patient is fully awake, he or she is shown the fixation object and given suggestions that the next time the object is presented drowsiness will occur faster and more deeply. Again, before leaving the room, this suggestion is repeated. The technique works best when positive transference phenomena are operative in the narcotic state. It may not succeed in the event the patient does not understand what to do, or if the patient is in a state of hostile resistance.

Induction of Narcosis

The actual technique of inducing narcosis is simple. Most therapists consider amobarbital sodium (Amytal) the drug of choice. There are various techniques of administration. Sodium Amytal is supplied in sterile powder form in ampules. Ampules of sterile water are also available. The 500-mg (74 gr) size of Amytal size is generally utilized, sterile water being added while rotating (not shaking) the ampule to dissolve the drug. It is important to employ fresh solutions (no older than 30 minutes) and to see to it

that they are clear (not cloudy). Rarely some patients require large amounts of the drug, and a second ampule of 7 ½ gr may be necessary. A small gauge intravenous needle attached to a large syringe is used for administration. The injection should be slow, about 1 cc per minute, to avoid depressing the respiration. While the injection takes place, the patient is asked to count backward from 100 to 1. When the patient becomes confused, mumbles, or stops counting, the injection should stop and treatment begun, such as questioning the patient about feelings, attitudes, and memories. Should too great anxiety intervene, more drug is slowly injected. However, in many cases reassurance that one will feel better after talking will alone suffice without the need for further sedation. The patient may be given interpretations and suggestions that one can if one wishes remember any of the material talked about after awakening or forget it until ready to talk about it. The patient may be requested to remember dreams. After the narcotic session he or she may be allowed to rest or sleep. An ampule of methamphetamine or similar stimulant is held in readiness in the event of respiratory embarrassment, and at the termination of the interview it may be introduced to facilitate awakening. Some therapists inject the 20 mg of methamphetamine intravenously at first. Slowly then, through the same needle, sodium Amytal (500 mg in 20 cc sterile water) is injected until drowsiness and dysarthia appear. Or, 500 mg of sodium Amytal in 9 cc sterilized distilled water are combined with a 20 mg ampule of amphetamine and introduced intravenously at the rate of 1 cc per minute.

Various drugs have been employed instead of amobarbital. Pentothal sodium (supplied in sterile vials) and injected at the rate of 2 cc per minute is a common substitute, the dosage (approximately the same as Amytal) varying with individual patients. Methohexital sodium (Brevital), a short-acting barbiturate, is another substitute being supplied in sterile powder in ampules of 500 mg, 2.5 g, and 5 g. It may be utilized as a continuous drip, 500 mg of Brevital being added to 250 cc of sterile isotonic sodium chloride solution. This provides a 0.2 percent solution. For slow intermittent injection a 1 percent solution is used titrating the amount injected against the reaction of the patient. Sometimes methamphetamine is given intravenously following a intravenous drip of Brevital (Green, DO, & Reimer, 1974). Scarborough and Denson (1958) described a

Pentothal-Desoxyn combination similar to that of Rothman and Sward (1956).

Because of the abuse potential, injectable Desoxyn is no longer available. If a substitute amphetamine can be found, this may be employed in proper dosage.

Methylphenidate hydrochloride (Ritalin) has been found helpful in breaking through blocks in the exploration of the problems of alcoholics (Hartert & Browne-Mayers, 1958). Exploratory interviews are carried out after intravenous injection of 20 to 40 mg of the drug. The patients respond by verbalizing freely with greater introspection and critical self-evaluation as well as more intensive involvement in the therapeutic situation. Since Ritalin in injectable form is not now available, oral administration prior to interviews may be considered with caution since Ritalin may be substituted by the alcoholic for alcohol.

In the course of narcotherapy, as has been mentioned previously, drug injections should be halted temporarily if the patient gets excessively incoherent. Should the patient become too alert, more drug is introduced. It goes without saying that adequate preparations must be made for the patient so that one can sleep off the effects of the medication.

In the event psychotic material is brought up during narcosis, giving evidence of a potential disintegrative tendency, therapeutic goals and methods should be reappraised. Where the patient becomes too upset through release of traumatic material, it is best not to let the excitement mount to the point of overtaxing the ego. More drug is injected to put the patient to sleep, which will enable one to overcome the cathartic effects of the narcosis.

The therapist questioning the patient during narcosis may have to utilize a firm authoritative tone. In posttraumatic stress disorders especially, one builds a dramatic word picture that approximates the original traumatic scene: military combat, rape, assault, fire, accident, flood, earthquake, etc. Kolb and Mutalipassi (1932) have introduced an audio tape with battle noises during narcosis which almost immediately may bring the veteran with combat stress back to the traumatic event. Abreaction takes many forms

ranging from controlled talking about the fearsome incident to a violent acting out—muscularly, emotionally, verbally—the anxieties and fantasies that are being repressed. Sufficient time should be set aside to discuss with the patient feelings and memories after one comes out of narcosis. Generally, repeated sessions of narcosis tend to desensitize the patient allowing the repressed incident to be faced with diminished fear. Some therapists make audiotapes and videotapes of the narcotic sessions which they play back to their patients, and this stimulates animated discussions and provides material for interpretation. It goes without saying that individual and group psychotherapy are important following narcosynthesis in order to deal with the personality vulnerabilities that have predisposed the patient to the dissociative reactions displayed following the trauma.

Narcosis should be avoided in patients with manifest or latent porphyria, or who have liver, cardiac, respiratory or kidney disease. It should not be used in persons who are or were addicted to sedatives or hypnotics. Because of the danger of respiratory depression some therapists prefer to have the actual narcosis done by a trained anesthesiologist who can stand by in case of emergencies.

VIDEO RECORDING

Videotape technology has been advancing at a rapid rate and it is being adapted to increasing areas of health and science. Among its many possibilities are self-observation and self-confrontation (Berger MM, 1971; Melnick & Tims, 1974, Roche Report, 1973, 1974a), which have been applied to the teaching and learning situation (Torkelson & Ramano, 1967). The evolvement of video psychiatry has followed in the wake of this. Videotapes are being produced to teach psychopathology, child development, and psychiatric treatment. A cassette entitled "Electronic Textbook of Psychiatry" has been prepared by the New York State Psychiatric Institute's Department of Educational Research. Written linear programmed texts are being arranged with interdigitating videotaped clinical illustrations to enliven the teaching of psychiatry.

The recording of psychotherapy sessions with opportunity for repeated playback

offers patients an unparalleled learning experience that can catalyze the entire therapeutic process. As recorders and cameras have become less and less expensive, the video adjunct has been employed with increasing frequency in clinics and private practice, particularly in group, family, and marital therapy (Alger & Hogan, 1969; Czajkoski, 1968; Danet, 1969; Stoller, 1967, 1969). In behavior therapy (Bernal, 1969; Melnick & Tims, 1974), and in role playing and psychodrama, its employment is proving valuable. In selected cases persons in individual therapy may find self-observation of substantial value (Geertsma & Reivich, 1965; Paredes et al, 1969). An additional dividend is the fact that a therapist may observe one's own therapeutic performance and interpersonal conduct including countertransference, which can enhance one's own development and sharpen one's skills. The objective data issuing from even fragments of a single session can provide material for study and discussion over weeks and months. Progress or regress may also be scrutinized by comparing the productions of successful sessions. The videotape recording may also be utilized for the purpose of supervising a therapist's work, providing more authentic data than can be conveyed orally by the therapist.

The technique is simple. There is no need to conceal the equipment because after going through the preliminary brief anxiety and self-consciousness phases, patients readily make an adaptation to videotaping. For use of the tape in therapy, 10 minutes of the beginning of the session may be recorded and then played back through the monitor, or recording may be started when a significant period of the session is being approached. The patients are instructed to interrupt the playback if they wish to comment on discrepancies of behavior or if they desire to describe the feelings that they had at the time or have now.

Replay of small segments over and over may be rewarding either for the purposes of clarification and discussion or for desensitization where patients manifest a "shock" reaction at their images. Most patients are surprised at how often their appearance and behavior fails to reveal their shyness, anger, fear, distress, and other emotions. They become sensitive to the pervasive contradictory and paradoxical communications from verbal and nonverbal sources. For example, some patients are not aware of how angry,

argumentative, and unpleasant they are in an interpersonal situation until they objectively see and listen to themselves. Opportunities for clarification, heightened awareness, and more constructive reactions are many. Where, as in group, family, or marital therapy, a patient's responses have been maladaptive and the patient realizes this, one may benefit from repeatedly playing back sessions to grasp incongruities of messages. Patients may be asked to try to repeat messages until they communicate clearly. Should resistance develop in therapy or a stalemate have been reached, videotaping may open up dimensions that succeed in breaking through the block. The availability of splitscreen and special-effects generators through which one may obtain video multiimage distortions to elicit repressed material is an interesting new use for this adjunct (Roche Report, 1973). Original and unique ways of employing tapes are being elaborated by researchers and clinicians, and innovations will undoubtedly continue to emerge. These eventually will provide material for scientifically controlled studies to test their utility and validity.

Melnick and Tims (1974) make some excellent suggestions regarding the physical surroundings and equipment for videotaping. The room should be of ample size to accommodate comfortably the patients while providing enough space to operate the camera. It should be well ventilated. Generally a 15 feet by 18 feet size is good for a group of 8 to 10 people. If a group is the subject, the patients are seated in a semicircle with the open end accommodating the camera. Sound-absorbing materials and furniture in the room, such as accoustic tile on the ceiling, carpeting on the floor, draperies on the windows, and cloth covered chairs help the acoustics. As to selection of equipment, various machines are readily available. One-half inch decks and video cameras are available at moderate price and are usually ample for the average psychotherapist. A camera with a zoom lens will require an operator to focus on the entire group and on individuals. The operator can be the therapist, cotherapist, or a group member. Where taping is on the entire group and not on individuals, selecting a camera with a wide-angle lens (12.5 mm) is convenient since once set up it does not need an operator. The best microphone is an omnidirectional dynamic table microphone placed on a table or microphone stand. A monitor for the video and sound signals is the final piece of equipment, and for this purpose an ordinary television set is usually ample. Additional

optional equipment is also available, such as the use of two cameras with a camera switcher, splitscreen apparatus, a special-effects generator, and a second recorder with an electronic editor, where tapes are to be used for educational purposes. The original choice of equipment should allow for expansion with optional items should the latter be contemplated. If one cannot afford or utilize the most sophisticated apparatus, the simple portable one-half-inch deck and an inexpensive camera and microphone are sufficient, and they may well merit an investment.

THE TELEPHONE

Discrete use of the telephone as an adjunctive device is valuable in emergencies that arise in the course of psychotherapy. These fortunately are rare. Therapists may, for their patients' own good and for their own peace of mind, discourage patients calling for anything other than severe problems that cannot await solution until the next treatment session. Should it become apparent that the patient is taking advantage of the privilege of discrete telephoning, the therapist may focus during interviewing on the patient's need for telephone contact. The patient may be reminded that making one's own decisions during therapy is both strengthening and helpful even where such decisions do not turn out well since this provides material for exploration. If the patient is given sanction to telephone at will the flood of inconsequential calls that can result will very likely annoy the therapist and create severe resentments; this annoyance will adversely affect relations with the patient. In addition, if allowed at all, the therapist may be unable to stop the calls without hurting the working relationship.

There are several exceptions, however, to the rule. First, patients with a suicidal tendency do need the assurance of immediate contact when necessary. Here the therapist may have to insist that the patient telephone when too depressed. The lives of many patients have been saved by their ability to communicate with the therapist in crisis situations, and prior to the effective working of prescribed psychotropic drugs. Moreover, should the patient have taken an overdose of drugs, unintentionally or with suicidal design, reporting this will enable the therapist to call an ambulance or the police to bring

the patient to an emergency unit of a hospital for therapy. Second, patients for whom drug therapy has been prescribed should routinely be requested to telephone if they have peculiar or upsetting reactions to the medication. Hypotension, symptoms of blood dyscrasias, and severe dystonic reactions may need immediate medical intervention.

It goes without saying that the telephone is a vital therapeutic instrument for crisis intervention (Lester & Brockopp, 1973; Williams T, 1971). "Hotlines" exist in larger cities where young polydrug abusers, suicidally inclined persons, rape victims, and others seeking help for some misfortune or for general information can make contact with knowledgeable persons for guidance and counseling. There are for some clients advantages in retaining anonymity over the telephone and also in talking to an anonymous person onto whom the client can project fantasies of a helping person suited to one's needs (Lester D, 1974). It is vital where nonprofessional persons staff such services that they be adequately supervised by professionals. The telephone is an important resource, functioning to provide people with a reassuring human contact and a conduit for referral to available agencies in the community.

Telephone therapy also has a place where patients, for one reason or another, are unable for physical reasons to come to treatment in person (Miller WB, 1972; Robertiello, 1972). There are times where ill health, or absence of transportation, or travel away from home makes it impossible for a patient in psychotherapy to keep appointments, and yet a continuity of treatment is vital. Interestingly, a telephone may make it easier for a patient to reveal certain kinds of information than a face-to-face interview, particularly where a transference reaction exists. This may initiate a breakthrough when the patient returns for regular sessions.

PLAY THERAPY

Play therapy provides children with a means of giving vent to conflicts, ideas, and fantasies that they cannot ordinarily verbalize. One may look upon it as a special nonverbal language through which a child communicates. It is, in a certain sense, an acting-out, permitting through varied activities overt, nonverbal expressions to innermost

feelings. "Play therapy does not belong to any specific school of therapy. Each therapist must first learn to understand and to master this particular language of the child, and then integrate the mastery of the therapeutic tool with the particular tenet of one's own therapeutic orientation. The child's play, in and by itself, is no more therapeutic than the patient's free associations and relating of dreams. It is the therapist's skill and sensitivity which helps the adult patient to understand the often meaningless stringing together of seemingly unrelated thoughts in free association. In a similar way the child therapist helps the child to understand the real meaning behind his spontaneous play activities " (Woltman 1959).

Children, in line with their developmental growth, play act and think differently at different age levels. A 3-year-old may be playing with only a single toy, while an 8- or 10-year-old child may build a complicated structure. It must further be recognized that a child will select that kind of play activity which is best suited for the expression of a particular problem. Burning paper, throwing paper airplanes, or playing out elaborate automobile crashes can be properly used in therapy as long as one alerts oneself to the fact that all three activities may constitute an acting-out of aggressive impulses. The specific meanings that play materials and activities have for the child have been described by R. E. Hartley et al. (1952 a & b), who also has summarized play activities of children in terms of year levels (1957). A comprehensive study of children's play activities with miniature life toys has been presented by Lois Murphy (1956). The seminal contributions of schools of therapy to play therapy are found in the writings of Melanie Klein (1935, 1955), Anna Freud (1928), and Virginia Axline (1947), who is a follower of Carl Rogers. Specific play media and activities described many years ago may still be useful in the therapeutic treatment of children (Bender & Woltmann, 1936, 1937; Erickson EH, 1944, 1951; Gondor, 1954; Lowenfeld, 1939; Lyle & Holly, 1941; Trail, 1945; Whiles, 1941; Woltmann, 1940, 1950, 1951, 1952, 1955, 1956). Play group therapy has been described by Ginott (1961). The free play technique of Gitelson (1939) is helpful in some cases. Where it is difficult to create in the child an attitude that is conducive to spontaneous play, or where specific problems or time limitations play a decisive role, the methods described by Conn (1938), D. Levy (1937, 1939), J. C. Solomon (1938, 1940, 1951), Muro (1968),

Nelson (1967), and Nickerson (1973) may be applicable.

The methods of play therapy appear to be particularly suited to the expression of unconscious aggression and to the acting-out of jealousies in relation to a parent or sibling. They are also an excellent media for exploration of sexual and excretory fantasies. The beneficial effects of play therapy in part accrue from the insight patients gain into their drives and problems. More immediately, a child acts out in play, hostile, sexual, excretory, and other fantasies as well as anxiety-provoking life situations. The cathartic effect of play therapy temporarily alleviates tension. This is not as important as the gradual understanding that develops into the nature and effects of unbridled impulses. The noncondemning attitude of the therapist, who neither criticizes nor restricts the patient, but accords the child freedom in expressing overtly impulses and fantasies of a dreaded nature, alleviates guilt feelings, and eventually makes is possible for the child to acknowledge and to tolerate repressed drives. As these are repeatedly acted out in play, the child becomes desensitized to their influence. Understanding and control are developed by the therapist's carefully timed interpretations.

Controversy exists regarding the preferred approach in play therapy. A research study of play therapy some years ago in 298 outpatient child clinics in the United States indicated that 75 percent of the reporting clinics regard their theoretical orientation as psychoanalytic, 17 percent as nondirective, 5 percent as directive, and 3 percent as between directive and nondirective (Filmer & Hillson, 1959). At the same time, the majority of clinics considered Frederick Allen (1942) as the authority most representative of their orientation. Allen, whose concepts, reflecting those of Rank, stressed the relationship fostered through play therapy as the very core of the therapeutic process. This is in contrast with the approach of Melanie Klein (1955 a & b), which bypasses ego defenses and actively and immediately interprets the deep unconscious meanings of the child's play. The less radical approach of Anna Freud (1946) advocates interpretation of unconscious motivation only after a relationship has been established with the child. At the present time there is some shift toward behavioral theory and practice.

The use of artistic media, such as drawing, painting, and finger painting, as ways of exploring and working through unconscious conflict has been advocated by many therapists (Arlow & Kadis, 1946; Bender, 1937; Brick, 1944; Fink et al, 1967; Hartley RE, & Gondor, 1956; Levick, 1973; Mosse, 1940; Napoli, 1946, 1947; Naumburg, 1947, 1953, 1966; Schopbach, 1964; Stern, MM, 1952 a & b). These productions, whatever their nature, serve as means of emotional catharsis and as vehicles for revealing inner problems, wishes, and fears. Art therapy is particularly valuable in patients who find it difficult to talk freely. It is predicated on the principle that fundamental thoughts and feelings, derived from the unconscious, often find expression in images rather than in words (Naumburg, 1966). Through art a method of symbolic communication develops between patient and therapist. Though untrained in art, individuals can often project their conflicts into visual forms, to which they may then expeditiously associate freely. Dreams, fantasies, and childhood memories may also more readily be represented in a pictorial way rather than in speech. Patients who are blocked in verbalizing may find that drawing or painting their dreams and fantasies expedites translation of their thoughts and feelings into words. The function of the art therapist, according to many authorities in the past, is not to interpret, but to encourage the patient to discover for oneself the meaning of productions that provide symbolic ways of representing unconscious phenomena (Lewis NDC, 1928; Griffiths, 1935; Fairbairn, 1938a & b; Pickford, 1938; McIntosh & Pickford, 1943). The patient projects in the creations significant emotional meanings. This is very much similar to what happens in the Rorschach test (Vernonon, 1935). Furthermore, the symbolized content permits of an expression of inner impulses without too many guilt feelings. The art therapist accepts the patient's projections without punitive or judgmental responses. Interpretations are offered to the patient at strategic times. Interpretive approaches to art symbols have been described by Appel (1931), Jung (1934), Pfister (1934), Lisls (1938), Baynes (1939), Harms (1939, 1941), Reitman (1939), Mira (1940), Naumburg (1944, 1950), and E. Kris (1952). Other informative articles are those of Levy (1934), F. J. Curran (1939), Despert (1937), Mosse (1940), and Bychowski (1947). Traditional concepts about art therapy are still currently accepted.

In the actual technique, the patient may draw or paint during the treatment hour, or may work at home and bring the productions to the therapist. Drawing and painting may be employed not only individually, but also in groups (Naumburg & Caldwell, 1959), being especially valuable in therapy with children (Kramer, 1972). Simple, easily manipulate art materials must be made available to patients, particularly if they have never drawn or painted. Semihard pastels and casein or poster paints are to be preferred to oil paints. The therapist may have to instruct and encourage beginners by what is known as the "scribble technique." In this the patient is instructed to draw without a conscious plan by making a continuous line which may assume an irregular pattern as it meanders over the paper in various directions. The patient is then encouraged to search for a design, object, animal or person while holding the paper in different directions. Once the patient has done this, he or she is enjoined to work in art as spontaneously as possible using different materials.

Where a patient appears emotionally blocked or does not express appropriate feeling toward a special person or situation, instruction to construct an image or make a drawing representing the person or situation may release productive emotions and associations. The fact that the patient can control the drawings gives one a feeling of greater leverage over affective life. This is especially important in individuals with weak defenses who in being encouraged to draw have an option of how far they wish to go.

An attempt may be made to influence mood by asking the patient to draw something that depicts a special emotion. Thus, a depressed person may be asked to draw a happy scene, an anxiety-ridden soul to depict a relaxed and peaceful sketch. In a more cathartic vein, a patient may be requested to delineate on paper exactly how he or she feels or one would like to express if one could. The patient may also be encouraged, and perhaps helped, to depict the completion of an action essential for one's well-being on the theory that one may through this means symbolize a breakthrough of the stalemate and then respond behaviorally. Sometimes the psychotherapist may utilize as an adjunctive helper an art therapist. When such a person is used, regular conferences of the two must be held.

In group therapy some therapists find it useful to suggest that patients draw pictures

on a common theme. Comparing the drawings and getting the group members' associations can provide much stimulation and enhance group activity. This technique has also been employed with smaller groups, as in family therapy (Kwiatowska, 1967).

The activity of the therapist in relation to the patient's drawings will vary. One may sit quietly and observe what is being drawn, waiting for the patient's explanations, or may comment on or ask questions about the images, or may interpret what one believes the patient is trying to say. The patient may be encouraged to draw certain items, (i.e., dreams, memories, fantasies, family members, etc.). The therapist may even sketch on the patient's picture or suggest additions or alterations. Questions about the symbols may be asked, and the patient may be encouraged to make associations.

Where a patient responds to images drawn with fear, anger, or detachment, it is likely that he or she has not been able cognitively to integrate what has been produced. This may provide valuable leads for the interview focus. Encouragement to repeat the same theme in drawing may result in therapeutic desensitization and conflict resolution.

There is a tendency among some art therapists to overvalue the medium of communication—the art production—and to confuse the latter with the therapeutic process itself. While therapy may thus be regarded as a constant uncovering phenomenon that brings up interesting material, there may be a denial or minimization of the true therapeutic vehicle—the relationship between patient and therapist. The use of art as an adjunct in therapy is, nevertheless, considered by some analysts as helpful to patients who express themselves better in drawing and in other artistic ways than in free association or dreams. While the content of therapy may be focused on the art expression, the therapeutic process goes through the usual phases of transference and resistance as in any reconstructive form of psychotherapy.

SEX THERAPY

People with sexual problems as their presenting complaint generally are not motivated to seek intensive treatment. What they desire is to function sexually as rapidly

and normally as possible. Catering to this wish is a group of new sex therapies (Kaplan HS, 1974; Leiblum & Pervin, 1980), originated by the research team of Masters and Johnson (1966, 1970), which are short term, behaviorally oriented, and symptomatically effective for most patients. What some of the authors advocated is a short intensive course of instruction and guidance in proper sexual attitudes and techniques administered to the patient and his or her sexual partner by a dual-sex team.

This format is undoubtedly an excellent one. Some therapists combine behavioral methods with exploratory techniques. They encourage their patients to verbalize their fears, guilt feelings, and misgivings and deal with resistances in traditional psychotherapeutic ways. Ideally, therapy following the intensive initial course continues on a weekly basis for a period until the newly acquired patterns are solidly integrated and the patients are able to manage relapses by themselves.

There are obviously advantages to the couples working with the dual-sex therapeutic team since cooperation of both patient members is more easily obtained, resistances can be dealt with directly, misconceptions about sexuality can be effectively brought out in the open, questions about technique are less likely to be distorted, and desensitization of embarrassment and alleviation of guilt feelings are enhanced. In many cases the core problem is that of communication, particularly in relation to mutual sexual feelings. Breaking into the facade that sex is dirty, not to be talked about, practiced in the dark, etc. can release both partners and lead to a more natural and spontaneous functioning.

Practical considerations, however, may make it impossible to utilize a dual-sex team, and the therapist may have to operate without a cotherapist. In some cases it will be impossible to get the patient's spouse or sexual partner to come for interviewing. Then the therapist will have to work with the patient alone, briefing him or her on how to instruct and work with the partner. If both partners are available, a 2-week vacation period to initiate treatment is best since there will be less distractions. Here, too, modifications may be necessary; thus when the couple is ready for sexual exercises, a 3- or 4-day holiday may

be all that is necessary.

A diagnostic assessment of any sexual problem is vital to the choice of treatment (Wasserman et al, 1980). It is important to determine which of four phases of sexual response is implicated. Is the disorder of one of inhibited desire, or inability to maintain excitement and genital tumescence, or to control or achieve orgasm, or to achieve postorgasmic relaxation and well-being? (Kaplan and Moodie, 1984; Lief, 1981). Distinction of these phases of sexual response is important because varying mechanisms and neural pathways are operative in each and different therapeutic interventions may be called for. For example, inhibited sexual desire may be the product of guilt about and repression of sexuality produced by overmoralistic promptings in childhood, with consequent needs for self-punishment, indulgence in rape or bondage phantasies and masochistic practices as a condition for the release of sexual feeling. Conquest of these developmentally inspired sexual inhibitions may provoke the individual to imagine or to act out violent fantasies sadistically (sexual sadism), with antisocial behavior serving to subdue or symbolically destroy one's conscience or the projected representations. Guilt feelings and masochistic self-punishment usually follow these releases, but rarely eliminate them. Treatment when sought will require psychotherapy, preferably dynamically oriented, and only later behavioral approaches should sexual functioning continue to fail. Inhibited sexual desire may also be associated with failing release triggers that open the gates to sexual feeling, such as fetishism, transvestism, zoophilia, pedaphilia, exhibitionism and voyeurism, which must be approached psychotherapeutically although prognosis for recovery in these ailments is guarded. Sexual desire can be deadened by ailments like depression. Finally, the relationship with a marital partner may be pathological (e.g., incestuous) or so steeped in ongoing hostility as to deaden all thoughts of sex. Here marital therapy and dynamic psychotherapy may be essential.

Appropriate treatment for all of these foregoing conditions will therefore require accurate diagnosis. In the case of inhibited sexual excitement with frigidity and impotence, once organic factors (endocrinopathies, diabetes, arteriosclerosis, etc.) and medicinal agents (antihypertensives, beta-adrenergic drugs, alcohol, tranquilizers, etc.) have been

ruled out, behavioral sex therapy may be effective in itself, especially when the onset has been recent or the causes minor. But where personality difficulties exist, or anxieties and phobias are strong, coordinate psychotherapy and behavioral sex therapy may be necessary. The same may be said for inhibited female and male orgasm, premature ejaculation, dyspareunia and functional vaginismus. For the fourth phasic disturbance of inhibited postorgasmic relaxation and well-being, such treatments as cognitive therapy to alter meaning systems, and dynamic psychotherapy to explore conflicts may be useful.

Sexual problems do not occur in isolation. They appear as a manifestation of coordinate physical, marital, interpersonal, or interpsychic difficulties that are overshadowed by the patient's concern with the sexual symptom. The initial successes scored with the traditional behavior approaches consequently have not been as consistently sustained as was originally anticipated (DeAmicis et al, 1984). One difficulty that is now becoming apparent is the symptom of low sexual desire, which is often masked by defective motivation for therapy.

What appear as limited or absent sexual feelings (Kaplan, 1979) are now being recognized as a symptom of emotional disorder. In many cases such sexual inhibitions are the product of repressed fear, anxiety and anger. Application of a probing dynamic approach will usually bring such repressed feelings to the surface. Non-analysts deal with this dimension by what they call "experiential sensory awareness exercises." The object is to recognize that inhibited sexual desires do not exist as a permanent passive state but are actively being promoted by emotions and attitudes that are in need of clarification and correction. Not only is psychoeducation required to rectify misconceptions about the right to experience pleasure and sexuality, but faulty belief systems and self-statements will require interpretation and restructuring. The action phase of the therapeutic process involves behavioral assignments and that concern the patient and a cooperative partner. Where marital problems exist these will have to be worked out, otherwise therapy will be sabotaged by one or both members. It goes without saying that physical causes of sexual disinterest such as diabetes, depression, use of cardiac medications, etc., will have to be considered in addition to working with psychological factors.

The presence of both members is an essential part of the treatment process. They are given an explanation of the number of sessions that will be involved (usually 15 to 25) and the fact that homework with sexual exercises will be employed. Brief mention may be made that all extramarital affairs, if any, must be halted for treatment to be successful. Readings may be suggested such as Heiman et al. (1976) and Zilbergeld (1973). In addition to meeting with the couple, individual sessions may be necessary. A usual form of therapy involves four phases: (1) experiential sensory awareness, (2) insight, (3) cognitive restructuring, and (4) behavioral assignments (Friedman & Hogan, 1985).

Several sessions of history taking and interviewing to gather relevant data and to clarify misconceptions are customary before starting behavioral conditioning. Important too is determination of what medications an individual is currently taking since heart and blood pressure drugs (e.g., beta-blockers, hydrochlorothiazides, anti-anginal pills, psychoactive drugs (e.g., tranquilizers, sedatives, antidepressants, neuroleptics), gastrointestinal drugs (e.g., Tagamet, Librax), hormonal drugs (e.g., estrogen, progesterone) and other drugs (e.g., fenfluramine, metronidazole, phenytoin) may cause loss of libido, impotence, ejaculatory dysfunction, and anorgasmia. Consultation with the patient's internist to see whether alternate medications can be prescribed will be important. There are a number of organic conditions, such as diabetes, hypopituitarism, hypothyroidism, vascular disorders, and neurogenic disturbances that may be implicated and that will require correction. Once these factors are eliminated, preliminary sessions may be started. These are best done individually with the partners since many personal sensitive areas and confidential secrets may be exposed. Where a dual-sex team is used, the male therapist interviews the man and the female therapist interviews the woman. Patients will often ask the therapist not to reveal secrets to their mates. Such material ranges from masturbation to past and present sexual affairs. Some of these confidences are not as dreadful as the patient imagines, and their revelation could clear the air between the couple. However, the therapist must promise (and hold to the promise) not to expose the patient. If it turns out that therapy cannot continue without bringing up the secret, the therapist must ask the patient's permission. But in all likelihood the revelation may not be necessary.

The sexual history should cover the following.

1. The earliest memory of sexual feeling.

2. The kinds of sexual information expounded to the individual as a child.

3. Preparation for and reactions to menstruation in the female and the first ejaculation in the male.

4. The first sexual experience (masturbating or in relation to another person, animal, or object).

5. Sexual feelings toward parents or siblings.

6. Early homosexual or heterosexual activities. (The first sexual experiences are very important and the patient may never have gotten over them).

7. Present sexual behavior and accompanying feelings and fantasies.

8. Sexual dreams.

9. Attitudes toward masturbation.

10. Conditions under which orgasm occurs.

11. If married, the kind of relationship with mate.

12. Tendencies toward promiscuity.

Attitudes toward sexuality should be explored, for example, how the patient feels about kissing of the mouth, breast, body, and genitals, about manual manipulation of the genitals, about mouth-genital contact, and about different sexual positions. What does the patient feel (like, dislike) about the partner? What makes him or her angry? What makes him or her feel sexy? The therapist should look for what positive and pleasurable things are present in the relationship, since these can be reinforced. Often the *way* the patient responds to these questions, the hesitancies, embarrassment, etc., will yield as much information about attitudes as the content of the answers.

The bulk of patients who come for sexual therapy are well motivated. This is very

much in their favor and permits the use of short-term approaches. The great majority of these patients can be helped without too great delving into dynamics. The empathic liberated attitude of the therapist coupled with correcting misinformation about sex may in itself suddenly liberate the patient.

Some of the more common questions plaguing patients are the following, suggested answers being indicated.

Q. What is the normal frequency of intercourse?

A. There is no such thing as "normal" frequency. Sexual needs vary with each person and the desire for pleasuring oneself can range from daily to bimonthly.

Q. Doesn't masturbation take away desire for intercourse?

A. If people learn better ways of pleasuring themselves, they engage in self-manipulation less frequently, although they can still derive pleasure from it.

Q. Isn't genital intercourse the most desirable form?

A. Sex has several forms and genital intercourse is certainly desirable, but at times other variations of pleasuring, like oral-genital contact, are indulged by many.

Q. I feel my penis is too small. Isn't this objectionable to women?

A. This is a common foolish concern of many men. The vagina is a flexible organ, accommodating itself and capable of being pleasured by all sizes. If you stop worrying about size and concentrate on pleasure in love-making, your partner will undoubtedly be more than satisfied.

Perhaps the most important element in the treatment is the manner and attitude of the therapist (or therapeutic team). In working with patients who are seeking to liberate themselves from their sexual fears and inhibitions, the therapist presents as a model of a permissive authority. Therapists have tremendous leverage in working with sexual therapy because they fit into the role of idealized parental figures who can make new rules. An easygoing, non-condemning, matter-of-fact approach is quite therapeutic in its own right. The ideal therapeutic philosophy is that the patient has been temporarily diverted from attaining the true joys of sex and that if there is the desire to do so, it is possible to move toward reaching this goal of enjoyable pleasure without guilt and fear.

This posture is difficult to simulate if the therapist has "hang-ups" about sex or harbors Victorian sentiments that harmonize with the patient's particular ideas or misconceptions. Many therapists falsely regard their own sexual attitudes and behavior as a norm. If these are too restrictive, they will prevent a full release of the patient's potentialities.

In brief sexual therapy, countertransference phenomena can fleetingly occur. One must expect that a patient of the opposite sex will sometimes openly or covertly express sexual transference. This is usually handled by a casual matter-of-fact attitude of nonresponse. Problems occur when the therapist is deliberately or unconsciously seductive with patients.

The following concepts will have to be integrated by the patient, hence they should be accepted by the therapist:

   1. Sex is a normal and natural function.

   2. The primary purpose of sex is pleasure not performance.

   3. People have many different ways of pleasuring themselves. They can derive satisfaction through manual manipulation, oral-genital contacts and genital-genital contacts. Unfortunately, the way we are brought up teaches many of us wrong attitudes about sexuality.

   4. People have a right to liberate themselves from these crippling attitudes.

   5. All people have the potential of enjoying sexuality.

If the therapist has scruples about these concepts, personal inhibitions may be passed on to the patient. Therefore, it may be preferable to refer patients with sexual difficulties to another therapist or team skilled in sexual therapy.

It is important to avoid the words "abnormal" or "pathological" since these may have frightening connotations. It is best to shy away from the word "masturbation" but rather refer to it as "deriving pleasure manually or through fondling the genitals oneself." The term "mutual masturbation" should also be avoided. Instead one may say "pleasuring each

other manually." It is advisable to ask the patient, "Are there thoughts or fantasies or objects that turn you on?" People often have wild fantasies and even covet harmless fetishes, symbolic residues of past conditionings, which help them to release sexual feelings. To ridicule or condemn these when they are revealed will serve merely to discourage the patient. The proper therapeutic stance is casually to emphasize that people have different ways of pleasuring themselves. The therapist may say, "For every lock there is a key, and each person has his own key for the release of sexual feeling. If there is something harmless that turns you on, there is nothing to be afraid of or ashamed of." The reason why it is important not to interfere with sexually releasing fantasies is that removing them too soon, before other more satisfactory sexually releasing stimuli are developed, may result in paralyzing inhibitions or in resentments that will drive the patient away from therapy.

The patient should be asked to have a complete physical examination if one has not been recently obtained. There are some physical conditions as has been mentioned that result in impairment of functioning as well as medications that are inhibiting to libido. It may be necessary to reduce or to substitute drugs that are not so sexually incapacitating.

Where a depression exists, antidepressant medications may be necessary (buprion [Wellbutrin] is a good antidepressant here) and instead of inhibiting sexual feeling they may release it. Loss of libido is one of the first signs of a depression. In the case of excessive tension *mild* tranquilization may help. Buspirone (BuSpar) is an anxiolytic that has a minimal adverse effect on sexual feeling.

After taking a history, joint conference of partners and therapist (or dual-sex team) is held with the object of outlining the problem or problems and of discussing effective ways that the partners can participate in helping each other toward a better adjustment. An idea is given the couple about the roles of each, played in the past, that have produced the difficulty. The therapist also comments on the behavior of the couple to each other. Transferential data especially should be looked for: "The way you treat your wife [husband] it seems to me is how you described your mother [father] treated your father

[mother]." Empathy must be displayed, and it is urgent to set up as good a working relationship as is possible. Reassurance is important. Sometimes women who have had hysterectomies believe that they will not be able to function sexually again. This mistaken notion should be clarified by the therapist, who may point out that the sexual response has nothing to do with the uterus. People with hysterectomies can function normally sexually. In males who have had suprapublic or transurethral prostatectomies any impotence that follows the operation usually disappears. This information can be reassuring to the prostectomized patient.

It may be advisable to use charts or illustrations to clarify the sex anatomy of male and female, even where no ostensible problems appear to exist. It is astonishing how ignorant some people are of their genital makeup. No matter how sophisticated they may imagine themselves to be, a great gap can exist in their education about how they are built.

Misconceptions will also have to be covered such as (1) that erections and orgasm can be brought on by will power, (2) that all sexual play must lead to intercourse, (3) that orgasms must be simultaneous, (4) that a clitoral orgasm is not an orgasm, (5) that orgasm is always essential during sexual contact, (6) that as one gets older desire for sex disappears.

The couple is then enjoined to start a new mode of sexual communication with each other. The therapist may interject these comments:

1. "Don't ask your spouse what he [she] wants in sex. Start every sentence with 'I want' or 'I would like.' "

2. "Express your feelings rather than act on them. If you are angry, say so. The minute you *act* angry with each other something has gone wrong."

3. "There is no reason not to reveal your performance fears to each other." The couple (or patient) should also be told at the start of therapy: "Until I [we] have given you the permission, to do otherwise, you are to limit your sexual activities to getting turned on with each other. There is to be no real intercourse in the meantime." Pressure removed from the male to penetrate with his penis and the female to have an orgasm may almost

immediately lead to penile erections and vaginal lubrication. This can form the basis for fruitful reconditioning of responses.

4. "You will make mistakes, but that is the best way to learn."

5. "You are not to analyze your performance, just let things happen as they will. The goal is pleasure, not how well you are doing."

6. "You don't have to have intercourse to give your partner sexual satisfactions."

The basic first step to be practiced* by the couple is what Masters and Johnson have called "sensate focus." The couple is instructed to begin in privacy the following assignment:

> *Th.* You are, in a comfortably warm room, to get into bed completely undressed. Turn on a soft light.

Some couples have actually never closely looked at each other nude. The partner with the problem, or with the most severe problem, is instructed:

> *Th.* You are to do with him [or her] whatever you always wanted to do, like touching the face, body, thighs, etc. But *not* the breasts or genitals. There is absolutely to be no intercourse. If you do anything that causes discomfort, your partner must tell you. Your partner is to get what he [or she] can get out of it. But the important thing is for you to experience pleasure in what you are doing. Do this for 5 to 15 minutes, no more. Then your partner is to do the same thing with you.

Very often this exercise will mobilize strong sexual feelings. Impotent men will have erections; nonorgasmic women will lubricate: premature ejaculators will maintain an erection.

The couple may also be told that if they get aroused too much, they may pleasure themselves (masturbate) in the presence of each other, but not to the point of orgasm. Couples often lose their guilt and feel released by the therapist giving them "permission" for them to manipulate themselves in the presence of each other.

If the couple is seen only once weekly rather than the intensive 2-week course at the beginning, they may be told to practice "sensate focus" only twice during the week or at

the most three times. They may also utilize a warm body lotion if they desire.

After such practice, the couple, seen together, is asked individually what has happened. The therapist may ask: "Describe how you felt when *you* did it; how did you feel when it was done to you." A good deal of benefit that comes from sexual therapy derives from the emotional catharsis that relieves patients of guilt, fear, and shame as they talk about their preoccupations and feelings. The fact that the therapist is empathic toward and non-condemning of past experiences and current fantasies and compulsions helps them to approach their problems from a less defiant and more objective perspective. They get the impression that there is nothing really "bad" or "evil" about what they are thinking, feeling, or doing; rather they feel that they can move ahead toward areas of greater sexual and emotional freedom and fulfillment. The therapist should search for factors that create anxiety and mutual hostilities. If not corrected, these may neutralize the effects of therapy. Where necessary, the therapist supplies data about physiology, prescribes books, and discusses techniques of symptom control. Useful suggestions may be found in the illustrated book by Helen Kaplan (1974). What went right and what went wrong? The accounts will usually vary. If things did not go well, this should be discussed and the couple sent out to repeat the exercises with the addendum: "Each person is to tell the other what he [or she] likes to have done." A common complaint is being ticklish. If this is the case, the ticklish partner should put his (or her) hands over that of the partner who does the stroking. They may be enjoined, "When you are more relaxed, the tickling will cease." Should the couple complain that there was no sexual feeling, they may be told: "This is not a sexual performance. It is a practice session." Successes should be praised but not analyzed.

As soon as this phase has gone well, the couple may be encouraged to practice genital pleasuring. "You may now gently stroke each others' genitals, directing each other as you go along. It is not necessary to have an orgasm unless you want to and are sufficiently stimulated. But spend not more than 15 minutes from the start." The man may be told: "It is enjoyable for a woman to be touched gently on the clitoris. You can put your forearm on her tummy and let your hand fall over the pubis." The woman is to direct the

man's hand on her own pubis, the lips, and the clitoris, and tell him when to stop. If the woman does not lubricate, lubrication should be employed especially on the clitoris.

Where an intensive 2-week program is utilized, it may be arranged as follows, varying it according to the reported reactions:

First day: History taking.

Second day: Joint session. Educational explanations. Correcting misconceptions about sex. Directions about "sensate focus."

Third day: Round table (therapists and couple) to discuss reactions. Directions to examine each other avoiding genitals and breast.

Fourth day: More sensate focus. If no anxiety, genitals may be included.

Fifth day: Sensate focus with stimulation of genitals, but not to orgasm. Orgasm may be reached by pleasuring self if desired.

Sixth day: If no anxiety is reported, a mutually pleasurable thing is to be done.

Seventh day: No sexual practice.

Eighth day: As desired with or without practice.

Ninth day: Insertion of penis into vagina for pleasure, but no orgasm, is essential. The goal is pleasure, not orgasm, even if the penis goes inside. If there is no erection, the soft penis with KY jelly or other lubrication can still be introduced. It should contact the clitoris if not inserted. "Even the soft penis gives pleasure."

Tenth day: Repetition of ninth day.

If after four or five sensate focus sessions the couple is not responding and moving ahead, they should not be made to feel that they are failures. Some other form of treatment (like psychoanalytically oriented psychotherapy) may be necessary. The failure is not with the couple. It is due to the limitations of this particular kind of therapy. There is a group of patients such as those with inhibited sexual desire whose defenses prevent them from enjoying sex. Often obsessive ideas about performance interfere with the drive,

excitement, and orgasm phases of the sexual act. In some cases the patient may be taught to disregard or bypass obsessive thoughts. In other cases the problem is too invested with unconscious conflict to disappear with simple sex therapy along behavioral lines. A combined dynamic and behavioral approach is best here.

Some special techniques may be necessary for different problems. In *premature ejaculation* the "squeeze" technique may be helpful. Here the man lies on his back. The woman with legs spread faces his pelvis. She strokes his body and then the penis until there is erection. She continues stroking the penis and randomly places thumbs on the raphe under the glans on the underside of the penis and the forefinger on the other side. She squeezes four times in 15 seconds, but not to the point of pain. Then he lies on his back, and she squats over him. She slowly inserts the lubricated penis and stops all movement for a moment. Then she moves slowly at a 45° angle, and he announces when he is getting too much pleasure. He then withdraws the penis, and the squeeze technique is utilized. Modifications of this technique may be used (Tanner BA, 1973). Where the female sexual partner becomes upset and *insists* on a "better performance," the problem of rapid ejaculation is augmented by guilt and conviction of failure. Tension builds up, which exaggerates the symptom. Here dynamic marital therapy along with sexual therapy along behavioral lines is the preferred approach.

A problem that disturbs many women is that of being *nonorgasmic.* Where the patient has sensuous feelings and can achieve orgasm with masturbation, the difficulty is generally not a serious one. Should a block to sensuous feelings exist, it is expedient to explore with the patient further the history of her sexual development from childhood and the store of misinformation that she has retained about sexuality.

The first step is helping the patient to develop greater sensuous feeling by exercises in relaxing, stroking her body, and self-pleasuring (masturbating). A book like *The Sensuous Woman,* by Lyle Huart, may be helpful. The sensate focus technique described above is then taught the couple with the object of pleasuring each other while avoiding intercourse. Pleasure in giving pleasure to the partner is the object while providing

feedback of how they both feel during the exercises.

McCarthy (1973) describes a technique that may be found helpful.

First day: Stroking and kissing various parts of the partner's body with eyes shut and no genital touching.

Second day: Sensate focus, eyes shut and couple guiding each other with no genital touch.

Third day: Sensate focus, guiding each other and eyes open.

Fourth day: Abstinence.

Fifth day: Sensate focus with lotion, no genital touch.

Sixth day: Sensate focus and genital touch with eyes closed.

Seventh day: Guided sensate focus with genital touch, eyes open.

After this greater spontaneity and experiment are encouraged. Some couples may take several days to execute the directions assigned for one day. When the exercises have been completed, once-a-week visits are possible. Teaching the couple sexual positions may be part of the instructions starting with the "no-demand" position. Oral-genital stimulation techniques may also be introduced and feelings aired about this. Should anxiety develop during any of the stages, a return to sensate focus techniques is advocated. Finally, after orgasms are reached by manual and oral-genital techniques, actual intercourse is encouraged. As much as 2 or 3 months of preliminary stimulation may be required before full intercourse is "permitted." Naturally, if full intercourse occurs prior to this, the therapist acts pleased.

Some therapists skilled in hypnosis have been able to bring their female patients to orgasm by training them in fantasy formation while the patients are in a trance. They are told they will have feelings of gentle warmth in the vaginal area and will be able to accept these feelings and feel excited and passionate deeply inside the vagina. Thereafter scenes are suggested of the patient meeting her secret lover and making exciting love with him.

Because repressive barriers are down and the imagination is so vivid in the trance, some patients are able to experience their first orgasm through such training. Posthypnotic suggestions are made to the effect that orgasms will come with intercourse without guilt or fear. The therapist must be a bit of a romantic poet to make such suggestions sound realistic. Should the therapist decide to utilize this technique, it is wise to have a female helper quietly present during and after trance induction for medico-legal reasons.

The use of vibrators should be avoided in nonorgasmic women, since they will probably respond to the intense stimulation and then find the actual sex experience nonstimulating. Moreover, if the vibrators are used too much, they may cause vaginal ulceration.

Where the complaint is *impotence,* we must differentiate between primary and secondary varieties. In *primary impotence,* the patient has never been able to sustain an erection with a partner sufficient for the sexual act. Some individuals here realize their failing, but they ascribe it to moral scruples, which they imagine will be resolved when they get married. Marriage fails to correct the condition and, recognizing that an annulment is imminent, husband and wife usually seek help from a minister or physician who, in turn, may refer the couple to a psychotherapist. Generally, primary impotence is an aspect of a severe personality problem characterized by strong feelings of inadequacy, inferiority, and doubts about one's masculinity. The principal approach here is dynamic psychotherapy with sex therapy as a supplementary, albeit useful, accessory that should involve the patient and his partner.

Secondary impotence is where, following a period of more or less successful intercourse, the male experiences a loss of erection. This may occur when he is fatigued, or physically ill, or excessively tense and anxious about some situational problem, or most frequently when he is feeling hostile toward his partner. Ever since women have come to regard sex as a right rather than a burden, the incidence of secondary impotence has risen. Especially affected are men who regard their partner's expectations as a challenge to their masculinity. Their reaction to "failure" is usually related to their self-image. If they have a

low feeling about themselves, they will overrespond and look forward to the next attempt with a sense of dread. The need to perform becomes more important to them than the desire to achieve pleasure in the sex act. Hypnosis in some cases, may be emminantly successful as a reinforcing intervention in impotency and premature ejaculation (Wolberg, 1948) utilizing suggestions patterned after the directions discussed previously.

Let us assume that we have eliminated physical causes (for example, diabetes, which is sometimes the source of secondary impotence) for the impotence. Therapy will involve restoration of confidence in the ability to function. No more may be required than clarification that impotence can occur temporarily in all males and that it will rectify itself if the person has no stake in maintaining it. The therapist should emphasize and reemphasize, "The best advice to follow is to forget the need for performance and to attempt satisfying yourself to the limit of your capacity without or with an erection." Treatment with sensate focus is generally successful, but cooperation of the partner is mandatory.

We sometimes encounter a situation where a middle-aged man is secondarily impotent with his wife and has become involved in an erotic stimulating situation with a younger woman. He is sexually disinterested in his wife, who he complains is getting obese, is losing her body firmness, developing wrinkles, neglects her grooming, and exposes him to a boring, stereotyped sexual experience. Often the relationship with the wife has deteriorated into one where the man regards her as a maternal substitute. He may come to therapy spontaneously out of guilt and with the hope the therapist will work some miracle and produce an erection even though he may not be interested so much in pleasing himself as in pleasing his wife. Generally, if the man is emotionally involved with the other woman, sex therapy will not work too well and the restoration of adequate sexual functioning will be unsuccessful. At some point it will be necessary to break up the triad. The therapist may under some circumstances, at the start, where the man's motivation to correct the situation is strong, have to tell him that he will need to break up his relationship with the young woman before therapy can be successful. In other cases where the man is deeply entangled in the affair, immediate rupture can be traumatic and

may be strongly resisted. Here, gradually the effort may be made to help the man see the inadequacy of the relationship with his mistress, an effort that may or may not prove successful. Marital therapy is sometimes useful where the relationship between husband and wife has not deteriorated too badly.

Brief periods of *frigidity* in women are normal, the product resulting from temporary physical disability or fleeting anxieties, tensions, and depressions. Frigidity can also occur when there is anger or irritation with a sexual partner. Short-term therapy with reassurance given that there is nothing seriously wrong, while permitting free verbalization of hostility toward the partner, may be all that is required.

Persistent frigidity may be divided into primary and secondary varieties. In *primary frigidity* the woman has never had an orgasm even during sleep or with masturbation, although she may have experienced some sexual arousal. Usually arousal reaches a pitch and then loss of feeling ensues without orgasm. Responsible for this may be fears of loss of control, of rejection, or of acting foolishly. In *secondary frigidity* the person was once orgasmic and then ceased to respond. Here untoward emotions and attitudes are often implicated, like hostility, distrust, disgust, and fear. Sometimes orgasm may be possible with certain fantasies, like being raped or punished, or with some practices, like being treated roughly, tied down, abused, etc. Sometimes masturbation succeeds while intercourse remains distasteful. Sex therapy may enable some women with secondary frigidity to respond satisfactorily. Should a patient require fantasies, the therapist should not disparage these. The patient may be encouraged to substitute thoughts about her present sexual partner at the start of orgasm in an effort to recondition a new way of thinking.

Long-standing primary frigidity, however, does not usually yield to sex therapy, particularly where it is a product of severe personality problems stemming from disturbed family relationships. There may be a fear of functioning like a woman, a repudiation of femininity, a disgust with and desire to renounce the female sexual organs, consciously or unconsciously conceived of as dirty or repulsive. There may be marked

competitiveness and hostility toward men. Long-term psychoanalysis or dynamic psychotherapy offers chances for improvement or cure after reconstructive changes have been brought about.

In *dyspareunia* and *vaginismus* intercourse is so painful that it becomes aversive rather than pleasurably rewarding. Here the patient should be sent to a gynecologist to rule out organic causes. Trauma during the birth of a child, episiotomy, a painful past abortion, a hysterectomy, endometriosis, allergic reactions to birth control sprays and jellies, and other physical factors may be at the root of the problem. In most cases, however, the cause is psychogenic. During vaginismus the muscles go into spasm, a kind of defensive splinting. Penetration is difficult or impossible even for the little finger. Reaction to erotic approaches then sponsors a panicky withdrawal. Sometimes vaginismus is a secondary response to premature ejaculation or impotence in a husband or lover. The woman's reaction frightens and discourages the man and aggravates his problem, which, in turn, creates further symptoms in the woman. The triad of dyspareunia, vaginismus, and impotence are often at the basis of an unconsummated marriage. Couples sometimes shamefacedly seek help for this situation, and sex therapy may be tried.

A useful method of feaiing with these reactions is to recondition the pain response through the use of graduated dilators. These may be obtained in a surgical supply house, one form being known as Young's Dilators. The smallest size, well lubricated, is slowly inserted by the woman, at first in the presence of her husband. She is encouraged to retain it for a while. Then gradually each day a larger size, well lubricated, is introduced. Next the husband slowly inserts the dilators in graduated size. The time dilators are retained in the vagina is increased from 15 minutes to 2 hours. The patient must be reassured that the dilators will not disappear in her body, a fearful misconception of some patients. Success rates are close to 100 percent, assuming no serious psychiatric problem coexists.

BIBLIOTHERAPY

Attempts are sometimes made by therapists to change faulty attitudes and to influence poor motivation in certain patients through the assigned reading of articles,

pamphlets, and books. By these measures the patient is helped to understand how personality is evolved, why adaptation breaks down, the manifestations of collapse in adaptation, and how psychotherapy may help repair the damage. Advice on the handling of specific problems in adjustment, marriage, and child rearing may also be obtained from some reading materials. This therapeutic use of reading (psychoeducation) has been designated as "bibliotherapy."

Bibliotherapy is of value chiefly to persons who have had little contact with psychotherapy and who require more information about emotional illness before they can admit of its existence in themselves or can recognize that beneficial results may be obtained from treatment. It may correct misconceptions about mental health, psychiatry, and psychotherapy. It is sometimes effective in correcting misconceptions through acceptance of written authoritative statements and directives that help the person to suppress inner fears, to gain reassurance, and to adopt socially acceptable attitudes and values. The latter influence makes bibliotherapy a useful adjunctive device in certain patients receiving psychotherapy. Patients may gain from readings a number of methods by means of which they may regulate their life, inspirational formulas that help in the achievement of happiness and success, and devices that permit of a regulation of those conflicts and strivings that are more or less under volitional control.

Bibliotherapeutic approaches to mental health, while praiseworthy, have definite limitations. People often refuse to accept facts due to a complete or partial unawareness of ego-syntonic personality distortions. To tell parents they must accept and love their children in order for the children to grow into healthy adults, does not mean that they will appreciate the significance of these precepts. Indeed, even though children are being rejected, spouses despised, and family life desecrated, the culprits may not consider their behavior in any way unusual. They may even hold themselves up as parental ideals.

In other instances the person may acknowledge one's difficulties but be totally unable to do anything about them. Educational media that warn people of the disasters to children or to society of their reactions may mobilize counterreactions and actually

exaggerate the existing problems.

The manner in which reading materials are prepared and presented is important. If they apprise of the fact that all parents commit errors, that children are resilient and can stand many mistakes if they feel loved and respected, and that youngsters with even severe difficulties can change, readings may create a corrective atmosphere.

On the whole, reading adjuncts will not prove to be remarkably corrective for the patient who is in reconstructive therapy. This is because no intellectual approach is of great service in modifying deeply repressed conflicts or in ameliorating symptoms that have strong defensive virtues for the individual. Indeed, the educational materials may be utilized by the patient as resistance, items being extracted out of context to justify neurotic patterns. The relative ineffectuality of reading materials in severe neurotic difficulties is attested to by the fact that scores of patients come to psychotherapy after having read more extensively from the psychiatric literature than has the therapist.

Nevertheless, bibliotherapy may help certain individuals to break through specific resistances and to gain limited insight, as, for instance, those patients who, unconvinced of the value of psychotherapy, require examples from the experiences of others of how therapy helps. Resistance to working with dreams may sometimes be handled by asking the patient to read books in which the rationale of dream interpretation is explained. A patient who has in therapy resolved crippling sexual inhibitions may be aided in achieving a more complete sexual life by reading appropriate materials dealing with marriage. Or a patient having problems with children may benefit greatly from books on child psychology. Personal involvement in short stories and case histories is also possible, and McKinney (1975) lists a bibliography that can be useful.

As a therapeutic medium, bibliotherapy is utilized in child therapy. Children readily get "caught up" in a story. A child identifies with one or more of the characters and releases emotional energy vicariously. This may result in greater awareness by the child of personal needs, feelings, and motivations (Ciancilo, 1965; Nickerson, 1975). Some of the ways that bibliotherapy is employed are described by Bell and Moore (1972), Chambers

(1970), Dinkmeyer (1970), Gardner (1974), Heimlich (1972), Mulac (1971), My rick and Moni (1972), and J. A. Wagner (1970).

The following is a list of recommended books and pampthlets, should the therapist decide that bibliotherapy is indicated.

Books on General Psychology, Psychiatry, and Psychoanalysis

Short-Term Psychotherapy

Most of the psychotherapeutic treatments given in this country are short-term by the patients' choice. At the Postgraduate Center for Mental Health, one of the largest outpatient clinics in the United States, for example, patients are seen for psychoanalytically oriented psychotherapy with no limit set for the number of sessions to be given. Patients terminate treatment when they have decided they need no more help. Under these circumstances, the average number of sessions given comes to 17, and this is accompanied by an improvement rate of over 80 percent. Even though the Center is a psychoanalytic training unit, and patients are encouraged to remain in long-term therapy, only 15 percent are deemed suitable candidates for protracted treatment focused on reconstructive goals.

Follow-up studies on patients who have improved with short-term therapy have shown that the majority retain their gains and that some continue to progress by themselves once the start has been made during formal treatment. This does not mean that they would not have improved even more with long-term therapy. It merely indicates that short-term therapy is an important cost-effective approach for many psychiatric problems. It also has been shown by the nation's pioneer health maintenance organization to reduce utilization of medical resources. Yet there are still many therapists who are reluctant to accept the value of short-term approaches. Hoyt (1985) has listed the following reasons for this reluctance: (1) the belief that "more is better" and that long-term methods are more penetrative and thorough, (2) the idea that one should not contaminate the "pure gold" of analysis with baser metals of a supportive nature, (3) the therapist's predetermined notion that long-term therapy is indicated in spite of the patient's wishes, (4) the belief that short-term therapy involves an overwhelming investment of work and energy, (5) the subtle economic factor of maintaining a steady rather than fluctuating source of income, (6) countertransference and undue therapist reactions to termination.

A number of studies have appeared that bear out that short-term therapy is a most efficient means of bringing about at least symptomatic improvement or cure. More than 25 years ago, this was proven by an experimental program of Group Health Insurance, Inc., in which 1200 participating psychiatrists treated a large sample of patients suffering from a wide spectrum of emotional problems (Avnet, 1962). At the end of the limited treatment period a 76 percent cure or improvement rate was scored. Follow-up investigation 2.5 years later recorded 81 percent of patients as having achieved recovery or improvement (Avnet, 1965). On the basis of these studies, it was grossly predicted that four of five patients receiving brief forms of treatment would report or feel some kind of improvement, even with current treatment methods executed by long-term oriented therapists.

That depth changes are also possible has been reported by psychoanalytically trained psychotherapists who present evidence that far-reaching and lasting changes may occur even with a limited number of dynamically oriented sessions (Sifneos, 1967, 1972; Davanloo, 1978; Malan, 1964a, 1976; Mann, 1973; Wolberg, 1980). This contention has understandably been subject to challenge. Personality distortions have a long history. They involve habit patterns and conditionings dating to childhood that have become so entrenched that they resist dislodging in a brief period. Repetitively they force the individual into difficulties with oneself and others, and they may persist even after years of therapy with an experienced psychoanalyst have revealed their source, traced their nefarious workings through developmental epochs, and painstakingly explored their present-day consequences. We can hardly expect that the relatively few sessions available for short-term therapy can effectuate the alchemy of extensive reorganization not possible with prolonged treatment. Reconditioning any established habit requires time; and time is of the essence in molding personality change if change is at all possible. *But experience persuades that this time need not be spent in all cases in continuous psychotherapy.* Removing some misconceptions about one's illness and one's background may dislodge the cornerstone, crumble the foundations, and eventually collapse some of the neurotic superstructure. This development may not be apparent until years have passed following a short-term treatment effort. Obviously, this bounty cannot always be realized. We may

hypothesize that the more experienced, highly trained, and flexible the therapist, the more likely it is to occur. Yet the environment in which the individual functions will undoubtedly also have a determining effect on any reconstructive changes that will evolve, since the milieu may sponsor and encourage or vitiate and crush healthy personality growth. But without having had the benefit of therapy, however brief it may have been, even the most propitious environment will have registered little improvement, save for exceptional cases.

There are patients who by themselves have already worked through a considerable bulk of their problems and who need the mere stimulation of a few sessions with a proficient therapist to enable them to proceed to astonishing development. Such an extensive dividend may not come about, nor should they be expected with many patients in short-term treatment, even where the therapist is sufficiently endowed by personality, training, and experience to do good psychotherapy.

Reasonable anticipations of what short-term treatment should accomplish in the average person are (1) relief of symptoms, (2) restoration to the optimal level of functioning that existed prior to the present illness, and (3) an understanding of some of the forces that initiated the immediate upset. When dynamic short-term therapy has been employed, we may, in addition, hope for (1) recognition of some pervasive personality problems that prevent a better life adjustment, (2) at least partial cognizance of their origin in past experiences and childhood conditionings, (3) recognition of the relationship between prevailing personality problems and the current illness, and (4) an identification of remediable measures that can be applied to environmental difficulties and perhaps to aspects of personality distortions as a whole. If treatment is managed well, patients will be given an opportunity to move beyond restoring their customary emotional balances. Should they possess sufficient motivation to propel them toward further development, should neurotic secondary gain elements be minimal, and should their environment be sufficiently accommodating to sponsor their continued movement, deeper alterations may occur. We may accept any reconstructive change as a welcome blessing if it comes, but, should it not, we must be satisfied that the patients have derived something worthwhile,

even though goal limited, out of their sparse sessions. If therapy is interrupted at the peak of the improvement curve, before the idealized relationship projections dissolve in the acid substratum of transference and resistance, and before dependency has had an opportunity to establish a permanent beachhead in the relationship, the rate of improvement can be substantial.

SELECTION OF CASES

While the best patients are undoubtedly those who are adequately motivated for therapy, intellectually capable of grasping immediate interpretations, proficient in working on an important focus in therapy, not too dependent, have had at least one good relationship in the past, and are immediately able to interact well with the therapist, they generally constitute only a small percentage of the population who apply to a clinic or private practitioner for treatment. The challenge is whether patients not so bountifully blessed with therapeutically positive qualities can be treated adequately on a short-term basis with some chance of improving their general modes of problem solving and perhaps of achieving at least a minor degree of personality reconstruction.

In practice one may distinguish at least five classes of patients who seek help. We have categorized them as class 1 through 5. In general, classes 1 to 3 require only short-term therapy. Classes 4 and 5 will need management for a longer period after an initial short-term regimen of therapy.

Class 1 Patients

Until the onset of the current difficulty class 1 patients have made a good or tolerable adjustment. The goal in therapy is to return them to their habitual level of functioning. Among such patients are those whose stability has been temporarily shattered by a catastrophic life event or crisis (death of a loved one, divorce, severe accident, serious physical illness, financial disaster, or other calamity).Some individuals may have been burdened with extensive conflicts as far back as childhood but up to the present illness have been able to marshal sufficient defenses to make a reasonable

adaptation. The imposition of the crisis has destroyed their capacities for coping and has produced a temporary regression and eruption of neurotic mechanisms. The object in therapy for these patients is essentially supportive in the form of *crisis intervention* with the goal of reestablishing the previous equilibrium. Reconstructive effects while not expected are a welcome dividend. Generally, no more than six sessions are necessary.

An example of a class 1 patient is a satisfactorily adjusted woman of 50 years of age who drove a friend's automobile with an expired license and in the process had a severe accident, killing the driver of the car with which she collided and severely injuring two passengers in her own car, which was damaged beyond repair. She herself sustained a concussion and an injured arm and was moved by ambulance to a hospital, where she remained for a week. Charged with driving violations, sued by the owner of the car she borrowed and by the two injured passengers, she developed a dazed, depressed reaction and then periods of severe dizziness. Therapy here consisted of a good deal of support, reassurance, and help in finding a good lawyer, who counseled her successfully through her entangled legal complications.

Sometimes a crisis opens up closed traumatic chapters in one's life. In such cases it may be possible to link past incidents, feelings, and conflicts with the present upsetting circumstances enabling the patient to clarify anxieties and hopefully to influence deeper strata of personality. In the case above, for example, the patient recalled an incident in her childhood when while wheeling her young brother in a carriage, she accidentally upset it, causing a gash in her sibling that required suturing. Shamed, scolded, and spanked, the frightened child harbored the event that powered fear and guilt within herself. The intensity of her feelings surprised her, and their discharge during therapy fostered an assumption of a more objective attitude toward both the past and the immediate crisis event. It may not be possible in all cases, but an astute and empathic therapist may be able to help the patient make important connections between the past and present.

Class 2 Patients

The chief problem for class 2 patients is not a critical situation that has obtruded

itself into their lives, but rather maladaptive patterns of behavior and/or disturbing symptoms. The object here is symptom cure or relief, modification of destructive habits, and evolvement of more adaptive behavioral configurations. Multiform techniques are employed for 8 to 20 sessions following eclectic *supportive-educational* models under the rubric of many terms, such as short-term behavioral therapy, short-term reeducative therapy, and so forth.

A phobia to air travel exemplifies the complaints of a class 2 patient. This was a great handicap for Miss J since job advancement necessitated visits to remote areas. The origin of the patient's anxiety lay in the last flight that she had taken 8 years previously. A disturbance in one of the engines reported to the passengers by the pilot necessitated a return to the point of origin. Since that time Miss J had not dared enter a plane. Therapy consisted of behavioral systematic desensitization, which in eight sessions resulted in a cure of the symptom.

In utilizing the various eclectic techniques, therapists alert themselves to past patterns that act as a paradigm for the present symptom complex, as well as to manifestations of resistance and transference. In a certain number of cases the patient may be helped to overcome resistances through resolution of provocative inner conflicts and in this way achieve results beyond the profits of symptom relief.

Class 3 Patients

Those in whom both symptoms and behavioral difficulties are connected with deep-seated intrapsychic problems that take the form of personality disturbances and inappropriate coping mechanisms make up the class 3 classification. Such patients have functioned at least marginally up to the time of their breakdown, which was perhaps initiated by an immediate precipitating factor. Most of these patients seek help to alleviate their distress or to solve a crisis. Some come specifically to achieve greater personality development. On evaluation either they are deemed unsuitable for long-term treatment, or extensive therapy is believed to be unnecessary, or for sundry other reasons cannot be done. They often possess the desire and capacity of work toward acquiring self-

understanding.

The goal for class 3 patients is personality reconstruction along with symptomatic and behavioral improvement. Techniques are usually psychoanalytically oriented, involving interviewing, confrontation, dream and transference interpretations, and occasionally the use of adjunctive techniques like hypnoanalysis. Some therapists confine the term *dynamic short-term therapy* to this class of patients and often employ a careful selection process to eliminate patients whom they feel would not work too well with their techniques (Buda, 1972; Davanloo, 1978, Malan, 1963; Sifneos, 1972; Ursano & Dressier, 1974).

An example of a class 3 patient is a young mother who brought her son in for consultation because he was getting such low marks in the final year of high school that the chances of his getting into college were minimal. Moreover, he firmly announced his unwillingness to go to college, insisting on finding a job after graduation so that he could buy an automobile and pursue his two hobbies: baseball and girls. During the interview with the boy it was obvious that he had motivation neither for further college education nor for any kind of therapeutic help. It was apparent too that his stubborn refusal to study and to go on to higher learning was a way of fighting off the domination of his mother and stepfather. Accordingly, the mother was advised to stop nagging the boy to continue his schooling. Instead she was urged to permit him to experiment with finding a job so that he could learn the value of a dollar and to discover for himself the kinds of positions he could get with so little education.

The next day the mother telephoned and reported that she had followed the doctor's instructions. However, she asked for an appointment for herself since she was overly tense and suffered from bad backaches that her orthopedist claimed were due to "nerves." What she wanted was to learn self-hypnosis, which her doctor claimed would help her relax. Abiding by her request, she was taught self-hypnosis-not only for relaxation purposes, but also to determine the sources of her tension. Through interviewing aided by induced imagery during hypnosis, she was able to recognize how angry she was at me for

not satisfying her desire to force her son to go to college. Images of attacking her father, who frustrated and dominated her, soon brought out her violent rage. She realized then that her obsequious behavior toward her husband was a cover for her hostility. Acting on this insight, she was soon able to express her anger and to discuss her reactions with her husband and the reasons for her rages. This opened up channels of communication with a dramatic resolution of her symptoms and an improvement in her feelings about herself and her attitudes toward people, confirmed by a 5-year follow-up.

Patients are generally considered unsuited for dynamic short-term psychotherapy if they are not motivated to search for sources of their problems, are unable to withstand the frustration of receiving immediate symptomatic relief, cannot establish a close interpersonal relationship, do not have the ability or ego strength to tolerate anxiety consequent to the challenging and yielding of neurotic patterns of behavior, are not sufficiently "psychologically minded" to be able to reflect on reasons for their maladjustment, or resort habitually to the abuse of tranquilizers, alcohol, or drugs as a way of dealing with tension.

Class 4 Patients

Patients of the class 4 category are those whose problems even an effective therapist may be unable to mediate in a brief span and who will require more prolonged management after the initial short-term period of formal therapy has disclosed what interventions would best be indicated. The word "management" should be stressed because not all long-term modalities need be, and often are not, best aimed at intrapsychic alterations. Among individuals who appear to require help over an extended span are those whose problems are so severe and deep-rooted that all therapy can do for them is to keep them in reasonable reality functioning, which they could not achieve without a prolonged therapeutic resource.

Class 4 patients include the following:

1. Individuals with chronic psychotic reactions and psychoses in remission who

require some supervisory individual or group with whom contact is regularly made over sufficiently spaced intervals to provide some kind of human relationship, however tenuous this may be, to oversee essential psychotropic drug intake, to regulate the milieu, and to subdue the perils of psychotic processes when these are periodically released. Such patients do not usually require formal prolonged psychotherapy or regular sessions with a psychotherapist; they could do as well, or better, with the supportive help of an empathic counselor. Milieu therapy, rehabilitation procedures, and social or group approaches may be useful.

2. Persons with serious character problems with tendencies toward alcoholism and drug addiction who require regular guidance, surveillance, group approaches, and rehabilitative services over an indefinite period.

3. Individuals with uncontrollable tendencies toward acting-out who need controls from without to restrain them from expressing impulses that will get them into difficulties. Examples are those who are occasionally dominated by dangerous perversions, desires for violence, lust for criminal activities, masochistic needs to hurt themselves, accident proneness, self-defeating gambling, and other corruptions. Many such persons recognize that they need curbs on their uncontrollable wayward desires.

4. Persons so traumatized and fixated in their development that they have never overcome infantile and childish needs and defenses that contravene a mature adaptation. For instance, there may be a constant entrapment in relationships with surrogate parental figures, which usually evolve for both subjects and hosts into a sado-masochistic purgatory. Yet such persons cannot function without a dependency prop, and the therapist offers to operate as a more objective and nonpunitive parental agency. Some of these patients may need a dependency support the remainder of their lives.

Many of the patients in this category fall into devastating frustrating dependency relationships during therapy or alternatives to therapy from which they cannot or will not extricate themselves. Realizing the dangers of this contingency, we can, however, plan our strategy accordingly, for example, by providing supportive props outside of the treatment situation if support is needed. Nor need we abandon reconstructive objectives, once we make proper allowances for possible regressive interludes. In follow-up contacts, I was pleased to find, there had been

change after 5,10, and in some cases 15 years in patients who I believed had little chance to achieve personality alterations.

5. Persons with persistent and uncontrollable anxiety reactions powered

(a) by unconscious conflicts of long standing with existing defenses so fragile that the patient is unable to cope with ordinary demands of life or (b) by a noxious and irremediable environment from which the patient cannot escape.

6. Borderline patients balanced precariously on a razor edge of rationality.

7. Intractable obsessive - compulsive persons whose reactions serve as defenses against psychosis.

8. Paranoidal personalities who require an incorruptible authority for reality testing.

9. Individuals with severe long-standing psychosomatic and hypochondriacal conditions, such as ulcerative colitis, or chronic pain syndromes that have resisted ministrations from medical, psychological, and other helping resources. Often these symptoms are manifestations of defenses against psychotic disintegration.

10. People presenting with depressive disorders who are in danger of attempting suicide and require careful regulation of antidepressive medications or electroconvulsive therapy followed by psychotherapy until the risk of a relapse is over.

Class 5 Patients

In class 5 we place those individuals who seek and require extensive reconstructive personality changes and have the finances, time, forbearance, and ego strength to tolerate long-term psychoanalysis or psychoanalytically oriented psychotherapy. In addition, they have had the good fortune of finding a well-trained, experienced, and mature analyst who is capable of dealing with dependent transference and other resistances as well as with one's personal countertransferences. Patients who can benefit more from long-term reconstructive therapy than from dynamically oriented short-term therapy are often burdened by interfering external conditions that may be so strong, or by the press of inner

neurotic needs so intense, that they cannot proceed on their own toward treatment objectives after the short-term therapeutic period has ended. Continued monitoring by a therapist is essential to prevent a relapse. In certain cases the characterologic detachment is so great that the patient is unable to establish close and trusting contact with a therapist in a brief period, and a considerable bulk of time during the short-term sessions may be occupied with establishing a working relationship.

In addition to adults a special group of patients requiring long-term therapy are highly disturbed children and adolescents who have been stunted in the process of personality development and who require a continuing relationship with a therapist who functions as a guiding, educational, benevolent parental figure.

Long-term patients in classes 4 and 5 usually constitute less than one-quarter of the patient load carried by the average psychotherapist. The bulk of one's practice will generally be composed of patients who may adequately be managed by short-term methods.

ESSENTIAL COMPROMISES IN SHORT-TERM THERAPY

Apart from the fact that acceptance of abbreviated goals may be necessary in short-term therapy, a number of other compromises may be essential. Prominent among these are (1) the employment of greater activity than in longer term treatment, (2) the flexible practice of differential therapeutics, (3) the overcoming of prejudices related to the "depth" of therapy, (4) avoiding denigration of short-term as compared with long-term approaches, and (5) utilization of interrupted rather than continuous treatments.

Encouragement of Therapist Activity

Anathema to short-term therapy is passivity in the therapist. Where time is of no object, the therapist can settle back comfortably and let the patient pick his or her way through the lush jungles of the psyche. To apply the same tactics in the few sessions that are available in short-term therapy will usually bring meager rewards. Treatment failures

are often the product of lack of proper activity. It is for this reason that the conventional non-directive, detached attitude is unwise, as are free association and the use of the couch. Focused interviewing in the sitting up position is almost mandatory.

There are some therapists, of course, whose personalities support a passive role. Such practitioners may still be able to make an effort at involving themselves more actively, assuming as their objective a rapid assay of the central problem, dealing with its most obvious aspects. If one concentrates one's fire, one will be able to hit the target with greater certainty. At least the therapist will prevent the patient from steering the course of treatment into unproductive channels.

In short-term therapy, one cannot afford the luxury as in prolonged treatment of permitting the patient to wallow in resistance until he or she somehow muddles through. Resistance will, of course, occur, but it must be dealt with rapidly through an active frontal attack before it paralyzes progress.

One of the most difficult things to teach students aspiring to become short-term therapists is that activity in the relationship, with an involvement of oneself as a real person, and open expressions of interest, sympathy, and encouragement, are permissible. Somehow passivity has become synonymous with doing good psychotherapy with the result that at the end of the prescribed sessions the patient is no further advanced toward resolution of the problem than when therapy first started. Often therapists are not aware of how uninvolved they are until observed working behind a one-way mirror or through videotaping and their passivity is pointed out to them by a supervisor. Whether they can do anything about their impassiveness is another matter, but, in my experience, encouragement to express a more open interest, to engage oneself more vigorously in the interview, to give one's facial expressions a free release, to offer advice where needed, and to make interpretations when necessary may vitalize the therapeutic situation sufficiently to convince that a stoic bearing, a blankness of countenance, and an unresourceful adherence to a phlegmatic role are not necessarily the "scientific" way of doing therapy. This does not mean that therapists will have to revolutionize their personalities in order

to do short-term therapy. Individuals are constituted differently. Some therapists by nature are quiet and reserved; forcefulness is not within their behavioral range. But they will still be able to exercise the essential activity through a communicative and reassuring relationship. Activity means being interested in the patient and immediate life problems; it does not mean being controlling of the patient. Neither does it give the therapist license to cuddle the patient, make the patient's decisions and otherwise rob the patient of the responsibility of doing things for himself or herself.

Use of Differential Therapeutics

Insofar as the use of a differential therapeutics is concerned psychoanalytically trained therapists are particularly fearful of therapeutic contaminants. Mindful of the long struggle for acceptance of analytic covenants, they are reluctant to take what they consider to be a backward step by dignifying nonanalytic techniques. In this attitude they attempt to delay Freud's prediction that it eventually may be necessary to blend the "gold" of psychoanalysis with the "copper" of other therapies.

Short-term therapy requires a combination of procedures from psychiatric, psychoanalytic, psychological, and sociological fields. Sometimes utilized in the same patient are psychotherapeutic techniques, casework, drugs, hypnosis, group therapy, psychodrama, and desensitization and reconditioning procedures. This fusion of methods, in which there are extracted from the different approached tactics of proven merit, promise the most productive results. To implement such an eclectic regimen, a degree of flexibility is required that enables the therapist to step outside the bounds of training biases and to experiment with methods from fields other than habitual ones.

Here we run headlong into prejudices about what will happen to a personally cherished system of psychotherapy if one introduces into it foreign elements. It may reassure therapists to keep reminding themselves that there is nothing sacred about any of our present day modes of doing psychotherapy. They all work in some cases and fail in others. We actually owe it to our patients, as well as to ourselves to experiment with as many techniques as we can in order to learn which of these will be effective and which do

not yield good results. Certain rigidities in the therapist will interfere with the proper experimentation. Eclecticism does not sanction wild therapy. It presupposes a scrupulous empirical attitude, assaying the values of the different methods for the great variety of conditions that challenge the therapist in daily practice.

Overcoming Prejudices About Depth

Important also is the overcoming of prejudices about "depth." Before a therapist is capable of doing effective short-term therapy he or she will need to abandon value judgments about "superficial" versus "deep" therapy. There is a tendency on the part of psychotherapists to put varying significances on levels of depth as they apply to the content of the therapeutic interviews. Material that relates to the past, from the dredgings of the unconscious, and from transferential interactions become emblazoned with special virtue. All else is labeled "superficial" from which little may be expected insofar as real personality change is concerned. Such notions are the product of a misuse of psychoanalytic wisdom that purports that the only true road to cure is through the alleys of the unconscious. This in spite of the fact that clinical experience persuades that the divulgence of unconscious content carries no guarantee that a patient will get well.

Psychotherapy is no mining operation that depends for its yield exclusively on excavated psychic ore. It is human interaction that embraces a variety of dimensions, psychological and social, verbal and nonverbal. Some of these elements are so complex that we can scarcely express them in words. How can we, for example, describe such things as "faith," "hope," "trust," "acquisition of insight," "meaning," "restoration of mastery," "self-realization," and "development of capacity to love." These are aspects of therapy fluctuating within the matrix of change. In the architecture of personality building, no one tissue or girder stands alone. They are all interrelated. Revelation of the unconscious blends into the total therapeutic Gestalt. It does not constitute it.

Even though in short-term therapy we can only deal with the immediate and manifest, we may ultimately influence the total personality in depth, including the unconscious. Human warmth and feeling, experienced by a patient in one session with an

empathic therapist, may achieve more profound alterations than years with a probing, detached therapist intent on wearing out resistance. This does not mean that one should be neglectful of the unconscious. Within a short span of therapy, repressed psychic aspects may still be elicited and handled.

Correcting Misconceptions About Time in Therapy

Rectification of prejudices about the superiority of long-term over short-term therapy is another must. It may be argued that if a few sessions can potentially induce corrective change, would not prolonged treatment do the job even more effectively, enabling the individual to apply to current life situation the kinds of discipline that sponsor a healthy perspective? There is no question that an extended time period permits the therapist to handle resistance that some patients mobilize toward the giving up of their neuroses. There is no question, too, that some patients, for instance, those that are masochistically inclined, gain a subversive gratification out of their neurotic misery and are loathe to yield it too readily. Here the therapist functions as a sentinel, alerting the patient to the presence and particular manifestations of resistance. Such patients would probably do better in prolonged treatment if we could avoid the trap of dependency and could successfully deal with transference elements that unleashed tend to enmesh the patient in the tangled folds of the past.

On the other hand, we may overemphasize the need for long-term treatment in many patients. We may assume that all persons possess healthy and resilient elements in their personality, which given half a chance, will burgeon forth. A brief period of treatment may be all that is required to set into motion a process of growth.

The question of the superiority of long-term over short-term therapy is therefore a rhetorical one. Experience persuades that some patients get nowhere with long-term therapy and do remarkably well with short-term approaches. There are others in whom short-term treatment does not succeed in denting the surface of their problem and who require a prolonged period of therapy before the slightest penetration is made. As has been pointed out the problem of selection of cases is as poignant a one as is the utilization

of proper techniques. It is doubtful that we can always define syndromes that best will respond to either approach. Factors other than symptomatology and diagnosis determine how the patient will progress. Nor is it possible to delineate precisely special tactics that can expedite treatment in all cases. What works with one therapist and patient may not work with others. Each therapist will need to experiment with methods best suited to individual style and personality.

At the present stage of our knowledge, long-term treatment is not always an indulgence. If the patient is so constituted as to be able to take advantage of explorations into the psyche, and if the therapist is equipped to work on a depth level, extended therapy may be a rewarding adventure. Without question the "working-through" of psychological blocks, and the resolution of the manifold facades and obstructions the mind concocts to defeat itself, can in some persons best be accomplished in a prolonged professional relationship. Here the therapist concentratedly and continuously observes the patient, dealing with resistances as they develop, and bringing the patient to an awareness of the basic conflicts that power defensive operations. Given the proper patient with a personality problem of longstanding, who possesses an adequate motivation for change, with an ego structure sufficiently plastic, an environment that is malleable, a social milieu that will accept the patient's new found freedoms, who can afford luxuries of time and finances, and who relates constructively in a treatment experience with a well-trained psychotherapist, long-term therapy will offer the best opportunity for the most extensive personality change.

Moreover, there are certain chronic conditions that respond to no other instrumentality than continuous psychotherapy, no matter how assiduously the therapist is applied toward releasing forces of health within the patient. The situation is akin to diabetes in which the patient survives solely because he or she receives life-giving insulin. In certain problems, dependency is so deep-rooted that the patient can exist only in the medium of a protective relationship in which the patient can receive dosages of support. The patient appears to thrive in therapy and seemingly may be utilizing insights toward a better integration. But this improvement is illusory; the patient constantly needs to

maintain a life-line to the helping authority to whom he or she clings with a desperation that defies all efforts at treatment termination. Such patients obviously will not do well with short-term methods, although long-term approaches may be inadequate also.

From the foregoing one may get the impression that long-term therapy is the preferred treatment where the patient has a severe personality disorder. This is not always the case. There are some risks in employing prolonged treatment in many patients. Dependent individuals who have been managing to get along on their own, albeit on a tenuous independency level, may become more and more helpless, and importune for increasing demonstrations of support with an exaggeration rather than a relief of their symptoms. Individuals with fragile ego structures will tend to develop frightening transference reactions in prolonged treatment, or they may go to pieces in the process of releasing repressions.

Patients who have been found to respond best to short-term therapy are those who possess a resilient repertoire of coping mechanisms, and who, prior to their immediate upset, were functioning with some degree of satisfaction. It is essential here to qualify the finding that acute problems are best suited for short-term approaches. Our frame of reference is the conventional body of techniques that we utilize today. There is no reason to assume that with the refinement of our methodology even severe personality difficulties may not be significantly improved on a short-term basis. This author has personally observed chronic cases treated with short-term methods, including obsessive-compulsive neurosis and borderline schizophrenia, and has noted many gratifying results. Indeed, had I believed that these patients should continue in extended therapy, I am certain that some would have marooned themselves in permanent treatment waters that would have swamped their tiny surviving islands of independence.

The best strategy, in this author's opinion, is to assume that every patient, irrespective of diagnosis, will respond to short-term treatment unless proven refractory to it. If the therapist approaches each patient with the idea of doing as much as reasonably possible within the span of up to 20 treatment sessions, the patient will be given an

opportunity to take advantage of short-term treatment to the limit of potential. If this expediency fails, a resort to prolonged therapy may be taken.

Use of Interrupted Treatments

Realization that therapy is not a close-ended matter with permanent beginning, middle, and end phases has introduced a new model for the delivery of services. This is oriented around the principle that termination of psychotherapy with a successful outcome does not necessarily immunize the individual against future emotional illness. Conditions outside the individual related to career, status, economic stability, marital situation, and social milieu, as well as within the person, e.g., increased vulnerabilities associated with aging, value change, and physical well-being may impose stresses beyond habitual adaptive capacities. Returning for treatment on a short-term basis may be as important for many people as visiting their personal physicians throughout their life for unexpected ailments that periodically develop. The idea that one can discharge a patient and never see the patient again is an erroneous one and should not be encouraged. This means that all therapy is relevant to a time frame, and that patients are seen as "evolving, receptive to and needing different interventions at different times" (Bennett, 1983).

CATEGORIES OF SHORT-TERM THERAPY

A number of attempts have been made to subdivide short-term therapy into a number of distinctive categories. In general these fall into three groupings (1) crisis intervention, (2) supportive-educational short-term therapy, and (3) dynamic short-term therapy. The goals of crisis intervention usually differ from those in the other brief methods. Here, after from 1 to 6 sessions, an attempt is made to restore habitual balances in the existing life situation. Supportive educational approaches, such as behavior therapy, constitute forms of intervention that are undertaken, along with educational indoctrination, to relieve or remove symptoms, to alter faulty habit patterns, and to rectify behavioral deficits. To attain these objectives, a variety of eclectic techniques is implemented, depending on the idiosyncratic needs of the patient and the skills and

methodological preferences of the therapist. The number of sessions varies, ranging from 6 to 25. In some cases less than six sessions may be ample, and occasionally even one session has proven productive (Rockwell & Pinkerton, 1982; Bloom, 1981). In dynamic short-term therapy the thrust is toward achieving or at least starting a process of personality reconstruction. Sessions here may extend to 40 or more.

In crisis intervention, sessions may have to be prolonged, psychotropic medications may have to be employed, family members may have to be actively involved, and a multidisciplinary treatment team may have to be available at times. Less urgent forms of crisis intervention that are being practiced are indistinguishable from the kind of counseling commonly done in social agencies. The focus is on mobilizing positive forces in the individual to cope with the crisis situation, to resolve remediable environmental difficulties as rapidly as possible, utilizing if necessary appropriate resources in the community, and to take whatever steps are essential to forestall future crises of a similar or related nature. No attempt is made at diagnosis or psychodynamic formulation. Other kinds of crisis intervention attempt provisionally to detect underlying intrapsychic issues and past formative experiences and to relate these to current problems. More extensive goals than mere emotional stabilization are sought.

The "social-counseling" forms of crisis intervention are generally employed in walk-in clinics and crisis centers where large numbers of clients apply for help and where there is a need to avoid getting involved too intimately with clients who might get locked into a dependent relationship. Visits are as frequent as can be arranged and are necessary during the first 4 to 6 weeks. The family is often involved in some of the interviews, and home visits may have to be made. The interview focus is on the present situational difficulty and often is concerned with the most adaptive ways of coping with immediate pressing problems. Vigorous educational measures are sometimes exploited to activate the patient. The employment of supportive measures and the use of other helping individuals and agencies is encouraged.

More ambitious, goal-directed forms of crisis intervention are often seen operating

in outpatient clinics and private practice. If the assigned number of sessions has been exhausted and the patient still requires more help, referral to a clinic or private therapist or continued treatment with the same therapist is considered.

Brief supportive-educational approaches have sponsored a variety of techniques, such as traditional interviewing, behavior therapy, relaxation, hypnosis, biofeedback, somatic therapy, Gestalt therapy, sex therapy, group therapy, etc., singly or in combination. The number of sessions will vary according to the individual therapist, who usually anchors the decision on how long it takes to control symptoms and enhance adaptation.

The philosophy that enjoins therapists to employ dynamic short-term treatment is the conviction that many of the derivatives of present behaviors are rooted in needs, conflicts, and defenses that reach into the past, often as far back as early childhood. Some of the most offensive of these components are unconscious, and while they obtrude themselves in officious and often destructive ways, they are usually rationalized and shielded with a tenacity that is frustrating both to the victim and to those around. The preferred way, according to prevailing theories, that one can bring these mischief makers under control is to propel them into consciousness so that the patient realizes what he or she is up against. By studying how the patient utilizes the relationship with the therapist, the latter has an opportunity to detect how these buried aberrations operate, projected as they are into the treatment situation. Dreams, fantasies, verbal associations, nonverbal behavior, and transference manifestations are considered appropriate media for exploration because they embody unconscious needs and conflicts in a symbolic form. By training, therapists believe themselves capable of decoding these symbols. Since important unconscious determinants shape one's everyday behavior, the therapist tries to establish a connection between the patient's present personality in operation, such as temperament, moods, morals, and manners, with early past experiences and conditionings in order to help the patient acquire some insight into how problems originated.

METHODOLOGY

A variety of short-term therapeutic methods have been proposed by different therapists (Barten, 1969, 1971; Beliak, 1968; Beliak & Small, 1965; Castelnuovo-Tedesco, 1971; Davanloo, 1978; Gottschalk et al, 1967; Harris, MR, et al, 1971; Levene et al, 1972; Malan, 1964, 1976; Mann, J, 1973; Patterson, V, et al, 1971; Sifneos, 1967; 1972; Wolberg, LR, 1980). There obviously are differences among therapists in the way that short-term therapy is implemented—for example, the focal areas chosen for attention and exploration, the relative emphasis on current as compared to past issues, the attention paid to transference, the way resistance is handled, the depth of probing, the dealing with unconscious material that surfaces, the precise manner of interpretation, the degree of activity, the amount of advice giving, the kinds of interventions and adjunctive devices employed, and the prescribed number of sessions. Moreover, all therapists have to deal with their own personalities, prejudices, theoretical biases, and skills, all of which will influence the way they work. In spite of such differences, there are certain basic principles that have evolved from the experiences of a wide assortment of therapists working with diverse patient populations that have produced good results. The practitioner may find he or she can adapt at least some of these principles to his or her own style of operation even though continuing to employ methods that have proven themselves to be effective and are not exactly in accord with what other professionals do. While many of the suggestions as to technique discussed in previous chapters are applicable, in the pages that follow 20 techniques are suggested as a general guide for short-term therapy.

The important operations consist of (1) establishing a rapid positive working relationship (therapeutic alliance), (2) dealing with initial resistances, (3) gathering historical data, (4) selecting a focus for therapy, (5) defining precipitating events, (6) evolving a working hypothesis, (7) making a tentative diagnosis, (8) conveying the need for the patient's active participation in the therapeutic process, (9) making a verbal contract, (10) utilizing appropriate techniques in an active and flexible manner, (11) studying the reactions and defenses of the patient to the techniques being employed, (12) relating present-day patterns to patterns that have operated throughout the patient's life, 13) watching for transference reactions, (14) examining possible countertransference feelings, (15) alerting oneself to resistances, (16) assigning homework, (17) accenting the

termination date, (18) terminating therapy, (19) assigning continuing self-help activities, and (20) arranging for further treatment if necessary.

These operations explained below, may be utilized in toto or in part by therapists who can adapt them to their styles of working.

Establish as Rapidly as Possible a Positive Working Relationship (Therapeutic Alliance)

An atmosphere of warmth, understanding, and acceptance is basic to achieving a positive working relationship with a patient. Empathy particularly is an indispensable personality quality that helps to solidify a good therapeutic alliance.

Generally, at the initial interview, the patient is greeted courteously by name, the therapist introducing oneself as in this excerpt:

> *Th.* How do you do, Mr. Roberts. I am Dr. Wolberg. Won't you sit down over there *(pointing to a chair),* and we'll talk things over and I'll see what I can do to help you *(patient gets seated).*
>
> *Pt.* Thank you, doctor, *(pause)*

A detached deadpan professional attitude is particularly fatal. It may, by eliciting powerful feelings of rejection, provoke protective defensive maneuvers that neutralize efforts toward establishing a working relationship.

It is difficult, of course, to delineate exact rules about how a therapeutic alliance may be established rapidly. Each therapist will utilize himself or herself to achieve this end in terms of own techniques and capacities in rapport. Some therapists possess an extraordinary ability even during the first session, as the patient describes the problem and associated feelings, of putting the patient at ease, of mobilizing faith in the effectiveness of methods that will be utilized, and of subduing the patient's doubts and concerns. A confident enthusiastic manner and a conviction of one's ability to help somehow communicates itself nonverbally to the patient. Therapist enthusiasm is an important ingredient in treatment.

The following suggestions may prove helpful.

Verbalize What The Patient May Be Feeling

Putting into words for the patient what he or she must be feeling but is unable to conceptualize is one of the most effective means of establishing contact. "Reading between the lines" of what the patient is talking about will yield interesting clues. Such simple statements as, "You must be very unhappy and upset about what has happened to you" or "I can understand how unhappy and upset you must be under the circumstances" present the therapist as an empathic person.

Encourage The Patient That The Situation Is Not Hopeless

It is sometimes apparent that, despite presenting oneself for help, the patient is convinced that he or she is hopeless and that little will actually be accomplished from therapy. The therapist who suspects this may say "You probably feel that your situation is hopeless because you have already tried various things that haven't been effective. But there *are* things that can be done, that *you can do* about your situation and I shall guide you toward making an effort." Empathizing with the patient may be important: "Putting myself in your position, I can see that you must be very unhappy and upset about what is happening to you."

Sometimes it is useful to define the patient's role in developing and sustaining the problem in a non-accusing way: 'You probably felt you had no other alternative than to do what you did." "What you are doing now seems reasonable to you, but there may be other ways that could create fewer problems for you."

While no promise is made of a cure, the therapist must convey an attitude of conviction and faith in what is being done.

> *Pt.* I feel hopeless about getting well. Do you think I can get over this trouble of mine?
>
> *Th.* Do you really have a desire to get over this trouble? If you really do, this is nine-tenths of the battle. You will want to apply yourself to the job of getting well. I will point out some things you can do, and if you work at them yourself, I see no reason why you can't get better.

Where the patient becomes self-deprecatory and masochistic, the positive aspects of reactions may be stressed. For example, should the patient say that he or she is constantly furious, one might reply, "This indicates that you are capable of feeling strongly about things." If the patient claims detachment and does not feel anything, the answer may be, "This is a sign you are trying to protect yourself from hurting." Comments such as these are intended to be protective in order to preserve the relationship with the therapist. Later when it becomes apparent that the relationship is sufficiently solid, the therapist's comments may be more provocative and challenging. The patient's defenses being threatened, anxiety may be mobilized, but the patient will be sustained by the therapeutic alliance and will begin to utilize it rather than run away from it.

Deal With Initial Resistances

Among the resistances commonly encountered at the first session are lack of motivation and disappointment that the therapist does not fulfill a stereotype. The therapist's age, race, nationality, sex, appearance, professional discipline, and religion may, as emphasized in previous chapters, not correspond with the patient's ideas of someone in whom he or she wants to confide.

> *Th.* I notice that it is difficult for you to tell me about your problem.
>
> *Pt.* (*Obviously in discomfort*) I don't know what to say. I expected that I would see an older person. Have you had much experience with cases like me?
>
> *Th.* What concerns you is a fear that I don't have as much experience as you believe is necessary and that an older person would do a better job. I can understand how you feel, and you *may* do better with an older person. However, supposing you tell me about your problem and then if you wish I will refer you to the best older therapist who can treat the kind of condition you have.

This tactic of accepting the resistance and inviting the patient to tell you more about himself or herself, as stated before, can be applied to other stereotypes besides age. In a well-conducted interview the therapist will reveal as an empathic understanding person, and the patient will want to continue with him or her in therapy.

Another common form of resistance occurs in the person with a psychosomatic

problem who has been referred for psychotherapy and who is not at all convinced that a psychological problem exists. In such cases the therapist may proceed as in this excerpt.

> *Pt.* Dr. Jones sent me here. I have a problem with stomachaches a long time and have been seeing doctors for it for a long time.
>
> *Th.* As you know, I am a psychiatrist. What makes you feel your problem is psychological?
>
> *Pt.* I don't think it is, but Dr. Jones says it might be, and he sent me here.
>
> *Th.* Do you think it is?
>
> *Pt.* No, I can't see how this pain comes from my head.
>
> *Th.* Well, it might be organic, but with someone who has suffered as long as you have the pain will cause a good deal of tension and upset. *[To insist on the idea that the problem is psychological would be a poor tactic. First the therapist may be wrong, and the condition may be organic though undetectable by present day tests and examinations. Second, the patient may need to retain the notion of the symptom's organicity and even to be able to experience attenuated pain from time to time as a defense against overwhelming anxiety or, in certain serious conditions, psychosis.]*
>
> *Pt.* It sure does.
>
> *Th.* And the tension and depression prevent the stomach from healing. Tension interferes with healing of even true physical problems. Now when you reduce tension, it helps the healing. It might help you even if your problem is organic.
>
> *Pt.* I hope so.
>
> *Th.* So what we can do is try to figure out what problems you have that are causing tension, and also lift the tension. This should help your pain.
>
> *Pt.* I would like that. I get tense in my job with the people I work. Some of them are crumbs. *[Patient goes on talking, opening up pockets of anxiety.]*

The object is to accept the physical condition as it is and not label it psychological for the time being. Actually, as has been indicated, it may be an essential adaptational symptom, the patient needing it to maintain an equilibrium. Dealing with areas of tension usually will help relieve the symptom, and as psychotherapy takes hold, it may make it unnecessary to use the symptom to preserve psychological homeostasis.

Motivational lack may obstruct therapy in other situations, as when a patient does not come to treatment on his or her own accord but is sent or brought by relatives or

concerned parties. Additional examples are children or adolescents with behavior problems, people who are addicted (drug, alcohol, food, gambling), and people receiving pensions for physical disabilities. More on handling lack of motivation is detailed elsewhere (p 573).

Gather Historical Material and Other Data

Through "sympathetic listening" the patient is allowed to tell the story with as little interruption as possible, the therapist interpolating questions and comments that indicate a compassionate understanding of the patient's situation. It is hoped that the data gathered in the initial interview permits a tentative diagnosis and a notion of the etiology and possibly the psychodynamics. Should the patient fail to bring up important immediate concerns and problems, the therapist can ask direct questions. Why has the patient come to treatment at this time? What has been done about the problem to date? Has the patient arrived at any idea as to what is causing the difficulty? What does the patient expect or what would he or she like to get from therapy?

It is often advantageous to follow an outline (see Ch. 24) in order to do as complete a history or behavioral analysis as possible during the first session or two. This may necessitate interrupting the patient after the therapist is convinced that he or she has sufficient helpful data about any one topic.

Among the questions to be explored are the following:

1. Have there been previous upsets that resemble the present one?

2. Were the precipitating events of previous upsets in any way similar to the recent ones?

3. What measures aggravated the previous upsets and which alleviated the symptoms?

4. Apart from the most important problem for which help is sought, what other symptoms are being experienced (such as tension, anxiety, depression, physical symptoms, sexual problems, phobias, obsessions, insomnia,

excessive drinking?

5. What tranquilizers, energizers, hypnotics, and other medications are being taken?

Statistical data are rapidly recorded (age, education, occupation, marital status, how long married, and children if any). What was (and is) the patient's mother like? The father? Any problems with brothers or sisters? Were there any problems experienced as a child (at home, at school, with health, in relationships with other children)? Any problems in sexual development, career choice, occupational adjustment? Can the patient remember any dreams, especially nightmarish and repetitive dreams? Were there previous psychological or psychiatric treatments?

To obtain further data, the patient may be exposed to the Rorschach cards, getting a few responses to these unstructured materials without scoring. This is optional, of course. The therapist does not have to be a clinical psychologist to do this, but he or she should have read some material on the Rorschach. The patient may also be given a sheet of paper and a pencil and be asked to draw a picture of a man and a woman. Some therapists prefer showing the patient rapidly the Thematic Apperception Cards. What distortions appear in the patient's responses and drawings? Can one correlate these with what is happening symptomatically? These tests are no substitutes for essential psychological tests where needed, which can best be done by an experienced clinical psychologist. But they can fulfill a useful purpose in picking up gross defects in the thinking process, borderline or schizophrenic potentialities, paranoidal tendencies, depressive manifestations, and so on. No more than 10 or 15 minutes should be utilized for this purpose.

An example of how Rorschach cards can help reveal underlying impulses not brought out by regular interviewing methods is illustrated in a severely depressed man with a controlled, obsessional character whose passivity and inability to express aggression resulted in others taking advantage of him at work and in his marriage. When questioned about feelings of hostility or aggression, he denied these with some pride. The following were his responses to the Rorschach Cards.

1. Two things flying at each other.

2. Something sailing into something.

3. Two figures pulling something apart; two adults pulling two infants apart.

4. Animals' fur spread out. X-ray *(drops card)*

5. Flying insect, surgical instrument forceps.

6. Animal or insect split and flattened out.

7. X-ray fluoroscope of embryo, adolescents looking at each other with their hair whipping up in the wind.

8. Two animals climbing a tree, one on each side; female organs in all of these cards.

9. Fountain that goes up and spilling blood.

10. Underwater scene, fish swimming, crabs. Inside of a woman's body.

The conflicts related to aggression and being torn apart so apparent in the responses became a principal therapeutic focus and brought forth his repressed anger at his mother.

Select the Symptoms, Behavioral Difficulties, or Conflicts that You Feel are Most Amenable for Improvement

The selection with the patient of an important problem area or a disturbing symptom on which to work is for the purpose of avoiding excursions into regions that, while perhaps challenging, will dilute a meaningful effort. Thus, when you have decided on what to concentrate, inquire of the patient if in his or her opinion these are what he or she would like to eliminate or change. Agreement is important that this chosen area is significant to the patient and worthy of concentrated attention. A patient who complains that the selection is too limited should be assured that it is best to move one step at a time. Controlling a simple situation or alleviating a symptom will help strengthen the personality, and permit more extensive progress.

Thus the focal difficulty around which therapy is organized may be depression, anxiety, tension, or somatic manifestations of tension. It may be a situational precipitating factor or a crisis that has imposed itself. It may be a disturbing pattern or some learned aberration. It may be a pervasive difficulty in relating or in functioning. Or it may be a conflict of which the patient is aware or only partially aware.

Once agreement is reached on the area of focus, the therapist may succinctly sum up what is to be done.

> *Th.* Now that we have decided to focus on the problem [*designate*] that upsets you, what we will do is try to understand what it is all about, how it started, what it means, why it continues. Then we'll establish a plan to do something about it.

Example 1. A symptomatic focus

> *Th.* I get the impression that what bothers you most is tension and anxiety that makes it hard for you to get along. Is it your feeling that we should work toward eliminating these?
>
> *Pt.* Yes. Yes, if I could get rid of feeling so upset, I would be more happy. I'm so irritable and jumpy about everything.

Example 2. A focus on a precipitating event

> *Th.* What you are complaining most about is a sense of hopelessness and depression. If we focused on these and worked toward eliminating them, would you agree?
>
> *Pt.* I should say so, but I would also like to see how I could improve my marriage. It's been going downhill fast. The last fight I had with my husband was the limit.
>
> *Th.* Well, suppose we take up the problems you are having with your husband and see how these are connected with your symptoms.
>
> *Pt.* I would like that, doctor.

Example 3. A dynamic focus

Whenever possible the therapist should attempt to link the patient's symptoms and complaints to underlying factors, the connections with which the patient may be only dimly aware. Carefully phrased interpretations will be required. It may not be possible to detect basic conflicts, only secondary or derivative conflicts being apparent. Moreover, the

patient may not have given the therapist all the facts due to resistance, guilt, or anxiety. Or facts may be defensively distorted. It is often helpful (with the permission of the patient) to interview, if possible, the spouse or another individual with whom the patient is related after the first or second interview. The supplementary data obtained may completely change the initial hypothetical assumptions gleaned from the material exclusively revealed by the patient.

Nevertheless, some invaluable observations may be made from the historical data and interview material that will lend themselves to interpretation for defining a focus. Thus a patient presenting great inferiority problems and repetitive difficulties in work situations with supervisors, who as a child fought bitterly with an older sibling, was told the following: "It is possible that your present anxiety while related to how you get along with your boss touches off troubles you've carried around with you for a long time. You told me you always felt inferior to your brother. In many cases this sense of inferiority continues to bother a person in relation to new substitutive older brothers. It wouldn't be mysterious if this were happening to you. What do you think?" This comment started off a productive series of reminiscences regarding his experiences with his brother, a focus on which resulted in considerable understanding and betterment of his current relationships.

More fundamental nuclear conflicts may be revealed in later sessions (for example, in the above patient an almost classical oedipal conflict existed), especially when transference and resistance manifest themselves.

Considering the short span of a session it would be most propitious to concern ourselves exclusively with issues related to a dynamic theme. It is obviously impossible to do this when so many urgent reality issues impose themselves during the alloted time. The duty of the therapist is to sift out issues that truly must be discussed (one cannot concentrate on early love objects when the patient's house is burning down) separating them from issues utilized for defensive resistance or indulgence of transference gratifications. Nevertheless, where our goal is personality reconstruction we must utilize every session to best advantage even when pressing reality matters require attention.

What the therapist readies himself or herself to do is to listen to the patient's legitimate immediate concerns and establish a bridge to dynamic issues in order to show how a basic theme weaves itself through every aspect of the patient's existence including the immediate reality situation and the relationship with the therapist.

Undoubtedly the relationship with the therapist offers the best focus from the standpoint of understanding personality distortions and their maladaptive consequences. In long-term approaches treatment may be considered incomplete unless adequate consideration is given to transference and countertransference issues. In short-term therapy the press of time and the need to deal with the immediate stressful concerns of the patient may tend to push this focus onto the back burner. At the end of the assigned limited number of sessions, transference phenomena may have received hardly any attention. This is all the more reason for sensitizing oneself to any relationship happenings that offer an opportunity for exploration. When such happenings do occur, or when the therapist discerns transferential distortions from dreams and acting-out, proper interpretation may make a deep imprint on the patient. Even in sessions limited to five or ten treatment hours, when one hits upon some transferential propitious happenings and explored them later on, the discussion is often considered by the patient a high point in therapy. Obviously, we can expect no miracles from such a brief interchange, but if the patient's resistance is not too great, it can have an important influence.

Define the Precipitating Events

It is essential that we identify clearly the precipitating factors that led to the patient's present upset or why the patient came to treatment at this time.

> *Th.* It seems as if you were managing to get along without trouble until your daughter told you about the affair she is having with this married man. Do you believe this started you off on the downslide?

> *Pt.* Doctor, I can't tell you the shock this was to me. Janie was such an ideal child and never was a bit of a problem. And then this thing happened. She's completely changed, and I can't understand it.

Sometimes the events are obscured or denied because the patient has an investment

in sustaining situational irritants even while seeking to escape from their effects. Involvement in an unsatisfactory relationship with a disturbed or rejecting person from whom the patient cannot extricate is an example. It may be necessary to encourage continuing conversation about a suspected precipitant, asking pointed questions in the effort to help the patient see the relationship between symptoms and what may have considered unrelated noxious events. Should the patient fail to make the connections, the therapist may spell these out, asking pertinent questions that may help the patient grasp the association.

Evolve a Working Hypothesis

After the first session the therapist should have gathered enough data from the present and past history, from any dreams that are revealed, and from the general attitude and behavior of the patient to put together some formulation about what is going on. This is presented to the patient in simple language, employing concepts with which the patient has some familiarity. This formulation should never be couched in dismal terms to avoid alarming the patient. Rather a concise, restrained, optimistic picture may be painted making this contingent on the patient's cooperation with the therapeutic plan. Aspects of the hypothesis should ideally bracket the immediate precipitating agencies with what has gone on before in the life history and, if possible, how the patient's personality structure has influenced the way the patient has reacted to the precipitating events.

A woman experiencing a severe anxiety attack revealed the precipitating incident of discovering her husband's marital infidelity. As she discussed this, she disclosed the painful episode of her father's abandoning her mother for another woman.

> *Th.* Is it possible that you are afraid your husband will do to you what your father did to your mother?
>
> *Pt. (breaking down in tears)* Oh, it's so terrible I sometimes think I can't stand it.
>
> *Th.* Stand his leaving you or the fact that he had an affair?
>
> *Pt.* If it could end right now, I mean if he would stop, it *(pause).*

Th. You would forget what had happened?

Pt. (pause) Yes—Yes.

Th. How you handle yourself will determine what happens. You can see that your present upset is probably linked with what happened in your home when you were a child. Would you tell me about your love life with your husband?

The focus on therapy was thereafter concerned with the quality of her relationship with her husband. There were evidences that the patient herself promoted what inwardly she believed was an inevitable abandonment.

The therapist in making a tentative thrust at what is behind a problem should present formulations in simple terms that the patient can understand. The explanation should not be so dogmatic, however, as to preclude a revision of the hypothesis at a later date, should further elicited material demand this. The patient may be asked how he or she feels about what the therapist has said. If the patient is hazy about the content, the confusion is explored and clarification continued.

For example, a patient with migraine is presented with the hypothesis that anger is what is creating the symptom. The patient then makes a connection with past resentments and the denial defenses that were erected, which apparently are still operative in the present.

Th. Your headaches are a great problem obviously since they block you in your work. Our aim is to help reduce or eliminate them. From what you tell me, they started way back probably in your childhood. They are apparently connected with certain emotions. For example, upset feelings and tensions are often a basis for headaches, but there may be other things too, like resentments. What we will do is explore what goes on in your emotions to see what connections we can come up with. Often resentments one has in the present are the result of situations similar to troubles a person had in childhood.

Pt. I had great pains and trouble fighting for my rights when I was small—a bossy mother and father who didn't care. I guess I finally gave up.

Th. Did you give up trying to adjust at home or work?

Pt. Not exactly. But fighting never gets anywheres. People just don't listen.

Make a Tentative Diagnosis

Despite the fact that our current nosological systems leave much to be desired, it may be necessary to fit the patient into some diagnostic scheme if for no other reason than to satisfy institutional regulations and insurance requirements. There is a temptation, of course, to coordinate diagnosis with accepted labels for which reimbursement will be made. This is unfortunate since it tends to limit flexibility and to invalidate utilizing case records for purposes of statistical research. Even though clinical diagnosis bears little relationship to preferred therapeutic techniques in some syndromes, in other syndromes it may be helpful toward instituting a rational program.

Convey the Need for the Patient's Active Participation in the Therapeutic Process

Many patients, accustomed to dealing with medical doctors, expect the therapist to prescribe a formula or give advice that will operate automatically to palliate the problem. An explanation of what will be expected of the patient is in order.

> *Th.* There is no magic about getting well. The way we can best accomplish our goals is to work together as a partnership team. I want you to tell me all the important things that are going on with you and I will try to help you understand them. What we want to do is to develop new, healthier patterns. *My* job is to see what is blocking you from achieving this objective by pointing out some things that have and are still blocking you. *Your* job is to *act* to put into practice new patterns we decide are necessary, you telling me about your experiences and feelings. Psychotherapy is like learning a new language. The learner is the one who must practice the language. If the teacher did all the talking, the student would never be able to carry on a conversation. So remember you are going to have to carry the ball, with my help of course.

Make a Verbal Contract With The Patient

There should be an agreement regarding the frequency of appointments, the number of sessions, and the termination date.

> *Example 1. Where Limitation of the Number of Sessions is Deemed Necessary in Advance*

> *Th.* We are going to have a total of 12 sessions. In that time we should have made an impact on your anxiety and depression. Now, let's consult the calendar. We will terminate therapy on October 9, and I'll mark it down here. Can you also make a note of it?

> *Pt.* Will 12 sessions be enough?

Th. Yes. The least it could do is to get you on the road to really working out the problem.

Pt. What happens if I'm not better?

Th. You are an intelligent person and there is no reason why you shouldn't be better in that time.

Should the therapist dally and compromise confidence in the patient's capacity to get well, the patient may in advance cancel the termination in his or her own mind to an indeterminate future one.

Example 2. When the Termination Date is Left Open

Th. It is hard to estimate how many sessions we will require. I like to keep them below 20. So let us begin on the basis of twice a week.

Pt. Anything you say, doctor. If more are necessary, OK.

Th. It is really best to keep the number of sessions as low as possible to avoid getting dependent on them. So we'll play it by ear.

Pt. That's fine.

The appointment times may then be set and the fee discussed.

Utilize Whatever Techniques are Best Suited to Help the Patient with Immediate Problems

After the initial interview, techniques that are acceptable to the patient, and that are within the training range and competence of the therapist, are implemented, bearing in mind the need for activity and flexibility. The techniques may include supportive, educational, and psychoanalytically oriented interventions and a host of adjunctive devices, such as psychotropic drugs, hypnosis, biofeedback, behavioral and group approaches, and so on, in whatever combinations are necessary to satisfy the patient's immediate and future needs. An explanation may be given the patient about what will be done.

Th. At the start, I believe it would be helpful to reduce your tension. This should be beneficial to you in many ways. One of the best ways of doing this is by teaching you some relaxing exercises. What I would like to do for you is to make a relaxing audio recording. Do you have an audio recorder?

Pt. No, I haven't.

Th. You can buy one quite inexpensively. How do you feel about this?

Pt. It sounds great.

Th. OK. Of course, there are other things we will do, but this should help us get off to a good start.

Many therapists practicing dynamic short-term therapy ask their patients to reveal any dreams that occur during therapy. Some patients insist that they rarely or never dream or if they do, that they do not remember their dreams.

Th. It is important to mention any dreams that come to you.

Pt. I can't get hold of them. They slip away.

Th. One thing you can do is, when you retire, tell yourself you will remember your dreams.

Pt. What if I can't remember?

Th. Keep a pad of paper and a pencil near the head of your bed. When you awaken ask yourself if you dreamt. Then write the dream down. Also, if you wake up during the night.

In some patients brief group therapy may be decided on. This is an active, goal oriented a historical, current-life approach, with emphasis on decision making and patient responsibility with modeling, feedback, and stress on behavioral practice (Imber et al. 1979; Marcovitz & Smith, 1983).

Study the Patient's Reaction and Defense Patterns

The utilization of any technique or stratagem will set into motion reactions and defenses that are grist for the therapeutic mill. The patient will display a range of patterns that the therapist can study. This will permit a dramatic demonstration of the patient's defenses and resistances in actual operation rather than as theories. The patient's dreams and fantasies will often reveal more than actions or verbalizations, and the patient should continually be encouraged to talk about these. The skill of the therapist in working with and interpreting the patient's singular patterns will determine whether these will be integrated or will generate further resistance. Generally, a compassionate, tentative type

of interpretation is best, sprinkling it if possible with a casual light humorous attitude. A patient who wanted hypnosis to control smoking appeared restless during induction:

> *Th.* I noticed that when I asked you to lean back in the chair and try relaxing to my suggestions, you were quite uneasy and kept on opening your eyes. What were you thinking about?

> *Pt.* (*emotionally*) My heart started beating. I was afraid I couldn't do it. What you'd think of me. That I'd fail. I guess I'm afraid of doctors. My husband is trying to get me to see a gynecologist.

> *Th.* But you kept opening your eyes.

> *Pt. (pause)* You know, doctor, I'm afraid of losing control, of what might come out. I guess I don't trust anybody.

> *Th.* Afraid of what would happen here, of what I might do if you shut your eyes? (*smiling*)

> *Pt.* (*laughing*) I guess so. Silly. But the thought came to me about something sexual.

While the Focus at ail Times is on the Present, be Sensitive to How Present Patterns Have Roots in the Past

Examination in dynamic short-term therapy of how the patient was reared and the relationship with parents and siblings is particularly revealing. An attempt is made to note established patterns that have operated throughout the patient's life of which the current stress situation is an immediate manifestation. This data is for the therapist's own consumption and should not be too exhaustive, since the patient if encouraged to explore the past may go on endlessly, and there is no time for this. At a propitious moment, when the patient appears to have some awareness of connections of the past with the present, a proper interpretation may be made. At that time a relationship may be cited among genetic determinants, the existing personality patterns, and the symptoms and complaints for which therapy was originally sought.

Watch for Transference Reactions

The immediate reaching for help encourages projection onto the therapist of positive feelings and attitudes related to an idealized authority figure. These should not be interpreted or in any way discouraged since they act in the interest of alleviating tension

and supporting the placebo element. On the other hand, a *negative* transference reaction should be dealt with rapidly and sympathetically since it will interfere with the therapeutic alliance.

> *Th. [noting the patient's hesitant speech]* You seem to be upset about something.
>
> *Pt.* Why, *should* I be upset?
>
> *Th.* You might be if I did something you didn't like.
>
> *Pt. (pause)* No—I'm afraid, just afraid I'm not doing what I should. I've been here six times and I still have that panicky feeling from time to time. Do other patients do better?
>
> *Th.* You seem to be comparing yourself to my other patients.
>
> *Pt.* I—I—I guess so. The young man that came before me. He seems so self-confident and cheerful. I guess I felt inferior, that you would find fault with me.
>
> *Th.* Do you think I like him better than I do you?
>
> *Pt.* Well, wouldn't you, if he was doing better than I was?
>
> *Th.* That's interesting. Tell me more.
>
> *Pt.* I've been that way. My parents, I felt, preferred my older brother. He always came in on top. They were proud of his accomplishments in school.
>
> *Th.* So in a way you feel I should be acting like your parents.
>
> *Pt.* I can't help feeling that way.
>
> *Th.* Don't you think this is a pattern that is really self-defeating? We ought to explore this more.
>
> *Pt. (emotionally)* Well, I really thought today you were going to send me to another doctor because you were sick of me.
>
> *Th.* Actually, the thought never occurred to me to do that. But I'm glad you brought this matter out because we will be able to explore some of your innermost fears about how people feel about you.

Examine Possible Countertransference Feelings

If you notice persistent irritability, boredom, anger, extraordinary interest in or attraction to any patient, ask yourself whether such feelings and attitudes do not call for

self-examination. Their continuance will almost certainly lead to interference with a good working relationship. For example, a therapist is treating an unstable middle-aged female patient whom he regards as a plumpish, sloppy biddy who sticks her nose into other people's affairs. He tries to maintain an impartial therapeutic stance, but periodically he finds himself scolding her and feeling annoyed and enraged. He is always relieved as the session hour comes to an end. He recognizes that his reactions are countertherapeutic, and he asks himself if they are really justified. The image of his own mother then comes to his mind, and he realizes that he had many of the same feelings of exasperation, displeasure, and disgust with his own parent. Recognizing that he may be transferring in part some of these attitudes to his patient whose physical appearance and manner remind him of his mother, he is better able to maintain objectivity. Should self analysis, however, fail to halt his animosity, he may decide to send the patient to another therapist.

Countertransference may also be a sensitive instrument in dynamic psychotherapy toward understanding of projections from the patient of aspects of inner conflict of which the patient may be incompletely aware.

Constantly Look for Resistances That Threaten to Block Progress

Obstructions to successful therapeutic sessions are nurtured by misconceptions about therapy, lack of motivation, needs to maintain certain benefits that accrue from one's illness, and a host of other sources, conscious and unconscious. Where resistances are too stubborn to budge readily or where they operate with little awareness that they exist, the few sessions assigned to short-term therapy may not suffice to resolve them. One way of dealing with resistances once they are recognized is to bring them out openly in a non-condemning manner. This can be done by stating that the patient may hold on to them as defenses, but if this is so, he or she must suffer the consequences. A frank discussion of why the resistances have value for the patient and their effects on treatment is in order. Another technique is to anticipate resistances from the patient's past modes of adaptation, dreams, and the like, presenting the patient with the possibility of their appearance and what could be done about them should they appear. The therapist should

watch for minimum appearances of resistance, however minor they may be, that will serve as psychological obstructions. Merely bringing these to the attention of the patient may help dissipate them.

Pt. I didn't want to come here. Last time I had a terribly severe headache. I felt dizzy in the head, *(pause)*

Th. I wonder why. Did anything happen here that upset you; did I do anything to upset you?

Pt. No, it's funny but it's something I can't understand. I want to come here, and I don't. It's like I'm afraid.

Th. Afraid?

Pt. (Pause; patient flushes.) I can't understand it. People are always trying to change me. As far back as I can remember, at home, at school.

Th. And you resent their trying to change you.

Pt. Yes. I feel they can't leave me alone.

Th. Perhaps you feel I'm trying to change you.

Pt. (angrily) Aren't you?

Th. Only if *you* want to change. In what way do you want to change, if at all?

Pt. I want to get rid of my headaches, and stomachaches, and all the rest of my aches.

Th. But you don't want to change to do this.

Pt. Well, doctor, this isn't true. I want to change the way *I* want to.

Th. Are you sure the way *you* want to change will help you get rid of your symptoms?

Pt. But that's why I'm coming here so you will tell me.

Th. But you resent my making suggestions to you because somehow you put me in the class of everybody else who you believe wants to take your independence away. And then you show resistance to what I am trying to do.

Pt. (laughs) Isn't that silly, I really do trust you.

Th. Then supposing when you begin to feel you are being dominated you tell me, so we can talk it out. I really want to help you and not dominate you.

Pt. Thank you, doctor, I do feel better.

In brief therapy with patients who possess a reasonably strong ego, confrontation and management of the patient's untoward reactions to challenges may be dramatically effective. Managing the patient's reactions will call for a high degree of stamina, sensitivity, and flexibility on the part of the therapist, an ability to cope with outbursts of anger and other disturbing reactions, and knowledge of how to give reassurance without retracting one's interpretations. However, because judgments about what is happening are made on fragmentary data, it is apt to create justifiable anger and resistance where a therapist is wrong about an appraisal of the problem. This is less the case in long-term therapy where the therapist has a firmer relationship with the patient and is more certain about the dynamics.

Give the Patient Homework

Involve the patient with an assignment to work on how the symptoms are related to happenings in the patient's environment, to attitudes, to fallacies in thinking, to disturbed interpersonal relationships, or to conflicts within oneself. Even a bit of insight may be a saving grace. As soon as feasible, moreover, ask the patient to review his or her idea of the evolution of the problem and what the patient can do to control or regulate the circumstances that reinforce the problem or alleviate the symptoms. Practice schedules may be agreed on toward opposing the situations or tendencies that require control. The patient may be enjoined to keep a log regarding incidents that exaggerate the difficulties and what the patient has done to avoid or resolve such incidents. The patient may also be given some cues regarding how one may work on oneself to reverse some basic destructive personality patterns through such measures as acquiring more understanding and insight, rewarding oneself for positive actions, self-hypnosis, and so on. These tactics may be pursued both during therapy and following therapy by oneself.

For example, the following suggestion was made to a patient who came to therapy for help to abate migraine attacks:

> *Th.* What may help you is understanding what triggers off your headaches and makes them worse. Supposing you keep a diary and jot down the frequency of your headaches. Every time you get a headache write down the day and time. Even more important, write down the events

that immediately preceded the onset of the headache or the feelings or thoughts you had that brought it on. If a headache is stopped by anything that has happened, or by anything you think about or figure out, write that down, and bring your diary when you come here so we can talk about what has happened.

Suggestions on homework assignments may be found in Chapter 53.

Keep Accenting the Termination Date if One was Given the Patient

In preparing the patient for termination of therapy, the calendar may be referred to prior to the last three sessions and the patient reminded of the date. In some patients this will activate separation anxiety and negative transference. Such responses will necessitate active interpretation of the patient's past dependency and fears of autonomy. Evidences of past reactions to separation may help the patient acquire an understanding of the underpinnings of present reactions. The therapist should expect a recrudescence of the patient's symptoms as a defense against being on one's own and as an appeal for continuing treatment. These manifestations are dealt with by further interpretation. *Do not promise* to continue therapy even if the patient predicts failure.

> *Pt.* I know we're supposed to have only one more session. But I get scared not having you around.

> *Th.* One of our aims is to make you stronger so you won't need a crutch. You know enough about yourself now to take some steps on your own. This is part of getting well. So I want you to give yourself a chance.

Many patients will resent termination of therapy after the designated number of sessions have ended. At the middle point of therapy, therefore, the therapist may bring up this possibility. The therapist should search for incidents in the past where separations have created untoward reactions in the patient. Individuals who were separated from their parents at an early age, who had school phobias produced by inability to break ties with the mother, and who are excessively dependent are particularly vulnerable and apt to respond to termination with anxiety, fear, anger, and depression. The termination process here may constitute a prime focus in therapy and a means of enhancing individuation.

> *Th.* We have five more sessions, as you know, and then we will terminate.

Pt. I realize it, but I always have trouble breaking away. My wife calls me a holder-oner.

Th. Yes, that's exactly what we want to avoid, the dependency. You are likely to resent ending treatment for that reason. What do you think?

Pt. (*laughing*) I'll try not to.

Th. Well, keep thinking about it and if you have any bad reactions let's talk about it. It's important not to make treatment a way of life. By the end of the five sessions, you should be able to carry on.

Pt. But supposing I don't make it?

Th. There you go, see, anticipating failure. This is a gesture to hold on.

Pt. Well, doctor, I know you are right. I'll keep working on it.

Terminate Therapy on the Agreed-upon Date

While some therapists do not consider it wise to invite the patient who has progressed satisfactorily to return, others find it a helpful and reassuring aid for most patients to do so at the final session. I generally tell the patient to write to me sometime to let me know things are coming along. In the event problems develop that one cannot manage by oneself, the patient should call for an appointment. Rarely is this invitation abused and if the patient does return the difficulty can be rapidly handled, eventuating in reinforcement of one's understanding.

Th. This is, as you know, our last session. I want you now to try things out on your own. Keep practicing the things I taught you—the relaxation exercises *[where these have been used],* the figuring out what brings on your symptoms and takes them away, and so forth. You should continue to get better. But setbacks may occur from time to time. Don't let that upset you. That's normal and you'll get over the setback. In fact, it may help you figure out better what your symptoms are all about. Now, if in the future you find you need a little more help, don't hesitate to call me and I'll try to arrange an appointment.

Actually relatively few patients will take advantage of this invitation, but they will feel reassured to go out on their own knowing they will not be abandoned. Should they return for an appointment, only a few sessions will be needed to bring the patient to an equilibrium and to help learn about what produced the relapse.

Stress the Need for Continuing Work on Oneself

The matter of continuing work on oneself after termination is very much underutilized. Patients will generally return to an environment that continues to sponsor maladaptive reactions. The patient will need some constant reminder that old neurotic patterns latently await revival and that one must alert oneself to signals of their awakening. In my practice I have found that making a relaxing tape (a technique detailed on p. 1019) sprinkled with positive suggestions of an ego-building nature serves the interest of continued growth. In the event the patient has done well with homework during the active therapy period, the same processes may continue. Institution of a proper philosophical outlook may also be in order prior to discharge. Such attitudes may be encouraged as the need to isolate the past from the present, the realization that a certain amount of tension and anxiety are normal, the need to adjust to handicaps and realistic irremediable conditions, the urgency to work at correcting remediable elements in one's environment, the recognition of the forces that trigger one's problems and the importance of rectifying these, and the wisdom of stopping regretting the past and of avoiding anticipating disaster in the future. It must be recognized that while the immediate accomplishments of short-term therapy may be modest, the continued application of the methods the patient has learned during therapy will help bring about more substantial changes.

Arrange for Further Treatment if Necessary

The question may be asked regarding what to do with the patient who at termination shows little or no improvement. Certain patients will require long-term therapy. In this reference there are some patients who will need help for a prolonged period of time; some require only an occasional contact the remainder of their lives. The contact does not have to be intensive or frequent. Persons with an extreme dependency character disorder, borderline cases, and schizophrenics often do well with short visits (15 to 20 minutes) every 2 weeks or longer. The idea that a supportive person is available may be all that the patient demands to keep him or her in homeostasis. Introducing the patient into a group may also be helpful, multiple transferences diluting the hostile transference that so often occurs in individual therapy. A social group may even suffice to

provide the patient with some means of a human relationship. Some patients will need referral to another therapist who specializes in a different technique, for example, to someone who does biofeedback, behavioral therapy, hypnosis, psychopharmacology, or another modality.

> *Th.* Now, we have completed the number of sessions we agreed on. How do you feel about matters now?

> *Pt.* Better, doctor, but not well. I still have my insomnia and feel discouraged and depressed.

> *Th.* That should get better as time goes on. I should like to have you continue with me in a group.

> *Pt.* You mean with other people? I've heard of it. It scares me, but I'd like to do it.

Where the patient is to be referred to another therapist, he or she may be told:

> *Th.* You have gotten a certain amount of help in coming here, but the kind of problems you have will be helped more by a specialist who deals with such problems. I have someone in mind for you who I believe will be able to help you. If you agree, I shall telephone him to make sure he has time for you.

> *Pt.* I'd like that. Who is the doctor?

> *Th.* Dr.____ If he hasn't time, I'll get someone else.

CRISIS INTERVENTION

Every individual alive is a potential candidate for a breakdown in the adaptive equilibrium if the stressful pressures are sufficiently severe. A crisis may precipitate around any incident that overwhelms one's coping capacities. The crisis stimulus itself bears little relationship to the intensity of the victim's reaction. Some persons can tolerate with equanimity tremendous hardships and adversity. Others will show a catastrophic response to what seems like a minor mishap. A specifically important event, like abandonment by a love object, can touch off an explosive reaction in one who would respond much less drastically to bombings, hurricanes, cataclysmic floods, shipwreck, disastrous reverses of economic fortune, and major accidents. The two important variables are, first, the *meaning* to the individual of the calamity and, second, the *flexibility of one's defenses,* that is, the prevailing ego strength.

The immediate response to a situation that is interpreted as cataclysmic, such as the sudden death of a loved one, a violent accident, or an irretrievable shattering of security, is a dazed shock reaction. As if to safeguard oneself, a peculiar denial mechanism intervenes accompanied by numbness and detachment. This defensive maneuver, however, does not prevent the intrusion of upsetting fantasies or frightening nightmares from breaking through-periodically. When this happens, denial and detachment may again intervene to reestablish a tenuous equilibrium, only to be followed by a repetition of fearsome ruminations. It is as if the individual is both denying and then trying somehow to acquire understanding and to resolve anxiety and guilt. Various reactions to and defenses against anxiety may precipitate self-accusations, aggression, phobias, and excessive indulgence in alcohol or tranquilizers. Moreover, dormant past conflicts may be aroused, marshalling neurotic symptomatic and distorted characterologic displays. At the core of this confounding cycle of denial and twisted repetitive remembering is, first, the mind's attempt to protect itself by repressing what had happened and, second, to heal itself by reprocessing and working through the traumatic experience in order to reconcile it with the present reality situation. In an individual with good ego strength this struggle usually terminates in a successful resolution of the crisis event. Thus, following a crisis situation, most people are capable after a period of 4 to 6 weeks of picking up the pieces, putting themselves together, and resuming their lives along lines similar to before. People who come to a clinic or to a private practitioner are those who have failed to achieve resolution of stressful life events.

In some of these less fortunate individuals the outcome is dubious, eventuating in prolonged and even permanent crippling of functioning. To shorten the struggle and to bolster success in those who otherwise would be destined to a failing adaptation, psychotherapy offers the individual an excellent opportunity to deal constructively with the crisis.

In the psychotherapeutic treatment of crisis situations (crisis therapy) the goal is rapid emotional relief—and not basic personality modification. This does not mean that we neglect opportunities to effectuate personality change. Since such alterations will

require time to provide for resolution of inner conflicts and the reshuffling of the intrapsychic structure, the most we can hope for is to bring the patient to some *awareness* of how underlying problems are related to the immediate crisis. It is gratifying how some patients will grasp the significance of this association and in the posttherapy period work toward a betterment of fundamental characterologic distortions. Obviously, where more than the usual six-session limit of crisis-oriented therapy can be offered, the greater will be the possibility of demonstrating the operative dynamics. Yet where the patient possesses a motivation for change—and the existing crisis often stimulates such a motivation—even six sessions may register a significant impact on the psychological status quo.

Crisis Therapy

Selection of techniques in crisis therapy are geared to four variables (Wolberg, 1972). The first variable we must consider relates to *catastrophic symptoms that require immediate handling.* The most common emergencies are severe depressions with strong suicidal tendencies, acute psychotic upsets with aggressive or bizarre behavior, intense anxiety and panic states, excited hysterical reactions, and drug and alcoholic intoxications. Occasionally, symptoms are sufficiently severe to constitute a portentous threat to the individual or others, under which circumstances it is essential to consider immediate hospitalization. Conferences with responsible relatives or friends will then be essential in order to make provision for the most adequate resource. Fortunately, this contingency is not now employed as frequently as before because of modern somatic therapy. Consultations with a psychiatrist skilled in the administration of somatic treatments will, of course, be in order. Electroconvulsive therapy may be necessary to interrupt suicidal depression or excitement. Acute psychotic attacks usually yield to a regimen of the neuroleptics in the medium of a supportive and sympathetic relationship. It may require almost superhuman forbearance to listen attentively to the patient's concerns, with minimal expressions of censure or incredulity for delusional or hallucinatory content. Panic reactions in the patient require not only fortitude on the part of the therapist, but also the ability to communicate compassion blended with hope. In an emergency room in

a hospital it may be difficult to provide the quiet objective atmosphere that is needed, but an attentive sympathetic doctor or nurse can do much to reassure the patient. Later, frequent visits, even daily, do much to reassure a frightened patient who feels himself or herself to be out of control.

Less catastrophic symptoms are handled in accordance with the prevailing emotional state. Thus during the first stages of denial and detachment, techniques of confrontation and active interpretation of resistances may help to get the patient talking. Where there is extreme repression, hypnotic probing and narcoanalysis may be useful. On the other hand, where the patient is flooded by anxiety, tension, guilt, and ruminations concerning the stressful events, attempts are made to reestablish controls through relaxation methods (like meditation, autogenic training, relaxing hypnotherapy, and biofeedback), or by pharmacological tranquilization (diazepam, Xanax), or by rest, diversions (like social activities, hobbies, and occupational therapy), or by behavioral desensitization and reassurance.

Once troublesome symptoms are brought under reasonable restraint, attention can be focused on the second important variable in the crisis reaction, *the nature of the precipitating agency.* This is usually in the form of some environmental episode that threatens the individual's security or damages the self-esteem. A developmental crisis, broken love affair, rejection by or death of a love object, violent marital discord, persisting delinquent behavior and drug consumption by important family members, transportation or industrial and other accidents, development of an incapacitating or life-threatening illness, calamitous financial reverses, and many other provocative events may be the triggers that set off a crisis. It is rare that the external precipitants that the patient holds responsible for the present troubles are entirely or even most importantly the cause.

Indeed, the therapist will usually find that the patient participates actively in initiating and sustaining many of the environmental misfortunes that presumably are to blame. Yet respectful listening and questioning will give the therapist data regarding the character structure of the patient, the need for upsetting involvements, projective

tendencies, and the legitimate hardships to which the patient is inescapably exposed. An assay of the existing and potential inner strengths in relation to the unavoidable stresses that must be endured and identification of remediable problem areas will enable the therapist better to focus the therapeutic efforts. Crucial is some kind of cognitive reprocessing that is most effectively accomplished by interpretation. The object is to help the patient find a different meaning for the upsetting events and to evolve more adequate ways of coping.

The third variable, *the impact on the patient of the family system,* is especially important in children and adolescents as well as in those living in a closely knit family system. The impact of the family may not be immediately apparent, but a crisis frequently indicates a collapsing family system, the end result of which is a breakdown in the identified patient's capacities for adaptation. Crisis theory assumes that the family is the basic unit and that an emotional illness in any family member connotes a disruption in the family homeostasis. Such a disruption is not altogether bad because through it opportunities are opened up for change with potential benefit to each member. Traditional psychotherapy attempts to treat the individual patient and often relieves the family of responsibility for what is going on with the patient. Crisis theory, on the other hand, insists that change must involve more than the patient. The most frequently used modality, consequently, is family therapy, the object of which is the harnessing and expansion of the constructive elements in the family situation. The therapist does not attempt to halt the crisis by reassurance but rather to utilize the crisis as an instrument of change. During a crisis a family in distress may be willing to let a therapist enter into the picture, recognizing that it cannot by itself cope with the existing emergency. The boundaries are at the start fluid enough so that new consolidations become possible. The family system prior to the crisis and after the crisis usually seals off all points of entry. During the crisis, before new and perhaps even more destructive decisions have been made, a point is reached where we may introduce some new perspectives. This point may exist for only a short period of time; therefore it is vital that there be no delay in rendering service.

Thus a crisis will permit intervention that would not be acceptable before nor subsequent to the crisis explosion. One deterrent frequently is the family's insistence on hospitalization, no longer being able to cope with the identified patient's upsetting behavior. Alternatives to hospitalization will present themselves to an astute therapist who establishes contact with the family. Some of the operative dynamics may become startlingly apparent by listening to the interchanges of the patient and the family.

The most important responsibility of the therapist is to get the family to understand what is going on with the patient in the existing setting and to determine why the crisis has occurred now. There is a understandable history to the crisis and a variety of solutions may have been tried. The therapist may be curious as to why these measures were attempted and why they failed, or at least why they have not succeeded sufficiently. The family should be involved in solutions to be utilized and should have an idea as to the reasons for this. Assignment of tasks for each member is an excellent method of getting people to work together and such assignments may be quite arbitrary ones. The important thing is to get every member involved in some way. This will bring out certain resistances which may have to be negotiated. Trades may be made with the object of securing better cooperation. Since crisis intervention is a short-term process, it should be made clear that visits are limited. This is to avoid dependencies and resentments about termination.

The fourth variable is often the crucial factor in having initiated the crisis situation and consists of *unresolved and demanding childhood needs, defenses and conflicts* that obtrude themselves on adult adjustment, and compulsively dragoon the patient into activities that are bound to end in disaster. These would seem to invite explorations that a therapist, trained in dynamic psychotherapeutic methodology, may be able to implement. The ability to relate the patient's outmoded and neurotic modes of behaving, and the circumstances of their development in early conditionings, as well as the recognition of how personality difficulties have brought about the crisis, would be highly desirable probably constituting the difference between merely palliating the present problem and providing some permanent solution for it. Since the goals of crisis intervention are limited, however, to reestablishing the precrisis equilibrium, and the time allotted to therapy is

circumscribed to the mere achievement of this goal, one may not be able to do much more than to merely point out the areas for further work and exploration. Because crisis therapy is goal limited, there is a tendency to veer away from insight therapies organized around psychodynamic models toward more active behavioral-learning techniques, which are directed at reinforcing appropriate and discouraging maladaptive behavior. The effort has been directed toward the treatment of couples, of entire families, and of groups of non-related people as primary therapeutic instruments. The basic therapeutic thrust is, as has been mentioned, on such practical areas as the immediate disturbing environmental situation and the patient's disruptive symptoms, employing a combination of active procedures like drug therapy and milieu therapy. The few sessions devoted to treatment in crisis intervention certainly prevent any extensive concern with the operations of unconscious conflict. Yet a great deal of data may be obtained by talking to the patient and by studying the interactions of the family, both in family therapy and through the observations of a psychiatric nurse, caseworker, or psychiatric team who visit the home. Such data will be helpful in crisis therapy planning or in a continuing therapeutic program.

In organizing a continuing program the therapist must recognize, without minimizing the value of depth approaches, that not all persons, assuming that they can afford long-term therapy, are sufficiently well motivated, introspective, and possessed by qualities of sufficient ego strength to permit the use of other than expedient, workable, and goal-limited methods aimed at crisis resolution and symptom relief.

Techniques in Crisis Intervention

The following is a summation of practical points to pursue in the practice of crisis intervention.

> 1. *See the patient within 24 hours of the calling for help* even if it means canceling an appointment. A crisis in the life of an individual is apt to motivate one to seek help from some outside agency that otherwise would be avoided. Should such aid be immediately unavailable, one may in desperation exploit spurious measures and defenses that abate the crisis but compromise an optimal adjustment. More insidiously, the incentive for therapy will vanish with resolution of the emergency. The therapist should, therefore, make every effort to see a person in crisis preferably on the very day that help is requested.

2. At the initial interview *alert yourself to patients at high risk for suicide.* These are (a) persons who have a previous history of attempting suicide, (b) endogenous depression (history of cyclic attacks, early morning awakening, loss of appetite, retardation, loss of energy or sex drive), (c) young drug abusers, (d) alcoholic female patients, (e) middle-aged men recently widowed, divorced, or separated, (f) elderly isolated persons.

3. *Handle immediately any depression in the above patients.* Avoid hospitalization if possible except in deep depressions where attempts at suicide have been made recently or the past or are seriously threatened now. Electroconvulsive therapy is best for dangerous depressions. Institute antidepressant medications (Tofranil, Elavil, Sinequan) in adequate dosage where there is no immediate risk.

4. *Evaluate the stress situation.* Does it seem sufficiently adequate to account for the present crisis? What is the family situation, and how is it related to the patient's upset? What were past modes of dealing with crises, and how successful were they?

5. *Evaluate the existing support systems available to the patient* that you can utilize in the therapeutic plan. How solid and reliable are certain members of the family? What community resources are available? What are the strengths of the family with whom the patient will live?

6. *Estimate the patient's ego resources.* What ego resources does the patient have to depend on, estimated by successes and achievements in the past? Positive coping capacities are of greater importance than the prevailing pathology.

7. *Help the patient to an awareness of the factors involved in the reaction to the crisis.* The patient's interpersonal relations should be reviewed in the hope of understanding and reevaluating attitudes and patterns that get the patient into difficulty.

8. *Provide thoughtful, empathic listening and supportive reassurance.* These are essential to enhance the working relationship and to restore hope. The therapist must communicate awareness of the patient's difficulties. The patient should be helped to realize what problems are stress related and that with guidance one can learn to cope with or resolve.

9. *Utilize tranquilizers only where anxiety is so great that the patient cannot make decisions.* When the patient is so concerned with fighting off anxiety that there is no cooperation with the treatment plan, prescribe an anxiolytic (diazepam, Xanax). This is a temporary expedient only. In the event a schizophrenic patient must continue to live with hostile or disturbed parents who fail to respond to or refuse exposure to family therapy, prescribe a neuroleptic medication and establish a way to see that medications are taken regularly.

10. *Deal with the immediate present and avoid probing of the past.* Our chief concern is the here and now. What is the patient's present life situation? Is trouble impending? The focus is on any immediate disruptive situation responsible for the crisis as well as on the corrective measures to be exploited. Historical material is considered only if it is directly linked to the current problem.

11. *Avoid exploring for dynamic factors.* Time in therapy is too short for this. Therapy must be reality oriented, geared toward problem solving. The goal is restoration of the precrisis stability. But if dynamic factors like transference produce resistance to therapy or to the

therapist, deal rapidly with the resistances in order to dissipate them. Where dynamic material is "thrown" at the therapist, utilize it in treatment planning.

12. *Aim for increasing self-reliance and finding alternative constructive solutions for problems.* It is essential that the patient anticipate future sources of stress, learning how to cope with these by strengthening adaptive skills and eliminating habits and patterns that can lead to trouble.

13. *Always involve the family or significant others in the treatment plan.* A crisis represents both an individual and a family system collapse, and family therapy is helpful to alter the family system. A family member or significant friend should be assigned to supervise drug intake where prescribed and to share responsibility in depressed patients.

14. *Group therapy can also be helpful* both as a therapy in itself and as an adjunct to individual sessions. Contact with peers who are working through their difficulties is reassuring and educational. Some therapists consider short-term group therapy superior to individual therapy for crises.

15. *Terminate therapy within six sessions if possible and in extreme circumstances no later than 3 months after treatment has started to avoid dependency.* The patient is assured of further help in the future if required.

16. *Where the patient needs and is motivated for further help for purposes of greater personality development after the precrisis equilibrium has been restored, institute or refer for dynamically oriented short-term therapy.* In most cases, however, further therapy is not sought and may not be needed. Mastery of a stressful life experience through crisis intervention itself may be followed by new learnings and at least some personality growth.

SUPPORTIVE, BEHAVIORAL AND EDUCATIONAL APPROACHES IN SHORT TERM THERAPY

By far the most common measures utilized in short-term therapy are supportive, behavioral, and educational approaches that aim at symptom relief and problem solving. These are employed without compromising the possibility that some reconstructive personality alterations may serendipitously germinate over time. The therapist assiduously avoids probing for unconscious conflicts or developmental difficulties in childhood, or issues of transference and resistance except where they interfere with the conduct of therapy. A focus on problems in the here-and-now is agreed on by patient and therapist, and the number of sessions may be set in advance. These usually are limited to from 6 to 10, but may sometimes be extended to 25 sessions. Upon agreement the therapist actively pursues the focus with selective inattention to and refusal to be diverted by peripheral aspects no matter how important they may seem. The theme is "get in fast

and get out fast." This usually precludes dealing with extensive dynamic factors. In the few sessions that constitute the treatment plan, all that may be reasonably expected is resolution of a current problem situation and restoration of the patient to a previous optimal level of functioning.

The fact that we have so many different techniques for the same emotional problem can be confusing. What may help is a system approach that considers behavior an integrate of coordinated individual systems that are tied together like links in a chain. I have tried to illustrate this in [Table 57-1](), which can help in the selection of a therapeutic focus and preferred treatment modality. Because of time restrictions one will want to select the one method or combination of methods that is most applicable to the prevailing difficulty. Thus if the patient complains about fatiguability, loss of appetite and weight, listlessness, diminished libido, and insomnia, and it becomes apparent that he or she is suffering from a depressive disorder, one may consider organizing the therapeutic thrust around the biochemical link and supplying an antidepressant medication. This would not preclude working with other links in the behavioral chain if these are implicated. If the patient suffers from a great deal of tension with gastrointestinal irritability and bouts of high blood pressure, the therapist may want to manage the somatic link with relaxation therapy or biofeedback while searching for coordinate etiological factors. A conditioned phobic complaint, e.g., fear of entering elevators or other enclosed spaces, would invite a working with the conditioning link through behavioral approaches such as in vivo desensitization. While recognizing that personality factors associated with intrapsychic conflict are probably present, one would have to bypass the intrapsychic link unless such factors constituted the primary complaint, or if personality problems were operating as resistance to symptom-oriented interventions. In the latter case dynamic therapy would be considered. Should the patient have a severe marital problem one would deal with the interpersonal link through couple therapy. In the event stress could not be eliminated because of intolerable environmental circumstances, the therapist would focus on situational difficulties, and institute the proper therapy associated with the social link. If the assessment of the problem points to the philosophic link because of noxious attitudes and belief systems (which can be as pathogenic as virulent viruses and bacteria), one

would attempt to detoxify thinking patterns through cognitive therapy. Unless this is done, disturbed cognitions can poison relationships with people and vitiate the self-image.

We can console ourselves in a minor way. No matter what technique is employed, if the therapist is skilled in its use, has faith in its validity, and communicates this faith to the patient, and if the patient accepts the technique and absorbs this faith, he or she will be influenced in some positive way. The therapist anticipates that in resolving a difficulty related to one disturbed link in the behavioral chain, this will influence by feedback other links. Thus, if neuroleptics are prescribed for a schizophrenic patient with a disturbing thinking disorder, the impact on the biochemistry will register itself positively in varying degrees on the patient's neurophysiology, general behavior, intrapsychic mechanisms, interpersonal relations, social attitudes, and perhaps even one's philosophical outlook. Applying behavior therapy to a phobia will in its correction influence other aspects from the biochemical factors to spiritual essences. Modifying disturbed interpersonal relations through group or interpersonal therapy, correcting environmental difficulties through therapeutic counseling, and altering belief systems through cognitive therapy will have an effect throughout the behavioral continuum. This global response, however, does not in the least absolve therapists from trying to select the best method within their range of skills that is most attuned both to the patient's immediate concerns and unique learning aptitudes.

Be this as it may, there are some general principles that are applicable to most patients. First, one starts therapy by allowing the patient to unburden verbally, to tell his or her story uninterruptedly, interpolating comments to indicate understanding and empathy and to keep the patient focused on important content. Second, the therapist helps the patient arrive at some preliminary understandings of what the difficulty is all about. Third, a method is selected that is targeted on the link that is creating greatest difficulty for that patient-biochemical, physiological, behavioral, interpersonal, social or philosophic. Fourth, as therapy progresses the therapist tries to show the patient how he or she is not an innocent bystander and that the patient, in a major or minor way may be involved in bringing trouble on him or herself. Fifth, the therapist deals with any

resistances that the patient develops that block an understanding of the problem and the productive use of the techniques employed. Sixth, the therapist tries to acquaint the patient with some of the disturbed attitudes carried around by the patient that can create trouble for him or her in the future, how they developed, how they operate now, and how they may show up after he or she leaves therapy. Seventh, the patient is given homework that is aimed at strengthening oneself enough so that problems may be minimized or prevented from occurring later on. Within this broad framework there are, of course, wide differences on how therapists with varying theoretical orientations will operate. By and large, however, psychotherapists with adequate training should anticipate satisfactory results with the great majority of their patients utilizing this format.

Employing whatever techniques or group of techniques are indicated by the needs of the patient and that are within the scope of one's training and experience, the therapist may be able to achieve the goals agreed on in a rapid and effective way. Where the therapist has become aware of the underlying dynamics, it may be necessary to mention at least some salient aspects and to enjoin the patient to work on these by oneself after treatment has ended. On the other hand, the therapist may not be able to achieve desired goals unless interfering dynamic influences that function as resistance are dealt with during the treatment period because the patient is blocked by such resistance toward making progress.

Dealing with Environmental Factors

In practically every emotional problem an improvement in well-being motivates the individual to alter circumstances of living. This comes about as the patient recognizes that he or she does not have to exist under conditions of stress and deprivation. Demoralized by the inner turmoil, the patient may have hopelessly accepted a bad environmental plight as inevitable. In desperation surcease may be sought through involvement in situations that offer asylum, but the patient then gets into predicaments that turn out to be a greater blight than boon. The patient may even masochistically arrange matters so that he or she can suffer as if to pay penance for pervasive guilt feelings. Over and over we observe the

phenomenon of people, distraught with inner conflict, deliberately attempting to give this objectivity by immersing themselves in outside vexations that consume their attention and concern.

In the course of therapy, it is essential to help the patient break the grip of forces that are hurtful or depriving by identifying them and pointing out their effects. Unless the patient has a basic understanding of the role he or she plays in supporting difficulties of which the patient bitterly complains, wresting from one jam will only result in arranging for another in a very short time.

Generally, it is better for the patient to figure out for oneself what can be done to straighten out his or her life. However, active suggestions may have to be given if the patient cannot devise a plan of action alone, and, toward this end, the therapist may suggest available resources that can aid the patient in this particular need. For instance, a patient who has withdrawn from activities may be encouraged to participate in sports, hobbies, and social recreations, the therapist guiding the patient to groups where such diversions may be found. The patient's economic situation may have to be supplemented through opportune expediencies to supply funds for medical and dental care. A husband, wife or child may be ill, and the pressures on the patient will require alleviation through referral to appropriate clinics or agencies. Better housing may be essential to remedy overcrowding or to remove the patient from neighborhoods where there is exposure to prejudice, threats to life, and crime. A handicapped child may require assignment to a special rehabilitative clinic. A child failing at school may need psychological testing. An aging parent with nothing else to do to occupy his or her time may rule a household with an iron fist and be responsible for an impending break-up of a family. Appropriate outlets may have to be found to consume the oldster's energies. Adoption of a child may be the best solution for a childless couple who are anxious to rear a boy or girl. A patient who has moved from another town may feel alone and estranged and need information about recreational and social facilities in the community. These and countless other situations may require handling in the course of short-term psychotherapy.

The therapist, may, of course, be as puzzled as the patient regarding how to fill an existing need. He or she may not know the suitable resources. The chances are, however, that resources do exist if a proper search is launched. A voluntary family agency, or the family agency of the religious faith of the patient, may be able to act as the initial information source, as may a Council of Social Agencies, Welfare Council, Community Council, local or State health or welfare department or children's agency like a Children's Aid Society. Public health nurses and social workers are often cognizant of immediate instrumentalities in the community, and it may be appropriate to call in a social worker to work adjunctively with the therapist as a consultant.

Perhaps the most pressing problems will concern the patient's relationships with members of the immediate family. Pathological interactions of the various family members are the rule, and the patient may be imprisoned by the family role. Indeed, the patient may not be the person in the family who needs the most help; he or she may be the scapegoat or the member with the weakest defenses. Active assistance may have to be given the patient in resolving family crises. For example, a woman sought help for depressive spells accompanied by sporadic lower abdominal spasms. Although she rationalized her reasons for it, it soon became apparent that she resented deeply a situation that she had brought upon herself. Her sister's son who was getting a Master's degree at college needed his thesis typed. The patient casually offered to help and soon found herself working steadily against a deadline, typing several drafts of a two hundred page manuscript. This she did without compensation and with only minimal appreciation from her sister and nephew. Yet the patient felt obligated to continue since she had promised to complete the thesis. Periodically she would abandon her typewriter when her abdominal cramps became too severe; but her guilt feelings soon drove her back to work. Encouraged by the therapist's appraisal of the unfairness of the situation, the patient was able to discuss with her nephew, with reasonable calmness, her inability to complete his manuscript. This precipitated a crisis with her sister who credited the patient's defection to ill-will. After several sessions were focused on the role she had always played with her exploitative sister, the patient was able to handle her guilt feeling sufficiently to desist from retreating from her stand. A temporary break with her sister was terminated by the

latter who apologetically sought to restore the relationship which assumed a much more wholesome tenor.

It may at times be necessary to see other family members to enlist their cooperation. Patients rarely object to this. For instance, a patient though married was being victimized by an over-concerned and dominating mother who visited her daily and assumed control over the patient's household. It was obvious that the patient's protests masked a desire to maintain a dependent relationship with her mother. She refused to get into a fight with her mother or to offend her by requesting that she stay away. She claimed that her mother never would understand her protest to be left alone; her mother was the one person concerned over the patient's depression and helplessness. This was why she commandeered the role of housekeeper in her daughter's home. The patient was urged to discuss with mother her need to become more independent and to take over increasing responsibility. It was pointed out that some of her depression and helplessness were products of her refusal to accept a mature status. The more she depended on her mother, the more inadequate she felt. This situation sponsored a retreat from self-reliance. It was important to urge her mother to stay away from her apartment. I then suggested to the patient that I have a talk with the mother. The presumed purpose as far as the mother was concerned was to get as much historical data as possible. Her parent readily acquiesced and the interview centered around the patient's great sensitivity as a child and her lack of confidence in herself. Feeling myself to be in rapport with the woman, I pointed out to her how urgent it was to help her daughter grow up. I suggested that it might be difficult to resist her daughter's pleas for help, but that it was vital that she do so in order to stimulate her daughter's independent growth. Nor should she come to her child's rescue when the latter made mistakes. It was important for her daughter to make her own decisions and to take the consequences of her blunders. As a matter of fact the more mistakes she made, the more she would learn. The mother agreed to assist me in helping her daughter, and her cooperation in restricting visits to weekly intervals, as a guest not as a housekeeper, was a principal factor in my being able to bring the patient to a much more self-confident adjustment.

Psychotherapy may have to be prescribed for one or more members of the patient's family in order to alter a family constellation that is creating difficulties for all. In our search for pathology we are apt to overlook the fact that every family unit contains healthy elements which if released can aid each of its constituent members. Instead of or in addition to individual therapy family therapy may best be employed. If family therapy is decided on, sessions may be held with as many of the family group as possible. Each person must be made to see how he or she is deprived and depriving, punished and punishing, and exploited and exploiting. Even a few sessions with this intimate group may serve to release feelings and attitudes that may rejuggle the family equation sufficiently to permit the emergence of healthy trends.

Managing Dependency

Most persons in trouble at the start of therapy feel helpless and want to lean on an idealized parental agency. Being permitted to do so relieves their fear and lessens their anxiety. Whether the therapist realizes it or not he or she will be a target for the patient's dependency yearnings, no matter if one tries to be detached and passive, or actively supportive, reassuring or persuasive. Gratification of dependency needs is hoped to be a temporary measure that is ideally followed by developing independence as mastery is restored. This is accompanied by such signs as a decrease in sensitivity, diminished tendencies to over-react to stimuli, a greater ability to handle criticism, a channeling off into more constructive channels of rage, a better management of feelings of rejection, an avoidance of destructive competition, a reduction of personal overambitiousness, and a correction of distorted ideas about one's world. There are no miracles regarding such developments. They come about as the patient is helped to overcome the symptoms, to solve problems, and to evaluate more rationally an immediate environmental situation that will then enable the patient to make better and less neurotic decisions. Basic personality patterns may not undergo alteration although methods of living around them may be handled more easily. Over time the therapist may hopefully discern some reconstructive changes if the patient has some awareness of underlying personality distortions and has motivation to change these. Engaging in additional dynamic therapy

may expedite these changes.

DYNAMIC SHORT-TERM PSYCHOTHERAPY

Where the therapist has decided to deal with the intrapsychic link in the behavioral chain with the object of reconstructive personality change, one would have to consider that patterns of behavior will generally follow a sequence of conditionings that date back to childhood. Many of the patterns have become firmly fixed, operate automatically, and, while the circumstances that initiated them no longer exist, and the memory traces are firmly embedded in the unconscious, they continue to display themselves often to the dismay of the individual and the consternation of those around him or her. Thus, where defiance in childhood was a prerequisite to expressing assertiveness in relation to overly restrictive and moralistic parents, defiant, recalcitrant, aggressive, or hostile outbursts may be essential before assertiveness can be released. Where self-worth was measured in terms of vanquishing a sibling or parent and proving oneself better than these adversaries, compulsive competitive activities may preoccupy the individual to an extraordinary degree. Where sexual feelings were mobilized by parental provocations, strokings, spankings, enemas, observation of adult sexual activities, or precocious stimulation in varied kinds of sex play, engagement in similar activities, or the exploitation of phantasies about such activities, may be requirements for the release of sexual feeling. These impulses may become organized into perversions. Recrudescence into adult life of unusual behavior is often explicable on the basis of the linkage of adult needs with outmoded anachronistic patterns. Such behavior is usually rationalized when it is manifestly out of keeping with the reality situation.

The individual is, more or less, at the mercy of personality distortions, since the experiences that produced them are sealed off from awareness by repression and are thus not easily available to conscious deliberation or control. The patient is driven by needs, drives and defenses that clash with the demands of society on the one hand and with personal values on the other.

Since the patient carries the burdens of conflict, which impose extraordinary

pressures, he or she will be prone to overreact to stressful circumstances in the environment, particularly when these create insecurity or undermine self-esteem. If one's coping mechanisms falter, one may become overwhelmed by a catastrophic sense of helplessness and by shattering of feelings of mastery. This contingency may bring the frightening experience of anxiety with which one will have to deal with whatever mechanisms of defense can be mustered. Often these revive early defenses, which at one time were employed in childhood, but which are now worthless, since though temporarily allaying anxiety, they foster complications that further tend to disorganize the individual in dealings with life.

One must not underestimate the importance of promptings developed in childhood that have been relegated by repression to the dubious oblivion of the unconscious. These underpinnings of personality—the drives and defenses of childhood—assert themselves throughout the life of the individual.

Thus a man, undermined by an over-protective mother who crushed his autonomy and emerging feelings of masculinity, may have sufficient ego strength to rise as an adult above his devalued self-image, by pushing himself into positions of power and achieving monetary success. To all outward appearances he may appear masterful, strong, and accomplished. Yet his feeble inner promptings to make himself dependent register themselves in passive impulses with homosexual phantasies. He will drive himself into compromising relationships with men, promoting fierce competitiveness, needs for identification with their strength, paranoidal outbursts and perhaps desires for sexual contact when under the influence of alcohol. Understandably, the individual will function under a great hardship being in almost constant conflict, with little awareness of what is going on inside of himself.

Essentially the process of therapy that is rooted in the dynamic theoretical model consists of utilizing the relationship situation with the therapist as a means of helping the patient to gain an understanding of himself in regard to how his current reactions and interpersonal involvements are related to formative experiences in his past. An attempt is

made to bring him to an awareness of unconscious needs, drives and value systems, as well as their origin, significance and contemporary manifestations through special techniques introduced by Freud, such as exploration of dreams. The resistances to unveiling these repressed ingredients are dealt with by interpretation. In the course of working with the patient, the therapist will observe the development of attitudes toward him that reflect early disturbed feelings toward authority (transference). Repeated in the medium of the therapeutic relationship ultimately will be some important incidents that resemble traumatic experiences with past authorities.

It goes without saying that the therapist must have the education, understanding and the personality stability to cope with the patient's projections in order to help the patient gain an awareness of his unconscious maneuvers. The therapist may tend to become frustrated by some patients. He or she may feel enervated by the acting-out, demandingness, hostility, critical attitudes, and unreasonableness of the patient who will watch carefully for the therapist's reactions. Should the therapist respond in ways similar to actions of the parents, the therapeutic process will tend to stop. Actually, the patient will probably engineer the situation so that certain traumatizing experiences can be reenacted with the therapist. If the therapist acts in a therapeutically positive manner the contrast to the past actions of the parents helps the patient gain a different conception of what rational authority is like. The hope is that eventually the patient will, because of new understanding, begin to relate to the therapist in a way different from the habitual responses to authority. Thus, the patient will utilize the therapeutic situation as a vehicle for the evolution of constructive attitudes towards oneself and others. New capacities as a person will develop, as will lessened severity of conscience, greater assertiveness and independence, and an ability to express basic drives in relation to the standards of a group.

The particular way of working will depend on the experience and skill of the therapist. One cannot, as a rule, due to lack of time, employ the time-honored devices of free-association, passivity, and anonymity. Nor should the couch be the preferred position. Transference reactions are dealt with rapidly with the objective of avoiding a transference

neurosis. While the latter may release the deepest conflicts, there is no time available for the essential working-through. If a transference neurosis develops without intention, this must be dissipated as soon as possible because of its interference with therapy. Resistance is managed by active interpretations.

To help the patient gain a better understanding of inner drives, the therapist utilizes focused interviewing, structures a broad picture of the existing dynamics, and encourages the patient to fill in the details through concentrated self-observation. If the therapist knows how to employ them, dreams can be advantageously utilized. For example, a patient in the early part of therapy experienced an unaccountable recrudescence of symptoms that discouraged him greatly. Productions were relatively sterile, and, since there was currently no concentration on depth material, and no explanation for the relapse on the basis of unusual environmental difficulties, I assumed that he was resisting talking about matters that bothered him. He denied having any particular feelings toward me, but, when I specifically inquired about dreams, he recalled the following:

> "I'm in a room where there is a performance going on, like a theatre. But I'm not paying attention to it. A quite heavy, unattractive, chunky man is there carrying a large gun, like a machine gun. This man—he and I are emotionally involved, but there is no connotation of physical sex. He gets up and leaves, and I follow. He said he was told by his doctor that day—I don't know how he put it—that he had a heart attack. He began to cry. It meant the end of everything between us. Life was not absolutely desolate for me. He was losing everything, but I was detached and unconcerned. The heart attack meant I would be free of him. Then later in the night I had a second dream involving you. A law suit is going on, something like a trial. You are the lawyer. You are cross examining people. I am disappointed in your performance, the way you handle the cross examination—jumping around, no logic. *(Patient laughs)* You make a reference to making money. I feel let down. All you want is to make money—calculating.' '

The portion of the session that follows brings out what was bothering the patient—a transference response in which he was equating me with his inadequate greedy father from whom he desired escape.

> *Dr.* You must have had some feelings about me that upset you. *(Pause. Patient laughs)*

> *Pt.* That day you took off on ethics. I felt you were taking off on something I had no desire to talk about. Also when I talked about the law suit I had contemplated and the lawyer handling the case, *(The patient was involved in a minor civil suit)* you said: "You act precipitously." I

felt you misunderstood me because I don't act precipitiously. I nullify action by indecision. You spoke strongly.

Dr. Yes.

Pt. I guess I seek perfection from you, like I do from my girl friend. When you make a grammatical error, I dwell on it all day.

Dr. You seem to have a need for a powerful, accepting, perfect person in whom you can put your trust, and you get infuriated when that person shows any weakness. *(Interpreting the patient's feeling as a response to not finding the idealized authority figure.)*

Pt. I see that, but this doesn't have to be that way.

Dr. Why do you think it *is* that way?

Pt. I don't know, *(pause)*

Dr. What about your ever having had a perfect person around? Have you?

Pt. Jesus, no. I wish I had. My father was cruel and weak. I couldn't depend on him. He left my mother and me. I felt helpless and dependent on my mother. *(The patient's father had abandoned his mother when the patient was a boy.)*

Dr. Maybe you hoped that a strong man would come into your life some day?

Pt. I always wanted one. Even now I get excited when I see such a person.

Dr. Perhaps you felt I was going to be such a person? (*Patient laughs.*)

Pt. This is a false outlook on life. I'm not in bondage. I'm not a slave. This is all a lot of crap.

Dr. What about bondage to me? In the dream you escape when the man claims to be sick.

Pt. I do feel I need you, but seeing you puts me in bondage. But I don't dare let myself feel angry toward you. Only toward my girl friend.

Dr. Perhaps that's why you had a return of your symptoms. The feelings of being trapped with me, in a dependency, with an inadequate father figure at that. (*Interpreting the patient's symptoms as a product of conflict.)*

Pt. Yes, yes, I am sure of it.

It is quite possible that the patient may have been able to work through his transference without the use of dreams. However, I felt that handling his dream short-circuited this process.

There is no substitute for experience in doing dynamic short-term therapy. The seasoned therapist will be able to attune himself or herself sensitively to what is going on, gauging the the manner of making an interpretation, and moving from challenge to support in response to the immediate reactions of the patient. It is difficult to outline specific rules that apply to every case since no two therapists will develop the same relationships with any one patient. And a patient will play different roles with different therapists, depending upon where in his or her characterologic scheme the patient happens to fit the therapist. Almost anything can happen in a therapeutic situation, but if the therapist is flexible, sensitive, and empathic mindful of the basic processes of psychotherapy, and aware of existing neurotic impulses as they are mobilized in a relationship with the patient, one should be able to bring the average patient to some understanding of basic problems within the span of a short-term approach. In long-term therapy, sooner or later, the patient's symptoms, the current precipitating factor, the immediate conflicts activated in the present disorder, the underlying personality structure, deeply repressed conflicts originating in childhood, the relationship with parental agencies, and the defensive mechanisms will slowly become defined and correlated. The working-through process proceeds on all levels of the psychic organization, and no aspect of personality or environment is usually considered unimportant in the painstaking investigative design.

In dynamic short-term therapy, we cannot afford the leisurely pace that so extensive a proceeding requires. It is essential to focus on areas that will yield the highest dividends. Generally these deal with problems of immediate concern to the patient. While aspects that trouble the patient topically may not actually be the most important elements of the disorder, they do engulf the attention. Skill as a therapist is revealed in the ability to establish bridges from the immediate complaints to more basic personality difficulties. Only when a continuity has been affirmed between the immediate stresses and the conflictual reservoirs within the personality, will the patient be able to proceed working on more substantial issues. Focusing on what the patient considers to be mere corollaries to the pain, before having shown the patient that they are actually the responsible mischief makers, will usually turn out to be an unproductive exercise. It would be as if in a

business faced with bankruptcy we were to advise delay in regulating office expenditures in favor of studying the economic picture of the world at large. The perturbations of management could scarcely be allayed with remote objectives when what immediately occupies them is the anxiety of meeting the weekly payroll. Were one to consider the day-to-day survival needs, and tangentially relate current operations to more comprehensive, and ultimately more important, general business factors, greater cooperation would be secured.

The particular problem area to be attacked at first in dynamic short-term therapy is, therefore, more or less of the patient's own choosing. Often this deals with the *precipitating stress situation* an exploration of which may alleviate tension and serve to restore the individual to an adaptive balance. Here an attempt is negotiated to identify the immediate trouble source, and to relate it to the patient's subjective distress. An endeavor is made at working-through, at least partially, of the difficulties liberated by the stress situation. These, derivatives of enduring and fixed underlying core conflicts, are handled as autonomous sources of anxiety. Historical material is considered only when it is bracketed to the current problems. Not only may the patient be brought back to emotional homeostasis rapidly, particularly when seen immediately after the stress situation has set in, but inroads may be made on deeper conflicts.

A bright young man of eighteen applied for therapy on the basis that he was about to fail his last year of high school. What worried him was that he would not receive a certificate and could, therefore, not enter college. His parents were no less disturbed than the patient at his impending educational debacle. While his first three years of high school work had yielded passable grades, these were far below his potential as revealed by an intelligence test. What was even more provoking was that in his college entrance examinations he had scored lowest in his class. He had also been unable to secure a passing grade in his midterm examinations. Embarrassed and manifestly upset, he expressed a futile attitude during the initial interview about better ability to study. What kept happening to him was that his mind wandered. When he forced himself to read his assignments, he could not retain what he read. The prospect of repeating his last year at

school was a severe blow to his pride. He envisaged accepting a position as a general helper at a local gasoline service station.

No comment was made to discourage him from stopping school. Instead my retort dealt with the wisdom of adjusting one's career to one's intellectual capacity. If it were true that he was unable to keep up with his class because of his inferior mental ability, it might be very appropriate to accept a less ambitious career status. Why burden oneself with impossibilities? The patient then spent the remainder of the session trying to convince me that his intelligence quotient was in the upper ten percentile. This was most extraordinary, I admitted. Perhaps there were emotional reasons why he had to fail.

During the next few sessions we feverishly explored his fears of competitiveness, his desire to remain the favorite child in his family, his dependency on his mother, his impulse to frustrate and punish his father for pushing him to satisfy a personal selfish ambitiousness, and his dread to leave home and to pursue an independent life. The meaning of his need to fail soon crystallized in his mind. He realized that it required an effort to avoid educational success, that he was actually trying to fail in order to retain the pleasures of irresponsible childhood.

No moral judgments were expressed as to the virtues of these aims. If he really wanted to be a child, if he desired to hurt himself in order to get back at his parents, if he had the wish to retreat from being as good as any of his colleagues, this was within his rights as a person. However, he had to realize that he was doing this to himself. Angrily he protested that such was not at all the case. He was convinced that his parents did not want him to grow up; they lamented losing their older children when they went to college. They wanted him to be dependent. Why then should he go along with their designs and nefarious intentions; why should he be the "fall guy"? The rage he vented at his parents was followed shortly by a recognition of his own dependency desires and his fear of growing up. As we explored this he discovered that there was a clearing of his mind and a greater dedication to his studies. His successful final examinations were a fitting climax to his fifteen sessions of therapy. Letters that I received from the patient from an out-of-town

college, and a follow-up visit one year later, revealed measures of personality growth hardly consistent with the relatively short period that he stayed in treatment.

Another early focus in therapy is on *distressing symptoms.* The patient is only too eager to talk about these. Their exploration may lead to a discovery of provocative anxieties and conflicts that initiate and sustain them. The importance of giving some meaning to disturbing or mysterious complaints cannot be overemphasized. So long as a symptom remains unidentified, it is like an autonomous and frightening foreign body. To label it, to explain its significance, gives the individual a measure of control helping one to restore one's sense of mastery. This enables one to function better, since, in finding out some reasons for the symptoms, one can utilize one's energies to correct their source.

Generally, the presenting symptom is explored thoroughly in the context of the question: "How is the symptom related to the individual's personality structure as a whole?" For example, a man comes to therapy undermined by uncontrollable bouts of anxiety. The history reveals that the first attack followed a quarrel with his wife. From the character of his relationship with his mother, his Rorschach responses, and his dreams it is apparent that he basically is a dependent individual who is relating disagreeably to his wife. The symptom of anxiety is explicable on the basis of his releasing hostility toward the parental substitute and fearing abandonment and counterhostility. Our focus shifts then from his symptom to his personality structure in operation.

Other areas of focus may present themselves, for instance transference and resistance manifestations which, when they appear, will occupy the therapist's attention to the exclusion of any other concern. But here, too, when such reactions arise, they should be integrated with the general theme of the patient's personality functioning.

All persons possess blind spots in understanding of themselves. Many of these are due to gaps in education; some are distortions promoted by parents and friends; some are perversions of factual data; some are misrepresentations initiated and sustained by misguided education. During therapy some of these falsifications will require greater clarification. In assuming a role geared toward clarification, the therapist disclaims being

an oracle of wisdom, but that there are some facts of which he or she is confident. If the therapist is not sure of the stand, ideas may be offered with some reasonable reservations, since it may turn out that they are wrong.

In short-term therapy, the interpretation of unconscious motives prior to their eruption into awareness is generally avoided. This is because the therapist may not in a brief contact feel sure of one's ground, and because one does not wish to stir up powerful resistances that will negate the therapeutic efforts. Interpretations deal with immediately discernible feelings and personality reactions. However, it is sometimes possible for an extremely experienced psychoanalytically trained therapist, who has established good rapport with a patient, to interpret in depth, albeit in a reassuring way. It may be possible also to utilize confrontation, which in some cases may be very productive with a dramatic impact on the patient. For example, a young man in a state of anxiety with uncomfortable somatic accompaniments reveals great fear of standing next to strong looking men in the subway. His dreams repetitively picture him fleeing from men with destructive weapons. The therapist, on the basis of his experience, and his intuitive feelings about the patient's problem, concludes that the patient is concerned about homosexual impulses. The therapist has, in the first few interviews, won the confidence of the patient. He decides to interpret the patient's inner conflict. The following is from a recording of the interview:

> *Dr.* You know it is very common for a person who has lost confidence in himself to assume he isn't masculine. The next thing that happens is that he gets frightened of being beat up, hurt, attacked and even sexually assaulted by strong men. He begins to feel that he is more feminine than masculine. The next thing he begins to assume is that he is homosexual and this scares the devil out of him. *(pause.)*

> *Pt.* Yes, yes. Isn't he? I mean how does one know?

> *Dr.* I get the impression this is something that is bothering you.

> *Pt.* I get caught in this terrible fear. I feel I'm not a man and that I'll do something terrible.

> *Dr.* You mean like letting yourself get involved sexually with a man?

> *Pt.* Not exactly, but when I have a few drinks, I find myself looking at the men with muscles and it scares the hell out of me.

> *Dr.* When you have a few drinks, you *might* get sexually aroused. This is not uncommon. But what

makes you think you are a homosexual?

Pt. I know I'm attracted to women and I enjoy being with women. But I constantly compare myself to other men and I come out the low man on the totem pole.

Dr. So the problem is your position in relation to other men, and your feelings about yourself. This seems to me to be your real problem. You've probably had a low opinion of yourself as far back as you can remember. What do you feel about what I have said?

Pt. (Obviously flustered) I ... I ... I think you're right (blushes). *(In this interchange the patient has been given an opportunity to face his inner phantasies and to give them another interpretation than that he is a hopeless homosexual. The emotional relief to the patient was manifest even in one interview.)*

Unless the therapist is on firm ground psychodynamically, and has developed a good working relationship, probings in depth are apt to pose a hazard. They may create great anxiety, or they may provoke resentment and resistance. The best rule is to preserve a good relationship with the patient by testing the patient's reactions to a few interpretations in depth that are presented in a casual and tentative manner.

A patient with an obsessive fear of being hurt, injured and cut, and thus of coming to an untimely death, had so gentle and obsequious a manner with people that I was convinced he was concealing profoundly destructive tendencies. On one occasion when he was discussing his fear of death, I said: "A problem like yours may be touched off by a number of things. I had one patient who imagined himself to be a killer. This scared him so that he had to push the idea out of his mind. Instead he substituted fears of being hurt or killed. This happens over and over again. Whether or not the same thing is happening to you, I don't know. But if so there may be reasons for it. In the case of the man I treated, he confused being assertive with being aggressive and murderous."

This initiated an exploration into the patient's childhood. There was little question that he had felt overprotected and thwarted in various ways, particularly in exploratory activities. Quarreling, fighting and even disagreeing with others were considered to be evil and "against God's will." My indirect interpretation was accepted and utilized. Where an interpretation is premature or wrong, or where the patient's ego resources are unable to sustain its implications, one may on the other hand, react badly. The therapist then will

have to retrieve the situation, working toward the reestablishment of a positive relationship.

The interpretation of a transference reaction is especially helpful when correct. An adolescent boy treated his visits with me as a casual incident in his routine, refusing to talk about himself and waiting for me to do something dramatic to remove his facial tic. At one visit I remarked, "You just won't say anything about yourself and your feelings. I get the impression that you don't trust me." The patient's reaction was a startled one. He blushingly revealed that he was embarrassed at his thoughts. He never was able to be frank with his family. Whenever he divulged any secrets to his brothers or his parents, they were immediately revealed to the whole family to his great embarrassment. When I retorted that there must be something about coming to see me that made him feel sheepish, he admitted wanting to ask me for some "sex books" to explain masturbation and sex. Perhaps, I replied, he felt I might get the idea he wanted to stimulate himself pornographically with this literature. He blushed furiously at this, whereupon I reassured him that there was nothing to be ashamed of, that a strong sexual interest at his age was normal, and that I certainly would reveal nothing about our conversations to his parents. After all, what we talked about was between ourselves. This maneuver had the effect of releasing a flood of memories of incidents in which his confidence had been betrayed. Our sessions thereafter took a new direction with the patient participating actively. I repeatedly assured him that his parents or family would never know about the content of our talks.

In some cases, it may be expedient to present the patient with a general outline of personality development, particularly what happens with delayed separation individuation, inviting the patient to see which elements apply to him or her. I have found that this is occasionally helpful where insufficient time is available in therapy to pinpoint the precise pathology. Patients are usually enthusiastic at first at having received some clarification, and they may even acknowledge that segments of the presented outline relate to themselves. They then seem to lose the significance of what has been revealed to them. However, much later on follow-up many have brought up pertinent details of the

outline and have confided that it stimulated thinking about themselves.

For instance, a man whose depression was set off by his losing face at work when a younger colleague was advanced ahead of him, came to therapy in an extremely discouraged state and with little motivation to inquire into his patterns of adjustment. Deep resentments were apparent from the violent responses to the Rorschach cards, and from his dreams, which centered around destruction and killing. When I commented that it would be natural for him to feel angry under the circumstances, he countered with the remark that he had written advancement off years ago, that he bore no resentment toward his victorious colleague, and that he was resigned to getting the "short end of the stick." From childhood on he was the underdog in the family, and he was accustomed to this role. Apparently, I retorted, he was not as resigned as he imagined himself to be, otherwise he would not have reacted to the present situation with such despair. Maybe he had not written himself off as a permanent underdog. Then I sketched an outline that followed along lines that I have used on other patients with minor variations. This deals with derivative conflicts much closer to awareness than the nuclear conflicts from which they come that are too deeply repressed to be available in the short period devoted to therapy. The following is from an audio tape that I made with the patient's consent:

> "I believe I have a fair idea of what is going on with you, but I'd like to start from the beginning. I should like to give you a picture of what happens to the average person in the growing up process. From this picture you may be able to see where you fit and what has happened to you. You see, a child at birth comes into the world helpless and dependent. He or she needs a great deal of affection, care, and stimulation. The child also needs to receive the proper discipline to protect him or her. In this medium of loving and understanding care and discipline, where one is given an opportunity to grow, to develop, to explore, and to express oneself, independence gradually increases and dependence gradually decreases, so that at adulthood there is a healthy balance between factors of dependence and independence. Let us say they are equally balanced in the average adult; a certain amount of dependence being quite normal, but not so much that it cripples the person. Normally the dependence level may temporarily go up when a person gets sick, or insecure, and independence will temporarily recede. But this shift is only within a narrow range. However, as a result of bad or depriving experiences in childhood, and from your history this seems to have happened to you to some extent *(the patient's father, a salesman was away a good deal of the time and his older brother brutally intimidated him.)*, the dependence level never goes down sufficiently and the independence level stays low. Now what happens when a person in adult life has excessive dependency and a low level of independence? Mind you, you may not show all the things that I shall point out to you, but try to figure out which of these

do apply to you.

"Now most people with strong feelings of dependence will attempt to find persons who are stronger than they are, who can do for them what they feel they cannot do for themselves. It is almost as if they are searching for idealized parents, not the same kind of parents they had, but much better ones. What does this do to the individual? First, usually he becomes disappointed in the people he picks out as idealized parental figures, because they never come up to his expectations. He feels cheated. For instance, if a man weds a woman who he expects will be a kind, giving, protective, mother figure, he will become infuriated when she fails him on any count. Second, he finds that when he does relate himself to a person onto whom he projects parental qualities, he begins to feel helpless within himself; he feels trapped; he has a desire to escape from the relationship. Third, the feeling of being dependent, makes him feel passive like a child. This is often associated in his mind with being non-masculine; it creates fears of his becoming homosexual and relating himself passively to other men. This role, in our culture, is more acceptable to women, but they too fear excessive passivity, and they may, in relation to mother figures, feel as if they are breast-seeking and homosexual.

"So here he has a dependency motor that is constantly operating, making him forage around for a parental image who will inevitably disappoint him. *(At this point, the patient interrupted and described how disappointed he was in his wife, how ineffective she was, how unable she proved herself to be in taking care of him. We discussed this for a minute and then I continued.)* In addition to the dependency motor, the person has a second motor running, a resentment motor, which operates constantly on the basis that he is either trapped in dependency, or cannot find an idealized parental figure, or because he feels or acts passive and helpless. This resentment promotes tremendous guilt feelings. After all, in our culture one is not supposed to hate. But the hate feelings sometimes do trickle out in spite of this, and on special occasions they gush out, like when the person drinks a little too much. *(The patient laughs here and says this is exactly what happens to him.)* If the hate feelings do come out, the person may get frightened on the basis that he is losing control. The very idea of hating may be so upsetting to him that he pushes this impulse out of his mind, with resulting tension, depression, physical symptoms of various kinds, and self-hate. The hate impulse having been blocked is turned back on the self. This is what we call masochism, the wearing of a hair shirt, the constant self-punishment as a result of the feedback of resentment. The resentment machine goes on a good deal of the time running alongside the dependency motor.

"As if this weren't enough, a third motor gets going along with the other two. High dependence means low independence. A person with low feelings of independence suffers terribly because he does not feel sufficient unto himself; he does not feel competent. He feels nonmasculine, passive, helpless, dependent. It is hard to live with such feelings, so he tries to compensate by being overly aggressive, overly competitive, and overly masculine. This may create much trouble for the person because he may try to make up for his feelings of loss of masculinity. He may have phantasies of becoming a strong, handsome, overly active sexual male, and, when he sees such a figure, he wants to identify with him. This may create in him desires for and fears of homosexuality which may terrify him because he does not really want to be homosexual. Interestingly, in women a low independence level is compensated for by her competing with men, wanting to be like a man, acting like a

man, and resenting being a woman. Homosexual impulses and fears also may emerge as a result of repudiation of femininity.

"A consequence of low feelings of independence is a devalued self-image with starts the fourth motor going. The person begins to despise himself, to feel he is weak, ugly and contemptible. He will pick out any personal evidence for this that he can find, like stature, complexion, physiognomy, and so on. If he happens to have a slight handicap, like a physical deformity or a small penis, he will focus on this as evidence that he is irretrievably damaged. Feelings of self-devaluation give rise to a host of compensatory drives, like being perfectionistic, overly ambitious and power driven. So long as one can do things perfectly and operate without flaw, he will respect himself. Or, if he is bright enough, and his environment favorable, he may boost himself into a successful position of power, operate like a strong authority and gather around himself a group of sycophants who will worship him as the idealized authority, whom in turn the individual may resent and envy while accepting their plaudits. He will feel exploited by those who elevate him to the position of a high priest. "Why," he may ask himself, "can't I find somebody strong I can depend on?" What he seeks actually is a dependent relationship, but this role entails such conflict for him that he goes into fierce competitiveness with any authority on whom he might want to be dependent. (*The patient nods and keeps saying "Yes, yes."*)

"So here we have our dependency operating first; second, resentment, aggression, guilt, and masochism; third, drives for independence; and, fourth, self-devaluation and maneuvers to overcome this through such techniques as perfectionism, overambitiousness and power strivings, in phantasy or in reality.

"To complicate matters some of these drives get sexualized. In dependency, for instance, when one relates to a person the way a child or infant relates to a parent, there may be experienced a powerful suffusion of good feeling which may bubble over into sexual feeling. There is probably a great deal of sexuality in all infants in a very diffuse form, precursors of adult sexuality. And when a person reverts emotionally back to the dependency of infancy, he may re-experience diffuse sexual feelings toward the parental figure. If a man relates dependently to a woman, he may sustain toward her a kind of incestuous feeling. The sexuality will be not as an adult to an adult, but as an infant to a mother, and the feelings for her may be accompanied by tremendous guilt, fear, and perhaps an inability to function sexually. If the parental figure happens to be a man instead of a woman, the person may still relate to him like toward a mother, and emerging sexual feelings will stimulate fears of homosexuality. (*If the patient is a woman with sexual problems, the parallel situation of a female child with a parental substitute may be brought up: A woman may repeat her emotions of childhood when she sought to be loved and protected by a mother. In body closeness she may experience a desire to fondle and be fondled, which will stir up sexual feelings and homosexual fears.*) In sexualizing drives for independence and aggressiveness, one may identify with and seek out powerful masculine figures with whom to fraternize and affiliate. This may again whip up homosexual impulses. Where aggressive-sadistic and self-punitive masochistic impulses exist, these may, for complicated reasons, also be fused with sexual impulses, masochism becoming a condition for sexual release. So here we have the dependence motor, and the resentment-aggression-guilt-masochism motor, and the independence motor, and the self-devaluation motor, with the various compensations and sexualizations. We have a very busy person on our hands. *(At*

this point the patient revealed that he had become impotent with his wife and had experienced homosexual feelings and fears which were upsetting him because they were so foreign to his morals. What I said was making sense to him.)

"In the face of all this trouble, how do some people gain peace? By a fifth motor, that of detachment. Detachment is a defense one may try to use as a way of escaping life's messy problems. Here one withdraws from relationships, isolates himself, runs away from things. By removing himself from people, the individual tries to heal himself. But this does not usually work because after a while a person gets terrified by his isolation and inability to feel. People cannot function without people. They may succeed for a short time, but then they realize they are drifting away from things; they are depriving themselves of life's prime satisfactions. Compulsively, then, the detached person may try to reenter the living atmosphere by becoming gregarious. He may, in desperation, push himself into a dependency situation with a parental figure as a way out of his dilemma. And this will start the whole neurotic cycle all over again.

"You can see that the person keeps getting caught in a web from which there is no escape. So long as he has enough fuel available to feed his various motors and keep them running, he can go on for a period. But if opportunities are not available to him to satisfy his different drives, and if he cannot readily switch from one to the other, he may become excessively tense and upset. If his tension builds up too much, or if he experiences great trouble in his life situation, or if his self-esteem gets crushed for any reason, he may develop a catastrophic feeling of helplessness and expectations of being hurt. *(The patient here excitedly blurted out that he felt so shamed by his defeat at work that he wanted to atom bomb the world. He became angry and weak and frightened. He wanted to get away from everything and everyone. Yet he felt so helpless he wanted to be taken care of like a child. He then felt hopeless and depressed. I commented that his motors had been thrown out of gear by the incident at work and this had precipitated excessive tension and anxiety.)*

"When tension gets too great, and there seems to be no hope, anxiety may hit. And the person will build up defenses to cope with his anxiety, some of which may succeed and some may not. For instance, excessive drinking may be one way of managing anxiety. Fears, compulsions, physical symptoms are other ways. These defenses often do not work. Some, like phobias, may complicate the person's life and make it more difficult than before. Even though ways are sought to deal with anxiety, these prove to be self-defeating.

"Now we are not sure yet how this general outline applies to you. I am sure some of it does, as you yourself have commented. Some of it may not. What I want you to do is to think about it, observe yourself in your actions and relations to people and see where you fit. While knowing where you fit will not stop the motors from running, at least we will have some idea as to with what we are dealing. Then we'll better be able to figure out a plan concerning what to do."

Self-observation should be encouraged and this will help the "working-through" process without which insight can have little effect. It is important then even though a patient can spend limited time in treatment that he or she gain some awareness of the

source of the problems. This ideally should establish the complaint factor as a parcel of a much broader design, and should point to the fact that self-defeating patterns are operating that are outcroppings of elements rooted in past experiences. Once the patient gets the idea that these troubles are not fortuitous, but are events related to definite causes—perhaps carryovers of childish needs and fears—he or she will be more apt to utilize energies toward resolving difficulties rather than expending them in useless resentment and self-recriminations. Insight may operate primarily as a placebo force at first, but if it enables the individual to relate significant forces in development to day-to-day contemporary functioning, this may enable the patient to establish inhibitory controls, and even to structure life along more meaningful and productive lines.

Because the degree of insight that can be inculcated in the patient in a short period of therapy is understandably limited, some therapists circumscribe the area of inquiry. Sifneos, for example, organizes interpretations around oedipal problems, Mann around issues of development, others around separation and grief. Whatever the focus, resistances will tend to sabotage self-understanding. Though the patient may seek to get rid of anxiety and disturbing symptoms, though possessing incentives to be assertive and independent, though wishing to be fulfilled happily and creatively, he or she is a prisoner of one's conditionings that tend compulsively and confoundingly to repeat. Moreover, there are virtues derived from a perpetuation of neurotic drives: symptoms do tend to give the patient temporary protection from anxiety; secondary gains operate that supply the individual with spurious dividends for the illness; normality poses dangers more disagreeable than being well. To work through resistances toward complete understanding, and to put insight into practice with corrective personality change, is a prolonged procedure that will have to go on outside of therapy, perhaps the remainder of the individual's life.

What will be needed is a form of discipline to approach the task of self-understanding toward liberation from destructive patterns. In order to get well the patient will have to acquire the strength to renounce patterns that have personal values. Even though awareness is gained into the need to renounce certain ways of behaving, the

patient may prefer to hang onto a preferred though neurotic way of life despite the inevitability of suffering. The patient may also become resentful to the therapist for not reconciling irreconcilable objectives of achieving the fruits of victory without bothering to till the soil and plant the seed, and of retaining neurotic patterns while avoiding the accompanying pain.

For example, a female patient seeks love from men at the same time that she is extremely competitive with them. To outdo and outshine them has intense values for her. When she fails to vanquish them, she becomes infuriated; when they stop short of giving her the proper affection, she goes into despair. Her lack of insight into her ambivalence toward men is startling in view of the fact that she is capable of advising her friends in *their* affairs of the heart. From her history it is suspected that her problem stems in part from her competitiveness with an older brother against whom she was pitted by her mother, who herself was in rivalry with her passive husband. Yet the patient loved and admired her brother. What bothers the patient is that she can never hold onto a strong male; only weak and passive men seek her out, for whom she has only contempt.

Within six sessions of therapy the patient became aware of her two antagonistic drives, to give affection and to defeat men. An inkling of her strong competitiveness with men also filtered through. She acknowledged how contradictory her motives were, but this had no effect whatsoever on her behavior. Indeed, she became embittered with and repudiated my suggestion that until a change occurred in her rivalrous attitudes toward men, she could not expect that they would respond to her, nor would she be able to realize the love she desired. She countered with the statement that she was looking for a man with "guts" who could fight back and make her feel like a woman.

Ordinarily, one would anticipate that a problem of this severity could be resolved only in prolonged treatment, preferably with the setting-up and working-through of a transference neurosis. For many reasons long-term therapy was not feasible, and after eighteen sessions treatment was terminated with symptomatic relief, but with no alteration of her patterns with men. What I enjoined her to do was to practice principles of

self-observation, which I encourage in all patients who have a desire to achieve more than symptomatic change. Follow-up visits over a 10-year period have revealed deep and continuing changes with a successful marriage to a man she respects with whom she has enjoyed raising two children.

Post-Therapy Self-Observation

Among the areas around which posttherapy self-observation is organized are the following:

1. *Relating outbursts of tension, anxiety and symptom exaggeration to provocative incidents in the environment and to insecurities within the self.* The patient may be told: "Whenever you get upset, tense or anxious, or whenever your symptoms get disturbing, ask yourself: 'What is going on? What has upset me?' Keep working at it, thinking about matters until you make a connection between your symptoms and what has provoked them." If the patient has gotten clues about the operative dynamics from the treatment experience, he or she will be in a position to pinpoint many of the current upsets. Even if the assigned determinants are not entirely complete, the fact that the patient attempts to identify the sources of trouble will help to overcome helplessness and to alleviate much tension.

2. *Observing circumstances that boost or lower feelings about oneself.* The patient is instructed to watch for incidents and situations that boost morale or that are deflating to the ego relating these, if possible, to operations of inherent personality assets and liabilities. For instance, when first forming a relationship with a person, a feeling of peace and contentment may follow on the assumption that the relationship will magically resolve problems. A realization may then dawn that such inordinate expectation can sponsor a parade of troubles since it is based on neurotic dependency. If, on the other hand, the patient experiences greater self-esteem in doing something constructive through personal efforts, the resulting feeling of independence and self-growth may encourage further efforts in this direction.

3. *Observing one's relationship with people.* The patient is encouraged to ask oneself: "What tensions do I get with people? What kind of people do I like or dislike? Are these tensions with all people or only with certain kinds of people? What do people do to upset me and in what ways to I get

upset? What do I do to upset them or to upset myself when I am with them? What do I do and what do they do that tends to make me angry? What problems do I have with my parents, my mate, my children, my boss, associates at work, authorities, people in general?" Whatever clues are gathered about habitual reaction patterns will serve to consolidate an understanding of one's general personality operations.

4. *Observing daydreams or dreams during sleep.* The patient may be reminded, if during therapy he or she has learned that dreams have a meaning, that one may be able to get some valuable data about oneself from phantasies or dreams. The patient may be instructed: "Make a note of any daydreams or night dreams especially those that repeat themselves. Try to remember them and to figure out what they mean." How valuable this exercise may be is illustrated by the case of a young man with fears about his masculinity who developed stomach pains the evening of a blind date that forced him to cancel his appointment. Unable to understand why his pains disappeared immediately after the cancellation, he asked himself to remember any dreams that night. The dream he recalled was this: "My father had his arm around my mother and kept me from her. I felt guilty." He was so enthusiastic that he had made a connection between the incident of the blind date and his oedipal problem that he telephoned me to say he was going to challenge his putting women into the role of his mother by seeing his date through another evening. This he was able to do. Obviously not all patients will be able to utilize their dreams in self-observational practices.

5. *Observing resistances to putting one's insights into action.* The patient is advised that every time understanding is applied to the challenging of a neurotic pattern, this will tend to strengthen one. "You will eventually get to a point where you will be able to block destructive or self-defeating actions before they get you into trouble. But expect some resistance, tension and fear. When you stall in doing what you are supposed to do, ask yourself why? What are you afraid of? Then deliberately challenge your fear and see if you can overcome it."

By a studied application of the above principles of self-observation, the patient may be able to achieve considerable personality growth after treatment has stopped. Gradually one may become aware of patterns that have to be revised before interpersonal horizons can be expanded. Understandably, this process is slow. First, the individual realizes that

symptoms do not occur at random, but rather are related to life situations and relationships with people which stir up tensions, hostilities, and anxieties. This leads to a questioning of the types of relationships that are habitually being established. It may seem incredible to the patient that other ways of behaving are possible. Even partial acceptance of this premise may spur an inquiry into origins of existing attitudes toward people and toward oneself, A continuity may be established between present personality traits and past conditionings. The "blueprint" of the personality that was tentatively sketched while in treatment becomes more solidly outlined, and essential revisions in it are made. The patient sees more clearly the conditions under which early fears and conflicts originated to paralyze functioning. In the course of this investigation one may recover memories long forgotten, or may revive feelings associated with early recollections that have been repressed. There is an increasing facility to master the anxiety associated with the past. He or she begins to doubt that life need be a repetition of past happenings and becomes increasingly convinced that it is unnecessary to inject past attitudes into present situations. Tenuously, against resistance, the patient tests new responses, which in their reward help gradually to extinguish old reactions. Throughout this reconstructive process, the old patterns keep coming back, particularly when the individual feels insecure or self-esteem becomes undermined. The recognition that one is trying to regress as a security measure assists in reversing the retreat. More and more one expresses a claim to a new life, the right to be more self-expressive. The ego expands; the conscience gets less tyrannical; inner promptings find a more healthy release; relationships with people undergo a change for the better.

There is, of course, no guarantee that these productive developments will take place in all cases. Nor can any estimate be made as to how long a period change will require after therapy has ended. But persistence in the practice of self-observation, and active challenging of neurotic patterns, are prime means of achieving reconstructive results. Where the patient has been taught self-relaxation or self-hypnosis, one may advantageously employ these techniques to catalyze self-observation.

58
Handling Emergencies in Psychotherapy

Although emergencies are not common in the practice of the average therapist, preparation for their proper management, should any occur, makes good sense, since mishandling can be destructive to the patient and ruinous to one's reputation, apart from the medico-legal complications that can ensue. Not only will the therapist have to palliate the patient's turmoil, but will also have to cope with the concerns of the patient's family, as well as the anxieties within oneself. To retain objectivity and composure in the face of ominous happenings will tax the resources of the most stable therapist. Responsibility should therefore be shared with a skilled consultant psychiatrist, especially if the therapist is a non-medical person.

Crucial decisions are essential in emergencies. Knowing when to pacify, when to confront, when to enjoin, when to direct, when to order, when to notify relatives or friends, when to hospitalize, when to prescribe medications, how to evaluate existing stress situations, how to appraise useful support systems, how to gauge available ego strengths, how to bring the patient to an awareness of factors that keep the crisis alive, when to involve the family in the treatment plan, and the solution to other troublesome points requires expertise in crisis intervention practiced in the medium of an empathic relationship.

Among such possible emergencies are suicidal attempts; psychotic attacks; excitement, overactivity, and antisocial behavior; panic states; acute alcoholic intoxication; acute barbiturate poisoning; hallucinogenic and other intoxications; severe psychosomatic symptoms; and intercurrent incurable somatic illness.

SUICIDAL ATTEMPTS

Suicide ranks among the 10 most common causes of death among adults and among

the three most common causes among adolescents. Statistics underestimate its true incidence due to flaws in reporting. Most (90 percent) of suicidal attempts are unsuccessful. This is because they are ill conceived and reflect the ambivalence of the perpetrator. Usually they constitute a gesture that communicates a plea for life. About 70 percent of successful suicides are among adults, most occurring in the syndrome of major depression and in alcoholics experiencing periodic depressed states. A disproportionate number of suicides are found among professional persons such as lawyers, physicians, dentists, and military men. The therapist should be alerted to a number of warning signs.

1. Symptoms of severe depression especially in males over the age of 55, social isolation, recent divorce or widowhood, unemployment, alcohol or drug abuse, and physical illness of a chronic or painful nature are predisposing factors.

2. At any age those who have made serious suicidal attempts, or where there is a history of suicide or of affective disorder in the family, these should be considered danger signals.

3. Dysthymia (reactive depression) resulting from broken or unhappy love affairs, disharmony in marriage, serious fights with parents among the young, bereavements in the elderly, and severe physical ailments may initiate a suicidal attempt. Likewise, personality problems of a psychopathic or hysterical nature with poor impulse control and peaks of violence and aggression may register themselves in suicidal gestures or in suicidal equivalents like reckless driving and dangerous sports.

4. Most likely to commit successful suicide are severe depressions during early stages of treatment when retardation and indecisiveness are replaced by a slight release of energy. Here prescribed psychotropic drugs and hypnotics may be massively incorporated.

Even in well-conducted psychotherapy vague suicidal threats may be expressed by some patients to the effect that they would be better off dead but they are too cowardly to try suicide. Where such statements lack the tone of conviction, it is best for the therapist not to subject the patient to concentrated interrogation around the matter of suicide. The therapist's expressed concern may frighten the patient badly resulting in loss of self-confidence. It may be found that the patient is trying to prove something or to hurt

someone with a suicidal threat. Actually, an individual is responsible for his or her own actions, and cannot be watched 24 hours per day to prevent executing a threat if this is what is urgently wanted. The family of the patient may also be helped to resist being blackmailed by suicidal threats.

The following signs, symptoms, and situations, however, do point to a potential suicidal risk in a patient:

1. Loss of appetite, severe weight loss, insomnia, listlessness, apathy, persistent expressions of discouragement and hopelessness, loss of sexual desire, extreme constipation, hypochondriac ideas, continuous weeping, and general motor retardation which are present at the start or appear in the course of therapy.

2. Irrespective of diagnosis, any patient who has made a suicidal attempt in the past, or who has a history of severe depression, or who is taking antihypertensive and other medications and drugs that are having a depressive effect.

3. A patient who, during therapy, insistently threatens suicide.

4. Dreams of death, mutilation, and funerals.

Where during treatment, the patient talks *openly and seriously* about a desire to "end it all," it is important not to change the topic or to reassure the patient unduly. Rather, a frank talk about the reasons why the patient feels that suicide is the best recourse gives the patient an opportunity to investigate hidden feelings. This will enable the therapist to determine whether the threat is real, whether it is casually made as a dramatic gesture, whether it is a hostile stab at the therapist, or whether it constitutes an appeal for reassurance. Under no circumstances should the therapist minimize the importance of the threat, cajole the patient, or administer a verbal attack. Arguing with the patient is generally useless. Where the threat seems ominous, the therapist might make helpful statements to the effect that suicide *seems* to be a way out of difficulty, but it actually accomplishes nothing; that there may be other solutions than suicide that are not now apparent; and that suicide is a final act that cannot be undone and that it could always be

resorted to later on if the patient so wishes. The attitudes conveyed to the patient in such statements are respect for one's right to self-determination and a reminder that one is not giving oneself an opportunity to explore more constructive actions. Talking frankly about suicide often serves to rob it of its awesome or appealing quality. Where suicide seems imminent in spite of anything the therapist can do or where an abortive attempt is actually made, there is no alternative than to advise responsible relatives to get the patient hospitalized immediately in a closed ward of a psychiatric hospital.

Suicide prevention centers do exist in the larger cities, and they have been used by depressed individuals and their families in crises. How effective these centers are in preventing suicide has not been evaluated adequately. Their impact may be minimal because individuals intent on suicide do not generally call in. Suicide centers do, however, serve a purpose if no more than to act as a referral source.

Hysterical Personalities

Suicidal attempts in hysterical personalities are common and consist of histrionic gestures calculated to impress, frighten, or force persons with whom the patient is in contact to yield attention and favors. Such attempts are incited by motives for display rather then by genuine desires to take one's life. Dramatic performances of an ingenious nature are indulged, during which there is a superficial slashing of the wrists, or feigned unconsciousness with stertorous breathing while placing an empty bottle of sleeping pills alongside the bed, or the gulping of tincture of iodine, or the impetuous opening of gas jets. Feverish demonstrations of suffering and martyrdom continue after the patient is restrained or "revived," until convinced of having emphasized protests sufficiently. The danger of these pseudo-suicidal maneuvers is that the patient's judgment may not be too good during dramatic overacting and one may accidentally go too far and commit suicide even though this was not the original intent.

In treating hysterical cases with suicidal threatenings, we must demonstrate to the patient that we are neither intimidated by nor angry at the actions of the patient. Interpretation of the purpose of the patient's frenzied behavior should be made in terms

of the broader neurotic patterns.

Psychopathic Personality

Of a related but more serious nature are the suicidal attempts of the psychopathic personality. During episodes of excitement, violence, deep remorse, excessive drinking, or temporary psychotic outbreaks, the psychopaths may slash the wrists or take an overdose of sleeping pills. The desire for self-punishment and death are genuine, though temporary. When their attempt has been aborted and they have been hospitalized, such patients recover rapidly, evidence no further suicidal impulses, and express great remorse at their folly. Yet, a short time later, under propitious circumstances, the attempt will be repeated, with further contrition and promises of abstention. Interpretation of the episode is essential, but it usually fails to act as a deterrent to the patient's actions. When the suicidal episodes are motivated by disturbed interpersonal relationships, as, for instance, a broken love affair or rejection by a love object, the continued exploration of the patient's feelings and patterns is indicated. In addition, the therapist may have to increase the frequency of visits and insist on being telephoned when the patient is tempted to indulge in suicide.

Where the patient persists in this impulsive suicidal behavior, after seeming to have acquired insight into operative patterns, the therapist may have no other alternative than to tell the patient that treatments will have to be discontinued. It may be suggested that the patient may perhaps want to start treatment with another therapist. This may give enough of a jolt to the patient to ensure insistence on the therapists continuing, based on the promise that all further suicidal attempts will be abandoned. Whether or not the therapist concedes to the patient's wishes to continue treatment will depend on how the therapist feels about the patient. Unfortunately, with some psychopaths the threat of discontinuance of therapy may be the only force that can control their explosive conduct. Even here the effect may be temporary.

Schizophrenia

In some types of schizophrenia suicide is a grave possibility. It is most common in

acute, excited catatonic states, particularly those associated with panic. Hallucinations may drive certain patients to mutilate or kill themselves. Fear of homosexual attack or of being persecuted may also force some paranoidal individuals to suicide. The methods of self-destruction employed in schizophrenia may be bizarre, including such mutilations as disembowelment and genital amputation.

The handling of the suicidally inclined schizophrenic patient is organized around administering ample sedation, communicating with the family so that they may assume some responsibility, and arranging for transportation and admission to a mental hospital. Electric convulsive therapy is often indicated. Chlorpromazine (Thorazine), thioridazine (Mellaril), perphenazine (Trilafon), or haloperidol (Haldol) in ample dosage (see the section on somatic therapy in Chapter 56) are indicated.

Pathologic Depressions

Depressed episodes may occur in people due to loss of security, status, or a love object; however, the depression is rarely of such depth as to inspire a desire to take one's life. Where the depressed state is extreme, suicide is always a possibility. Among the most vulnerable pathologic depressive conditions are major depression, bipolar depression, depressions in alcoholics, involutional depression, senile depression, and depressions in organic brain disease.

To manage a patient with a pathologic depression, certain palliative measures are helpful. The handling of diet with the inclusion of stimulating and appetizing foods and the prescription of tonics and vitamins may be indicated in anorexia. In mild depression, a stimulant like Ritalin may be useful temporarily to activate the patient during the day, while sedation may be required at night for insomnia. Here small amounts of a mild hypnotic like chloral hydrate (Noctec) may be prescribed to prevent the patient from accumulating a lethal quantity. In more severe depressions, the patient's family or a reliable friend should be contacted and acquainted with the potential dangers. Where the patient remains at home while in a deep depression, a trustworthy adult person should be in constant attendance. The patient should not be permitted to lock oneself into a room,

including the bathroom. Sleeping pills, tranquilizers, poisonous drugs, razor blades, rope, and sharp knives and instruments should be removed. Window guards are necessary if there is a chance that the patient may destroy oneself by leaping through a window. Hospitalization on a closed ward with constant supervision by efficient nurses or attendants may be essential. The treatment of choice is electroconvulsive therapy, which may prove to be a lifesaving measure. Antidepressants are second best where the patient refuses ECT, but the patient must be watched carefully since the early "lift" from the medication may give enough energy to try suicide. Psychotherapy during severe depression is generally confined to supportive measures, as insight approaches tend to stir up too much anxiety.

Fear and guilt feelings are common in the therapist who will usually be in a dilemma about hospitalization. It is urgent that a non-medical therapist secure a consultation with a psychiatrist to share responsibility, to prescribe ECT or proper medications, or to arrange for hospitalization should the patient need it and is willing to consider it. Although a desperate patient can terminate life in spite of any safeguards, there is a lesser chance in a hospital setting, particularly when ECT is immediately started. Usually there is little problem in decision making when the patient has made an unsuccessful attempt. Here relatives and neighbors rush the patient to an emergency hospital service, or the police are brought into the picture and arrange for admission and perhaps for transport of the patient.

Difficulties in decision are greater in the event a patient has mildly threatened to take his or her life, but makes no active gesture to do so, and has no history of past suicidal attempts. Under these circumstances the therapist may have to utilize the greatest interviewing skills (Murray, 1972). The patient may be told that the ultimate responsibility for one's life is one's own. "You probably won't believe this, but you *will* get over this depression and will feel better. Right now it is natural for you to imagine your suffering will continue indefinitely. It will not." Here it is assumed that the patient is started on a regime of antidepressant drugs (e.g. Tofranil, Elavil, Sinequan) in adequate dosage (see the section on somatic therapy in Chapter 56). In the great majority of

patients a frank empathic talk will tide them over the crisis.

It is often important to see the patient frequently and to telephone between sessions to maintain as close a tie as possible.

Miscellaneous Suicidal Conditions

Sometimes a therapist is consulted by the parents or friends of a child or adolescent who has made a suicidal attempt. Examination may fail to reveal hysteria, depression, or schizophrenia, especially when the child is non-communicative to the point of mutism. It is possible here that the child is internalizing destructive feelings. Young drug abusers are particularly vulnerable. Because the youth is non-motivated for therapy and resents having been taken to a psychiatrist, it may be difficult to treat the patient. By following the rules outlined in Chapter 32. Dealing with Inadequate Motivation, and by indicating to the patient that he or she seems to be angry at someone, it may be possible to establish rapport.

A 14-year-old girl, for example, who had made a suicidal attempt by swallowing 50 aspirin tablets was brought in for a consultation. Refusing to talk except in monosyllables, it was difficult to carry on an interview. The therapist finally remarked, "You must have been awfully angry at someone to have done this to yourself," The patient blanched, then brought her hands to her face and started compulsive sobbing, which went on for 15 minutes. Intermittent were outbursts in the form of protestations of how "bad" she was for feeling the way she did about her mother. Ventilation of her resentment produced immediate emotional relief and established sufficient contact with the therapist to start psychotherapy.

Should a suicidal attempt have been made, the immediate injuries will have to be treated and artificial respiration instituted if necessary. If concentrated oxygen is available, it should be given. In asphyxiation with gas or from fumes of an automobile 50 cc of 50 percent glucose, injected intravenously, may help prevent cerebral edema. Intramuscular adrenaline (epinephrine), 0.5 to 1.0 cc of 1:1000 concentration, may also be

administered.

If suicide was attempted with poisons or drugs, identification of these will permit selection of the proper antidote. Patients who are not unconscious and who have not taken corrosives or petroleum products may be induced to vomit by tickling the pharynx with a finger or spoon, and by giving them a glass of water containing 1 tablespoonful of salt or 1 teaspoonful of powdered mustard or soap suds. This should be repeated several times if necessary and followed by a gastric lavage with 1 quart of water containing 1 tablespoonful of (a) "universal antidote," or (b) 2 parts burnt toasts to 1 part strong tea and 1 part milk of magnesia, or (c) table salt. Next, a neutralization of the specific poison with the antidote is attempted and demulcents (flour, starch, gelatin in a paste, or 12 beaten eggs mixed with milk) are given. Finally, the poisons remaining in the intestinal tract are removed by administering magnesium sulfate (Epsom salts: 30 g in a glass of water). Suicidal attempts with barbiturates are handled by inducing emesis, administering "universal antidote," and preventing shock with measures to be described in a later part of this chapter, under Acute Barbiturate Poisoning.

The Telephone Threat

Where a patient telephones the therapist and states that he or she is about to take a lethal dose of medication (or engage in another kind of suicidal act) the therapist should try to keep communication going especially around any incident that has inspired the impulse to die. The patient's name should be repeated to firm up the sense of identity and some constructive action may be suggested as well as a reminder that the therapist wants to help as much as possible, and that others care for the patient and want to help. If the patient has already taken the lethal pills or opened a gas jet the address should be obtained while the patient is kept talking on the telephone. Another person should be dispatched (perhaps by a note written by the therapist during an interval when the patient is talking) to call the police, trace the call if the patient refuses to say where he or she is, and immediately send an ambulance to escort the patient to an emergency room.

PSYCHOTIC ATTACKS

In the course of psychotherapy anxiety may be released that is beyond the endurance of certain patients. A psychotic episode occurring during treatment may be the product of too early or too avid an attack on resistances and defenses in a patient with fragile ego strength. It may be the consequence of a transference neurosis that gets out of control. A good psychotherapist is capable of gauging the ego strength of the patient and of introducing supportive measures should signs of shattering appear. Nevertheless, even good psychotherapists may be unable to control the outbreak of psychosis in vulnerable patients. The quality of the working relationship is a crucial factor. Some therapists are capable of operating sensitively and empathetically with potentially psychotic and even overtly psychotic patients. Other therapists, particularly those who are unable to manage their countertransference, may be unable to work with infantile dependent personality disorders, with borderline, or with psychotic patients. They may have to transfer patients who show tendencies toward psychotic outbursts once the treatment process is under way.

Symptoms that lead one to suspect beginning ego disintegration during psychotherapy are feelings of unreality, depersonalization, excessive daydreaming, ideas of reference, paranoidal ideas, bizarre somatic sensations, motor excitement, uncontrollable sexual and hostile impulses, propensity for perversions, heightened interest in toilet activities, compulsive talking, fears of castration, and fleeting hallucinations and delusions. These symptoms may appear individually or in combination. For a while the patient may maintain a good grasp on reality, recognizing the unusual or irrational nature of his or her ideas, impulses, and acts. Later on, distortions of reality may occur in the form of fixed delusions and hallucinations, perhaps accompanied by panic reactions, suicidal tendencies, and violent aggression. The first step is to identify any immediate stress factor that is upsetting the patient. Is it in the current life situation? If so, the patient should be helped to resolve the problem or to extricate satisfactorily from it. Is it a consequence of what is happening in therapy? Transference reactions are extremely common, and in a patient with weak ego strength this may pitch protective defenses

overboard. Such reactions in stronger patients may be concealed and evidence of them manifested only in acting-out or in dreams. Getting the patient to talk about feelings in regard to the therapist, with proper clarification and interpretation, may restore the patient's equilibrium. It may be necessary to increase the patient's visits during a period of emotional turmoil.

Second, if the precipitating factor cannot be identified, an attempt should be made to get the patient to speculate as to some cause for the trouble. The preferred explanation may then be used as a focus around which interviewing is organized to explore the patient's suppositions or to discover more cogent etiologic factors.

Third, where the support offered through psychotherapy does not restore the patient to an equilibrium in a short time, a neuroleptic drug, like Thorazine (chlorpromazine), Haldol (haloperidol), Stelazine (trifluoperazine), or Permitil (fluphenazine), in proper dosage may be prescribed. Too frequently, inadequate doses of medication are used. A non-medical therapist will have to bring a psychiatrist who knows drug therapy into the picture.

Should a psychotic attack take place it may be handled within the therapeutic situation by a therapist who has a warm feeling for the patient, who is not disturbed by the existing symptoms, and who is capable of modifying the approach so as to bring about the restoration of repressive barriers. The fact that a psychosis has precipitated is usually indicative of something having gone amiss in the therapeutic relationship. If one can admit to oneself the possibility of errors in handling and if one is able to restore the patient's feelings of trust and confidence, such a therapist may be capable of bringing the retreat from reality to a halt. In line with this objective it is best to discontinue probing for conflictual areas and to keep the content of the interview focused on current reality problems. The relationship with the therapist should be kept on as positive a level as possible, the therapist assuming a helpful active role. Under no circumstances should the therapist express alarm at or condemnation toward any of the patient's misconceptions. Listening attentively to the patient's productions, the therapist counters with reality,

suggesting that perhaps things seem to be as they are because the patient has been so upset. If disturbing transference is at the basis of the patient's turmoil, measures to lessen transference, described in Chapters 42 and 46 may be invoked. Should the patient require more support, the frequency of interviews may be increased.

Where these practices fail to bring relief to the patient, it is likely that the therapeutic relationship has deteriorated and the patient may have to be referred to another therapist. The referral can be upsetting to the patient, and he or she is apt to consider it a further manifestation of rejection or an indication of failure. The therapist may explain that the patient's specific problem will probably be helped more by another therapist with a slightly different approach. If the patient is incapable of thinking rationally and if the difficulties are potentially dangerous to oneself and others, a reliable family member should be asked to assume some responsibility in the matter of referral. Should the patient object to the therapist's making contact with the family, the therapist may, if the situation is sufficiently dangerous, have to communicate with the family irrespective of the patient's wishes.

Where self-injury, suicide, homicide, violent aggression, ruinous spending, criminality, or other disasters are possible, hospitalization may be mandatory. If the therapist is a non-medical person, a consulting psychiatrist should be called in. Discussion may convince the patient to enter an institution voluntarily. Hospitalization will, however, have to be accomplished against the wishes of the patient where one is dangerous to oneself or others and sees no need for confinement. In the event that one is actively resistant and must be hospitalized, intravenous sodium Amytal to the point of deep sleep will permit transport to an institution without the need for physical restraint. A physician should be in attendance in the ambulance that transports the patient in order to handle such emergencies as respiratory paralysis.

The therapist will have to arrange the details of hospital admission in cooperation with the patient's family and, in addition, may have to explain the reasons for hospitalization to them in a reassuring way. In doing this, the therapist may experience

some guilt and anxiety, as if accountable for the patient's collapse. It is important, however, not to castigate oneself for what has happened nor to confess to failure; rather, the family may be informed that the patient's personality structure has been unable to stand inner tensions and that the patient has temporarily broken down. A period of hospitalization is necessary to restore equilibrium.

The specific treatment rendered in the hospital will depend on the severity and type of psychosis. In acute excitement or depression with exhaustion it will be necessary to sedate the patient adequately, to correct dehydration by injecting fluids and salts parenterally, and to administer electroconvulsive therapy or intensive drug therapy, whichever is indicated. In milder excitements or depressions sedatives and hospitalization alone may suffice to restore the patient's stability. It is important that the person assigned to look after the patient avoid arguing with or "psychoanalyzing" the patient, no matter what the provocation, since this will upset the patient even more.

Postoperative reactions after extensive surgery are not uncommon and probably occur in persons who have been maintaining a tenuous emotional homeostasis. For example, a considerable number of cases of psychosis have been reported following open heart surgery. Even in less major procedures, a temporary massive outbreak of pathology (brief reactive psychoses) may occur in unstable personalities. One sees this in some patients receiving hemodialysis for chronic kidney failure. The clinical picture in postoperative reactions will vary, syndromes may resemble organic brain upsets (confusion, disorientation, memory loss), acute schizophrenia (delusions, hallucinations), or affective disorders (depression, agitation, mania).

EXCITEMENT, OVERACTIVITY, AND ANTISOCIAL BEHAVIOR

States of excitement and overactivity developing during psychotherapy are signs of acting-out or manifestations of ego shattering.

During acting-out the patient may engage in destructive, antisocial, or unusual sexual behavior. In attempting to understand acting-out, one's first suspicion is that the

patient is protecting the self from awareness of transference by projecting it away from the therapist. Hostile or aggressive outbursts, delinquency, criminality, marked promiscuity, and perverse sexuality are often products of hostile and sexual impulses toward the therapist that the patient is unable to acknowledge. It is natural to react emotionally when a patient becomes antagnostic toward the therapist. Counteraggression, even though verbal, will only stir the patient up more. Recognizing one's own fear of violence, as well as the pot of anger one may be trying to control that always seeks some kind of release is vital. One should try to get the patient to verbalize anger and outrage without being judgmental and without trying to justify untenable conditions against which the patient is rebelling. If the patient's reaction is an aspect of negative transference, this may be interpreted, but the patient should not be made to feel guilty for his or her behavior. If the patient is responding to some outside stimulus, one should ask oneself: "How would I feel if I were in the patient's situation?" Since the other side of violence is fear, one should try to find out what frightens or upsets the patient and try to act empathic, supportive and reassuring. A simple statement such as "I don't blame you for being upset," may do much to quiet the patient. By acting composed, the therapist may be able to calm the patient. If fear is shown, this may engender more fear and violence in the patient.

MANAGING DANGEROUS PATIENTS

When a patient is being treated who makes a substantial threat against an identifiable third person, the therapist should first assess the degree of dangerousness and possibilities of acting-out as indicated by past history and present lack of impulse control. Then if violence is felt to be possible, a course of action to protect potential victims should be evolved. Documenting one's decisions in the case record is important. It may be that hospitalization, medication, and intensified psychotherapeutic interventions will eliminate the possibility of actualizing the threat. Non-medical therapists should seek the help of a psychiatrist where a dangerous situation impends. In some cases, confidentiality will have to violated and the intended victim notified. A considerable literature has accumulated around the California Tarasoff case (Appelbaum, 1985; Beck,

1982; Monahan, 1981; Dix 1981; Stone, 1976) that initiated the ferment about dangerousness in patients.

The best way to resolve acting-out is to explore the patient's feelings and attitudes toward the intended victim, to determine which of these are rooted in realities and which are irrational carryovers from the past, and to see if concealed transference is at the basis of the patient's aggression. As long as the patient is unaware of and cannot verbalize proclivities toward the therapist, the patient will continue to "blow off steam" outside of therapy. Skillful use of the interviewing process that brings out verbalizations related to the transference may put a halt to the patient's destructive patterns.

Sometimes it is difficult or impossible to get the patient to analyze transference and in this way to terminate acting-out. The therapist here may attempt to deal with this obstruction by (1) stimulating transference, through devices already described, in order to make its manifestations so obvious that the patient cannot help but talk about his or her feelings, or (2) controlling acting-out by increasing visits to as many as daily sessions and by the assumption of a prohibitive, authoritative role. If these measures fail to help the situation, therapy will have to be terminated with transfer to another therapist.

Excitement and antisocial behavior that occur as a result of ego shattering may be dealt with after identifying the cause of the present difficulty. A struggling patient may have to be restrained and 5 mg of Haldol injected into the nearest available muscle. Rapid neuroleptization may be essential (Schwarcz, 1982). Supportive techniques are generally indicated, and the patient may have to be put on a regimen of Haldol (2-5 mg), Thorazine (25-100 mg), or Valium (10 mg), repeated at intervals until adequate sedation occurs. If the decline continues, the therapist had best transfer the patient to another therapist, since the therapist is probably unable to control the situation. Where a dangerous psychotic condition develops, the patient's family will have to be apprised of it, for hospitalization will in all likelihood be necessary. Where violent rages or excitement continue, an organic cause such as temporal lobe lesions including epilepsy should be ruled out. It is not usual that a dangerously disturbed or assaultive patient will have to be

handled in one's office, but if this is unavoidable common sense dictates that the therapist should be reasonably protected. This means that where a patient is potentially dangerous to oneself or to others, he or she should be sent to a hospital or place where adequate treatment can be given and protection is available if necessary. In emergency units in general hospitals, sufficient personnel should be available to restrain the patient, (at best four accessory persons are needed, one for each limb should restraint be essential) The attitude of the therapist is a most important factor, an easygoing, calm manner being reassuring for a patient. Since most violence is a consequence of fear, a quiet, secure atmosphere surrounding the consulting room is desirable. Angry threats directed at a disturbed patient merely aggravate the fear and create further violence. More can be accomplished with calming demeanor than with drugs, which, of course, also should be administered where necessary. Once communication is established with the patient and the patient has confidence that he or she will not be hurt, psychotherapy may be possible under the usual office conditions.

INTENSE ANXIETY ATTACKS

Severe anxiety sometimes breaks out in the course of psychotherapy. It may become so overwhelming that the patient feels helpless in its grip. One's coping resources have seemingly come to an end, and one can no longer crush the fear of imminent disintegration. Demands on the therapist then may become insistent, and the patient will bid for protection and comfort.

The handling of intense anxiety reactions will require much fortitude on the part of the therapist. By assuming a calm, reassuring manner, the therapist provides the patient with the best medium in which to achieve stability. Accordingly, the therapist will have to tolerate the emotions of the patient, conveying a feeling of warmth, understanding, and protectiveness while respecting the patient's latent strengths that have been smothered by the turmoil. Upbraiding the patient for exhibiting foolish fears and attempting to argue away anxiety serve to stimulate rather than to reduce tension.

The best means of handling acute anxiety is to permit the patient to verbalize freely

in an empathic atmosphere. Helping the patient to arrive at an understanding of the source of the anxiety, whether it be environmentally oriented or rooted in unconscious conflict, transference, resistance, or the too abrupt removal of existing defenses, promises the quickest possibility of relief. The triad of emotional catharsis, insight, and reassurance operates together to permit of a reconstitution of defenses against anxiety.

Where anxiety is intense, it is usually impossible to work with the patient on an insight level. Here, supportive measures will be necessary to restore the habitual defenses. If the patient is living under intolerable environmental circumstances, a change of environment may be indicated to lessen harsh pressures on him. In the event that anxiety has followed intensive mental probing, a holiday from exploration may be necessary, with a focusing on casual or seemingly inconsequential topics. A patient who has spent many sleepless nights tossing about restlessly or, once asleep, has awakened periodically with frightening dreams may benefit from a benzodiazepine like Valium (5 or 10 mg) orally. In highly disturbed patients 10 mg of Valium intramuscularly or intravenously may be given. The use of sedatives during the day is to be minimized, if possible, to forestall the sedative habit. If anxiety continues, the frequency of sessions may be increased and the patient may be assured that he or she can reach the therapist at any time in the event of a real emergency. Referral to an experienced psychiatrist skilled in the somatic therapies may be necessary.

Excessive anxiety in psychoneurotic patients is best handled psychotherapeutically, increasing the frequency of sessions if necessary. Where this fails to bring relief, several sessions devoted to "narcosuggestion." that is, reassurance and suggestion under intravenous Pentothal or Amytal (see Narcotherapy, Chapter 56), may be tried. Oral Librium (25 mg, 3 to 4 times daily) or Valium (10 mg, 3 to 4 times a day) may restore the individual's composure, following which the drugs are diminished, then discontinued. Where anxiety is out of control and constitutes an emergency, 50 to 100 mg of intravenous Librium, repeated in 4 to 6 hours if necessary and followed by oral Librium, may be helpful. Some patients respond better to barbiturates than to tranquilizers. In acute anxiety pentobarbital (Nembutal) ¾ to 1½ gr, or secobarbital (Seconal) ¾ to 1½ gr may

dissipate symptoms in about 30 minutes. Some patients prefer to take ¼ to ½ gr of phenobarbital sodium every 3 or 4 hours. Barbiturate administration is to be halted as soon as possible because of the danger of habituation.

In borderline or psychotic patients it is wise to institute drug treatments immediately. Haldol, Thorazine, or Mellaril in adequate dosage (see Table 56-3) may bring anxiety to a halt.

These measures will rarely fail to control severe anxiety in borderline or psychoneurotic patients. In the rare case where they fail, and especially where a transference neurosis is present and cannot be resolved, the patient may have to be referred to another therapist or a short period of hospitalization may be required.

PANIC STATES

The treatment of panic states is more difficult than the management of anxiety. Here the patient is victimized by a wild, unreasoning fear that plunges one into disorganized thinking and behavior or drives one to the point of immobilization. Suicide is always a grave possibility. Admission to an emergency unit in a hospital may be essential, the therapist giving the admission doctor pertinent information about the patient.

Where a patient in panic is seen for the first time, the therapist will be somewhat in a dilemma. The initial step in the management of a panic state with a strange patient is attempting to promote calm by quiet, empathic listening in a quiet atmosphere. Thereafter prescribed a tricyclic antidepressant or MAO inhibitor may be all that the therapist may want to do at the moment. Reassuring the belligerent individual that one is belligerent because one is frightened may have a dramatic effect. Often lit-tie more will be needed than to display interested attention and to express sympathy at appropriate times. Sorting out the problem in this way will give the therapist clues about appropriate therapeutic steps to take, whether medication or hospitalization necessary (emergency units unfortunately do not usually have a secluded place where quiet interviewing can take place). Where the patient is out of contact with reality, is suicidal, or is aggressively

excited, however, he or she will require rapid sedation or tranquilization and probably hospitalization.

Diagnosis is important. The patient may be psychotic as a result of a functional ailment like schizophrenia. Or the patient may be manifesting a toxic psychosis as a result of taking too many drugs or because of a physical ailment. Giving the patient more medication in the latter instances will merely compound the injury. Information about the patient from relatives or friends is highly desirable, even indispensable, in ruling out drug intoxication or physical ailments, such as cardiovascular illness, diabetes, etc., that may be responsible for delirium.

If drug intoxication is ruled out, drug therapy is the treatment of choice for schizophrenic or manic excitements. Rapid tranquilization is indicated to reduce social consequences of morbidity. Not everybody agrees with this, however. In young schizophrenics who are having a first attack there are some who believe that they should be allowed spontaneously in a protected environment to reach a baseline. Thus, Mosher and Feinsilver (1973) state, "We believe that the inner voyage of the schizophrenic person, which is induced by environmental crisis, has great potential for natural healing and growth, and we therefore do not attempt to abort, rechannel, or quell it before it has run a natural course." Whether one heeds this advice or not will depend on the existing social support systems on which the patient will depend. A congenial hospital regimen with empathic nurses and attendants is helpful. On the other hand, and particularly in older patients or those who have had a previous minimum absence from work and their families, it may be vital to avoid prolonged disability and unemployment which can operate as stress factors after the schizophrenic episode is over.

Restoration to a non-psychotic state is possible within a few hours employing powerful neuroleptic drugs that act on the limbic system and influence the psychotic thinking process. The drug often chosen is haloperidol (Haldol) given intramuscularly. The first dose is 5 mg, then 2-5 mg every 30 minutes until the patient is sedated; the blood pressure should be monitored to avoid hypotension. The objective is to get the maximum

therapeutic impact with a minimum of side effects (dystonia, akithesia, and other Parkinsonian symptoms). If the patient falls asleep after the first 5 mg injection, he or she is probably suffering from a toxic psychosis like drug intoxication (e.g., alcoholism), and Haldol is stopped.

Some therapists still prefer chlorpromazine (Thorazine) which is given intramuscularly in 25 to 75 mg dosage according to the size of the patient and degree of disturbance. If the systolic blood pressure standing is below 95, the Thorazine is discontinued; the patient's head is lowered and the feet elevated. If the blood pressure is maintained satisfactorily, the drug is given every hour until control of the excitement is achieved. The dosage is either increased or decreased depending on how the patient responded to the previous dose. The intramuscular medication is discontinued should the patient fall asleep or quiet down sufficiently. The choice of being subsequently seen on an outpatient basis or immediately hospitalized will depend upon whether the patient is dangerous to oneself or others, the attitude of the family, hospital resources in the community, and the patient's cooperativeness.

What dosage of drug orally for ensuing 24-hour periods will be required can be estimated by multiplying the intramuscular dosage of Thorazine that it has taken to tranquilize the patient by 2⅔ (Ketal, 1975). With Haldol one may give the same dose orally as was given intramuscularly. If the patient is too sedated, this can be reduced. Patients should be seen daily or every other day to make sure that they do not slip back.

Drowsiness and hypotension with Haldol are less than with Thorazine. Extra-pyramidal side effects are more common, however. Where such side effects occur with Haldol or other antipsychotic drugs, 1 to 2 mg of Cogentin by mouth (or intravenously if emergent) or 50 mg of Benadryl by mouth or intravenously may be given. Continuance of the drug for several days is indicated. Reassurance of the patient and the family are important. To avert the pyramidal symptoms, some therapists give Cogentin prophylactically, but others do not recommend this.

Where intramuscular injection is not possible or urgent, oral medications are used.

Here 10 to 20 mg of Haldol may be given in liquid concentrate form for the first day; if no response, this is raised to 40 mg the second day and 60 mg the third day until an effect is achieved. Or Thorazine in liquid concentrate form of 50 to 150 mg dose may be given and regulated according to response.

Intravenous sodium Amytal (up to 15 gr) will put the patient into narcosis. If panic continues following this, the patient may require hospitalization on a closed ward. Electroconvulsive treatments will also often interrupt the excitement. As many as 2 ECTs daily may be needed for a few days, followed by one treatment daily, until equilibrium is established. Where delirium and confusion appear in elderly patients or those with respiratory and cardiovascular disorders, Thorazine may be given for restlessness and paraldehyde or chloral hydrate for insomnia. Should epileptic seizures develop and continue (status epilepticus), intravenous sodium Amytal, phenobarbital sodium parenteral, or diphenyl hydantoin (Dilantin) may be administered.

In hospital settings "sleep therapy" is occasionally instituted, especially in psychotic patients, where panic cannot be arrested through other means (Azima, 1958). Here sleep, which lasts 20 to 24 hours a day, is induced by giving the patient a combination of 100 mg (1.5 gr) Seconal, 100 mg Nembutal, 100 mg sodium Amytal, and 50 mg of Thorazine. The patient is aroused three times daily, and the dosage of medication is regulated according to the degree of wakefulness. Good nursing care is urgent; indeed, without it sleep therapy is hazardous. During the waking period the pulse rate, blood pressure, temperature, and respiration are recorded; the patient is gotten out of bed, washed, and fed. Daily 2000 cc of fluid and at least 1500 calories in food are supplied, while vitamins are administered parenterally. A half-hour prior to meals 5 units of insulin are injected to stimulate the appetite. Milk of magnesia is supplied every other day if necessary, and a colonic irrigation is given should a bowel movement not occur in 2 days. Catherization is performed if the patient does not urinate for 12 hours. The bed position of the patient must be changed every 2 hours, and should the patient's breathing become shallow, oxygen and carbon dioxide are administered. Sometimes ECT is instituted with sleep therapy, either daily during the first waking period or three times weekly. In this way a deep regression is

induced. The average treatment duration is 15 to 20 days. Rehabilitative therapy must follow the sleep-treatment episode.

In manic reactions, after the acute psychotic disturbance is brought under control, lithium therapy may be started. Where panic has occurred as a result of battle conditions or civil catastrophes, a withdrawal from the stressful situation for a few days may be necessary. This should not be prolonged to avoid chronicity in cases where the patient will have to function in an unstable atmosphere.

Once the panic state has subsided psychotherapy is essential to forestall further attacks.

TOXIC DRUG PSYCHOSES

Mixed drug intoxications are common and may constitute important emergencies. It is difficult, if not impossible, to determine what substances the patient has imbibed since even he or she may not know their true nature, purchased as they have been from dubious sources. Knowledge of the local drug scene may be of some help, at least in screening out certain possibilities. The kinds of drugs utilized vary in different parts of the country. They include amphetamine, barbiturates, meprobamate, alcohol, phencyclidine, THC, nonbarbiturate hypnotics (like Doriden, Quaalude), marijuana, morning glory seeds, nutmeg, LSD, mescaline, codeine, DMT, STP, MDA, psylocybin, and a variety of mescaline and amphetamine combination compounds.

In many cases adequate therapy can be administered only in a hospital, which unfortunately may not provide the quiet, relaxed atmosphere that excited patients need. Gastric lavage is limited to instances where the drug was recently taken. After a number of hours it is relatively useless. Hemodialysis is valuable for certain drugs and not for others. In all cases maintenance of an airway, of respiration, and of the cardiovascular apparatus is fundamental.

If the nature of the drug that has been taken is known, for example, from the blood

or urine analysis, it may be possible to prescribe certain antagonistic medicinal agents. Thus, if amphetamine is the culprit, Thorazine or other neuroleptic or antipsychotic drugs can be given. If the patient has taken STP or LSD, antidotes may block some sympathomimetic effects without influencing the hallucinogenic aspects. As yet there is no totally effective antagonist for these hallucinogens. Indeed, Thorazine is contraindicated in STP toxicity because of the hypotensive and convulsive potentiating effect, which can be dangerous. Mildly excited patients may respond to a mild tranquilizer like Valium given parenterally.

Global nystagmus is a frequent symptom in drug psychosis and may serve as a valuable diagnostic indicator. Disorientation, confusion, and hallucinations are common, of course. Because, in the average toxic patient, the kinds of drugs that the patient has been taking are difficult to diagnose, it is best to err on the side of caution in administering antipsychotic drugs. Some of the effects of the substances the individual has been taking, like THC (the pure extract of marijuana), may be reinforced by antipsychotics. After reassuring the patient that recovery will soon occur, he or she may be given 10 to 20 mg of Valium intramuscularly. If there is no improvement in the patient after a few hours and no anticholinergic symptoms, such as a lowering of blood pressure and rapid pulse, a major antipsychotic, such as 5 mg of Haldol or 4 mg of Navane or Trilafon, may be given. These drugs have a marked antipsychotic effect without too great sedation. Where an opiate drug is suspected, an airway is introduced, the heart monitored, fluids introduced intravenously with 50 cc of 50 percent dextrose, 2 mg of naloxone (Narcan) and 100 mg thiamine.

Handling the "Bad Trip"

Individuals experimenting with hallucinogenic drugs, including marijuana and amphetamines, may occasionally experience a frightening journey away from reality and need emergency intervention. In the street vernacular such an experience is referred to as a "bad trip." Hallucinations may be vivid, and there may be an inability to communicate. Such reactions may be inspired by an overdose of drug or may be the consequence of

something frightening that the patient perceives or imagines in the environment or even may occur with small dosage in schizophrenic patients. The atmosphere in which the "bad tripper" is treated is important. It should be as quiet as possible. Sending the person to an emergency hospital unit may induce more panic. The therapist or person managing the patient should be reassuring and gentle and never question the patient about the experience, for this may tend to stir the patient up. One should be asked to concentrate one's attention on something in reality, like an object in the room, in order to shift the focus from one's inner life. Rarely are physical restraints or drugs necessary, except when the patient becomes violent. Valium (10 mg intramuscularly, repeated if necessary) is helpful in the latter instance.

The treatment of severe amphetamine psychosis is similar to that of schizophrenic psychosis, namely, prescribing Thorazine or Haldol intramuscularly. In the case of LSD, psylocybin, or marijuana intake with a psychotic-like response, the therapist should stay with the patient while reassuring that the reactions are temporary and will pass in a few hours. Valium (5-10 mg) or Librium (25-50 mg), or a short-acting barbiturate, may be helpful. Where not successful and panic increases, Thorazine intramuscularly may be utilized with all of the precautions outlined under the section on Panic States. Great caution must rule the use of phenothiazines because of the danger of lowering the blood pressure too much, especially where phencyclidine (PCP) has been ingested. In the event of overdose of sleeping medications containing scopalamine, Thorazine should be avoided. Valium may be utilized as may physostigmine (2-4 mg).

The most frightening consequence of a toxic drug absorption is a status epilepticus, a constant series of seizures without the patient regaining consciousness in between. Here one must establish an adequate airway, particularly being sure that the patient's tongue does not block respiration. Diazepam (Valium) 5 to 10 mg intravenously followed by 200-400 mg of phenobarbital intravenously, or reinjecting Valium alone every 10 to 15 minutes for up to one hour (maximum of 40 mg per hour for adults). Phenobarbital (100-200 mg intramuscularly) is also commonly utilized after a single seizure to prevent status epilepticus. It may be given intravenously (200-400) very slowly. A respirator should be

available in the event respiration stops. Phenobarbital may thereafter be given intramuscularly (100-200 mg) every 2 to 6 hours up to 1 g of the drug in 24 hours. The next day the patient may be started on Dilantin (200 mg intramuscularly).

Acute Alcoholic Intoxication

Pathological intoxication sometimes presents itself as a psychiatric emergency. The reactions range from stupor or coma to excited, destructive, combative, homicidal, or suicidal behavior. Comatose states are best treated in a hospital where a neurological study may be made to rule out other causes of unconsciousness, such as apoplexy, brain concussion, status epilepticus, cerebral embolism or tumor, subdural hematoma, toxic delirium, uremic or diabetic coma, and carbon-monoxide or morphine poisoning. Where alcoholic intoxication exists, a hospital with a 24-hour laboratory service permits of the testing of blood sugar and carbon-dioxide levels required for the administration of insulin and dextrose. Nursing care is important. The patient must be turned from side to side regularly and the head lowered to prevent aspiration pneumonia. The pulse, respiration, and blood pressure are recorded every half hour. Oxygen is given by tent or nasal catheter where respiration is depressed. Intravenous sodium chloride should be injected in amounts of 250 cc every 3 or 4 hours.

Where the patient is conscious and gag reflexes are present, a gastric lavage may be provided, external heat applied, and strong coffee administered by mouth or rectum. Intramuscular caffeine and sodium benzoate (0.5-1.0 g) may be dispensed every hour until the patient is alert. Intravenous dextrose solution (100 cc of 50 percent dextrose) may be introduced and repeated, if necessary, every hour, and 10 to 20 units of insulin may be provided, repeated in 12 hours. Thiamine hydrochloride (100 mg) intravenously is also a useful medicament.

Excited reactions, including acute alcoholic intoxication, alcoholic hallucinosis, and delirium tremens are treated by intramuscular injection of Haldol (5 mg), or Navane or Trilafon (4 mg), or Thorazine (25-50 mg) repeated if necessary. Many psychiatrists use Librium intramuscularly or intravenously (50-100 mg) or Valium (10-20 mg) repeated, if

necessary, in 2 to 4 hours, for alcoholic agitation and impending or active delirium tremens or hallucinosis. Dextrose (100 cc of a 25 percent solution), thiamine hydrochloride (100 mg), and 20 units of insulin are given routinely. Morphine and rapid acting hypnotics (Nembutal, Seconal) are contraindicated; however, sodium Amytal (0.5-1.0 g) is sometimes administered intravenously (1 cc per minute) to quiet a violently disturbed patient. Ample fluids should be given intravenously to combat acidosis and dehydration (approximately 3000 cc daily, containing magnesium and potassium minerals). Other drugs include thiamine hydrochloride (20-50 mg), intramuscularly, and nicotinamide (niacinamide, 100 mg), intravenously, substituted in several days by oral thiamine hydrochloride; vitamin C (100 mg), caffeine and sodium benzoate (0.5 g every 4 to 6 hours for 4 to 6 doses) for stimulation, saline laxatives to promote proper elimination, and Compazine (10 mg intramuscularly) for uncontrollable nausea and vomiting. Milk and eggnog may be offered the patient; if not tolerated, 10 percent dextrose and sodium chloride solution intravenously may be required. The need to protect the patient from convulsions is urgent in delirium tremens and here anticonvulsant therapy (e.g., diphenylhydantoin) may be necessary.

Acute Barbiturate Poisoning

The popularity of barbiturates as sedatives has resulted in a relatively large incidence of barbiturate poisoning. Patients who have developed a sedative habit may accidentally take an overdose of barbiturates, or the drugs may be purposefully incorporated with suicidal intent. Sometimes the patient, having swallowed a lethal dose, will telephone the therapist informing of his or her act. At other times relatives or friends will chance on the patient before respiratory paralysis has set in.

The usual therapy consists of immediate hospitalization, if possible, and the institution of the following measures:

1. Establishing an airway, such as with an endotracheal tube with suction of secretions.

2. Administration of oxygen, or artificial respiration if necessary, using a

mechanical resuscitator.

3. Early gastric lavage carefully administered.

4. Fluids given parenterally (5 percent glucose); in extreme hypotension, plasma injected intravenously.

5. Stimulants—vasopressors like Neosynephrine (2-3 mg) if blood pressure is low or L-norepinephrine (4 mg/L of 5 percent glucose solution).

6. Turning the patient hourly with head slightly lower than feet. (Trendelenburg position)

7. Catherization of the bladder if necessary.

8. Prophylactic antibiotics.

9. Hemodialysis with an artificial kidney, if available, or peritoneal dialysis.

10. Digitalis for heart failure.

11. Avoidance of analeptics.

Clemmesen (1963) has described the treatment of poisoning from barbiturates in Denmark, where the incidence of attempted suicide has always been relatively high. A special intoxication center helps control the clinical condition day and night. The pulse, respiration, temperature, blood pressure, and hemoglobin are monitored every 2 or 4 hours; each day the barbiturate acid content of the blood is determined, as is plasma chloride and bicarbonate, blood urea, and serum protein. The gastric contents are *not* aspirated unless the drug was taken within the past 4 or 5 hours, and the pharyngeal and laryngeal reflexes are present. Gastric lavage is avoided. The Trendelenburg position is maintained during the first few days to prevent aspiration of gastric contents. Patients are moved to a different position in bed every 2 hours. There is intensive slapping of the chest and suction of secretion from the air passages. Procaine penicillin (2 million units x 2) are injected each day as a prophylactic against infections. Fluids of 2-3 L are given parenterally. Shock, if present, is managed by blood transfusion and perhaps by drugs such as norepinephrine. Complications, such as pulmonary edema, pneumonia, and

atalectasis are treated. Stimulation with analeptics is avoided. In the absence of pronounced hypotension, pulmonary edema, and reduced renal function, after the clinical condition is under control, osmotic diuresis and alkalinization by infusions of urea and electrolyte solutions reduce the duration of coma two to four times. Of 92 patients with severe barbiturate poisoning, 85 recovered with this treatment approach.

Poisoning from overdose of nonbarbiturates or tranquilizers like the benzodiazepines, may be managed in essentially the same way, although these drugs are somewhat safer than barbiturates. Amphetamine and pressor amines are contraindicated, although norepinephrine may be given. Should inordinate restlessness or tonic and clonic convulsions follow excessive phenothiazine intake, careful administration of sodium Amytal may be helpful, recognizing the potentiation possibility. Cogentin or Artane may also be valuable.

SEVERE PSYCHOSOMATIC SYMPTOMS

There are a number of psychosomatic symptoms for which the patient initially seeks treatment, or that develop suddenly in therapy, that may be regarded as emergencies. Most of these are hysterical conversion or dissociative reactions, such as blindness, seizures, fugues, vomiting, aphonia, amnesia, paralysis, astasia-abasia, violent contractures, and anorexia nervosa. The patient may be so disabled by the symptom that he or she will be unable to cooperate with any attempted psychotherapeutic endeavor. Immediate removal of the symptom may thus be indicated. Such removal need not block the later use of more ambitious therapeutic measures. In the course of symptom removal, efforts may be made to show the patient that the symptoms are rooted in deeper personality problems, the correction of which will necessitate exploration of conflictual sources.

Hypnosis is an ideal adjunctive technique to expedite the emergency relief of hysterical symptoms. Once symptom removal has been decided upon, it is necessary to determine whether to attempt the removal at one session or whether to extend therapy over a period of several weeks. The severity of the symptom, its duration, the nature of the

patient's personality, and the aptitude for hypnosis have to be considered. The approach is an individual one, and suggestions must be so framed that they will conform with the patient's personality, the type of symptom, and its symbolic significance. It is essential to adapt one's language to the patient's intelligence and education. Many failures in symptom removal are due to the fact that what the hypnotist is trying to convey is not clearly understood by the patient.

If hypnotic removal of the symptom at one session is decided upon, sufficient time must be set aside to devote oneself exclusively to the problem. As many as 2 to 3 hours may be necessary. A new patient may be encouraged to discuss past history and symptoms in order for the therapist to determine the patient's reaction to the illness as well as to gain clues to the patient's attitudes, motivations, and personality structure. Accenting of the patient's protestations of how uncomfortable he or she is, the therapist may emphasize that there is no reason why, if the patient has the motivation, the symptom cannot be overcome.

An optimistic attitude is important because many patients are terrified by their illness and have convinced themselves of the impossibility of cure. However, a cure should not be promised. The patient may be told that hypnosis has helped other people recover and that it can help him or her, too, if one will allow oneself to be helped.

The patient may be informed that it is necessary to test individual responses to suggestion; there is no need to concentrate too hard on what is said because, even though attention wanders, suggestions will get to the subconscious mind and produce desired reactions. An urge to rid oneself of suffering stimulates the desire to relax and follow suggestions. No indication is given the patient at this time that the symptom will be removed in its entirety, since the symptom may have hidden values and resistance may occur if the patient suspects that its immediate loss is at hand.

Hypnosis is then induced, and confidence in the ability to follow suggestions is built up by conducting the patient through light, medium, and, finally, if possible, deep trance states. Where the patient has a symptom that consists of loss of a physical function, it may

be expedient to suggest that the therapist does not want the patient now to use the part. This is done in order to associate malfunction with the hypnotist's command instead of with a personal paralysis.

The next step in treatment is to get the patient, if so desired, to discuss under hypnosis reactions to the illness and what is happening in the immediate life situation.

In some patients active participation is encouraged. A reasonable explanation is given for the suggestions that will be made. The patient may even be encouraged to veto suggestions should there be any suspicion that they are against one's best interests or if there is no real desire to follow them. Active participation is encouraged in patients with relatively good ego strength who shy away from too authoritarian an approach.

Symptom removal by suggestion is far more effective where it is demonstrated to the patient that one has not lost control over one's functions, and hence is not the helpless victim of symptoms that cannot be altered or removed. This is achieved by showing the patient, while in a trance, that it is possible to create on command such symptoms as paralysis, spasticity, and anesthesia. Once the patient responds to these suggestions the important influence that the mind had over the body is stressed. Then a symptom identical with the patient's chief complaint is suggested in some other part of the body. Should the patient respond successfully, a partial removal of the symptom in the original site is attempted. For example, where there is a paralyzed arm, the suggestion is made that the fingers will move ever so little. Then paralysis of the other arm, which has been artificially produced, is increased in intensity, while a strong suggestion is made that the patient will find that function is restored to the ailing part. In the case of a paralyzed arm it is suggested that the hand will move, then the arm, and, finally, that the paralysis will disappear altogether.

The fact that symptoms can be produced and removed so readily on suggestion may influence the patient to accept the fact that one is not powerless and that one can exercise control over the body.

In order to protect the patient, should the symptom have a defensive function, some residual symptom that is less disabling than the original complaint can be suggested. It is hoped that the residual symptom will take over the defensive function. For instance, in the case of a paralyzed arm, paralysis of the little finger may be induced, and a suggestion may be given the patient that the finger paralysis will have the same meaning as the arm paralysis and that the finger paralysis will remain until the patient understands fully the reasons for the original paralysis and no longer needs the paralysis. In the event of an extensive anesthesia, numbness of a limited area may be suggested as a substitute.

Posthypnotic suggestions are next given the patient to the effect that the restored functions will continue in the waking state, except for the induced residual symptom. An activity may then be suggested that brings into use the ailing part; the patient finally being awakened in the midst of this action.

These suggestions are repeated at subsequent visits, and, if desired, the patient is taught the technique of self-hypnosis so that suggestive influences may continue through one's own efforts.

Although removal of the patient's symptom at one sitting may be possible and desirable in certain acute disabling hysterial conditions, it is usually best to extend therapy over a longer period. Suggestions are carried out very much better where the patient is convinced that one has been hypnotized and that hypnosis can have a potent influence on one's functions. It may, therefore, be advisable to delay giving therapeutic suggestions until the patient achieves as deep a trance as possible and gains confidence in the ability to experience the phenomena suggested. The employment of therapeutic suggestions at a time when the patient lacks confidence in his or her ability to comply, and where faith in the therapist is not sufficient may end in failure and add discouragement and anxiety to the patient's other troubles.

A deep trance seems to increase therapeutic effectiveness in most patients. Where only a light trance is possible, the patient may not be able to get to a point where he or she becomes assured of the capacity to control the symptom.

All suggestions must be as specific as possible and should be repeated several times. The therapist should build, as completely as possible, a word picture of what the patient is supposed to feel or to do.

The lighter the trance, the less emphatic should the suggestions be. In extremely superficial hypnotic states the patient may be instructed that there is no need to concentrate too closely on the suggestions of the therapist, but rather to fixate attention on a restful train of thought. This technique is based on the idea that the patient's resistances can be circumvented. A logical explanation may be presented of why suggestions will work, along such lines as that the mind is capable of absorbing and utilizing suggestions even though some resistance is present.

If the patient is in a medium or deep trance, suggestions should be framed as simply as possible. The patient, especially when in deep hypnosis, should repeat the suggestions to be followed. Otherwise the therapist will not know whether the commands have been understood. Somnambules, may be instructed to carry out instructions even though they do not remember that these were formulated by the therapist. It is also a good idea in somnambulistic patients to give them a posthypnotic suggestion to the effect that they will be unresponsive to hypnotic induction by any person except the therapist. This will prevent the patient from being victimized by an amateur hypnotist who may very well undo therapeutic benefits.

If facts important in the understanding of the patient's condition are uncovered in hypnosis, these may or may not be brought to the patient's attention, depending upon their significance and upon the ability of the patient to tolerate their implications. It is best to make interpretations as superficial as possible, utilizing knowledge one has gained in working with the patient to guide him or her into activities of a creative nature that do not stir up too much conflict.

Termination of hypnosis by having the patient sleep for a few minutes before interruption is advantageous. The patient is instructed to continue to sleep for a designated number of minutes, following which he or she may awaken. The period of

sleep may range from 2 to 15 minutes. Where the patient is able to dream on suggestion, this period may profitably be utilized to induce dreams either of a spontaneous sort or of a nature relevant to the particular trends elicited during the trance.

There is no set rule as to how much time to devote to hypnosis during each session. Except for the initial induction period, the trance need not exceed one-half hour. Ample time should be allowed to take up with the patient problems both before and after hypnosis. Reaction to the trance may also be discussed. Prejudice against symptom removal continues in force. On the whole, it is unjustified. Needless to say, more extensive psychotherapeutic measures will be necessary to insure lasting relief.

INTERCURRENT INCURABLE SOMATIC ILLNESS

The incidence of an intercurrent incurable physical illness constitutes an emergency in some patients. Development of certain conditions, such as multiple sclerosis, brain tumor, Hodgkin's disease, cancer, cerebral hemorrhage or thrombosis, or a coronary attack, will make it necessary for the therapist to take stock of the reality situation and perhaps to revise therapeutic goals. Essential also is a dealing with the emotional impact of the intercurrent illness on the individual. Insight therapy may have to be halted, and supportive approaches implemented.

Where the person is suffering from a nonfatal illness and where there is a possibility of a residual disability, as in coronary disease, apoplexy, tuberculosis, and various neurologic disorders, an effort must be made to get the patient to accept the illness. A desensitization technique may be utilized, encouraging the patient to discuss the illness and to ventilate fears concerning it. The need to recognize that this illness does not make one different from others, that all people have problems, some of which are more serious than one's own, that it is not disgraceful to be sick, may be repeatedly emphasized.

Persuasive talks may be given the patient to the effect that the most important thing in the achievement of health is to admit and to accept the limitations imposed on one by one's illness. This need not cause the patient to retire in defeat. One will still be able to

gain sufficient recognition and success if one operates within the framework of the handicap. It is most important for self-respect that one continue to utilize remaining capacities and aptitudes, expanding them in a realistic and reasonable way. Many people suffering from a physical handicap have been able to compensate for a disability in one area by becoming proficient in another.

In patients who tend to regard their disability as justifying a completely passive attitude toward life, an effort must be made to stimulate activity and productiveness. The dangers of passivity and dependency, in terms of what these do to self-respect, are stressed. The person is encouraged to become as self-assertive and independent as the handicap will allow.

Where it is important for the patient to relax and to give up competitive efforts, persuasive or cognitive therapy may be combined with a reassuring, guidance approach aimed at externalizing interests along lines that will be engaging, but not too stimulating. The cultivation of a different philosophy toward life, directed at enjoying leisure and looking with disdain on fierce ambitious striving, will often help the patient to accept this new role.

Tension may be alleviated by Librium, and Valium; nausea, by Compazine; severe pain in dying patients, by regular administration of narcotics such as heroin. Intractable and unbearable pain that does not respond to the usual analgesics and to hypnosis may require psychosurgery (lobotomy). The practice of permitting a terminal patient to die with dignity (passive euthanasia) without being burdened with useless and desperate artificial means and heroic measures is becoming more and more accepted (Fletcher MI, 1974; Jaretzki, 1975). Interesting also is the publication called *A Living Will* (Euthanasia Education Council, 1974). Antidepressant drugs are often valuable for reducing pain as well as depression.

In progressive, incurable, and fatal ailments there may be a temptation to stop therapy on the basis that nothing more can be done for the patient. Actually, the patient may need the therapist more than before the ailment had developed. Where the patient

has no knowledge of the seriousness of the condition, as, for instance, inoperable cancer, the decision of whether or not to reveal fully the calamity is a grave one that will influence the degree of suffering in the remaining days of one's life. In many cases it is unwise to burden one with the full seriousness of the condition. Statements may be made to the effect that a condition exists that the physician has classified as one that will get worse before it gets better. There is an obligation, of course, not to withhold facts from the patient, but honesty can be tempered with optimistic uncertainty. Many persons cling to a straw extended to them by an authority and maintain a positive attitude to the end. This is especially important in an illness such as AIDS where the degree of suffering may be influenced by the hopeful outlook that a cure may eventually be discovered through research.
